In spite of significant progress in the last few decades, understanding the connections among structure, dynamics, and function continues to be a major challenge in protein science. The enormous development of computer technology has made possible the study of protein motions on subnanosecond time scales by computer simulations. However, many biomolecular processes occur on much longer time scales, and other theoretical approaches are necessary. Statistical models, borrowed from the physics of disordered materials, have led to exciting new insights. For the development of theories, experimental studies of the conformational energy landscape have played a guiding role, and they will continue to do so. The arsenal of experimental methods that are available for the study of proteins is impressive. However, because of the enormous complexity of biomolecules, every technique reveals only a projection of the many dimensions of the problem. Combining the results of many different experiments, performed on selected model systems, may finally lead to fundamental theories of the dynamics of proteins.

GLOSSARY

In this Glossary, definitions of crucial concepts in the field of protein dynamics are listed. Readers are referred to the article Proteins and Enzymes, preceding this article, for definitions of terms and concepts from biochemistry.

Complex System: A system, such as a glass or protein, with a rugged conformational energy landscape with many relative energy minima (conformational substates) separated by relative energy maxima.

Conformation, Conformational State: The three-dimensional structure of an equilibrium state of a protein as determined, for example, by x-ray diffraction.

Conformational Energy: The potential energy of a conformational state of a protein resulting from interactions among all the constituent atoms of the molecule.

Conformational Energy Landscape: A rugged conformational energy surface of a complex system, such as a protein or glass, obtained by plotting the conformational energy as a function of all relevant spatial or conformational coordinates of the molecule.

Conformational Substate: One of a manifold of states of a protein molecule having the same overall structure (i.e., conformational state) and performing the same biological function, but with different structural details and possibly other properties such as the rate at which the function is performed or absorption spectra. A conformational substate refers to a local minimum in the conformational energy landscape of the protein.

Conformational Transition: A process in which the conformational state or substate of a protein changes.

Distribution of Activation Barriers, $g(H_{BA})$: A continuous distribution of activation barriers resulting from a large manifold of conformational substates with slightly different barriers for the biochemical transition, $B \rightarrow A$.

Equilibrium Fluctuation: A conformational transition between two different conformational states or substates of a protein resulting from interactions with the thermal bath.

Ergodic: Refers to a protein experiencing equilibrium fluctuations among all conformational substates of a given conformational state on the time scale of an experimental observation.

Molecular Dynamics: A computational theory in which the coupled classical equations of motion for all atoms of a protein are solved by any one of several algorithms using high-speed digital computers. Molecular dynamics also includes algorithms for minimizing the potential energy of a protein.

Nonequilibrium Relaxation: A conformational transition between two different conformational states or substates of a protein occurring after a perturbation that leaves the protein in a nonequilibrium state.

Nonergodic: Refers to a protein molecule being trapped in a region of the conformational energy landscape on the time scale of an experimental observation.

Relaxation Function, $\Phi(t,T)$: A function that describes the relaxation of an experimental observable of a system from an initial nonequilibrium state to an equilibrium state. The relaxation function is defined to be 1 at time $t = 0$ and to be 0 at time $t = \infty$.

Statistical Substates: Substates of a protein with properties, such as reaction rates and absorption spectra, that must be described by distributions resulting from the very large number of substates.

Taxonomic Substates: A relatively small number of substates of a protein with properties that can be easily classified, including thermodynamic parameters, reaction rates, and absorption spectra. Distributions need not be used to describe taxonomic substates.

INTRODUCTION

Proteins belong to the most important class of compounds of the living world. The first proteins, fibrin from blood and casein from milk, were isolated by the Swedish chemist J. J. Berzelius in 1813. The word *protein* (from the Greek word *proteton,* "precedence," "superiority") was introduced by G. J. Mulder in 1838. He found that proteins

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

are the main components of the living matter and also that they are similar in their composition. The catalytic activity of a protein was first demonstrated by A. Payen and J. F. Persoz with the example of the liquefication of starch by amylase (diastase) from malt extract in 1833. For catalytic proteins, W. F. Kühne created in 1876 the word *enzyme* (from the Greek phrase *en zyme*, "in yeast"). In 1897, H. E. A. Buchner discovered the first metabolic pathway in a cell-free system, alcoholic fermentation in yeast juice. J. B. Sumner crystallized in 1926 the first enzyme, urease, and after crystallization of several digestive enzymes by J. H. Northrop, the protein nature of enzymes became generally accepted. In 1984, however, S. Altman and in 1986, T. Cech found ribonucleic acids with catalytic activities (ribozymes). The first amino acid sequence of a protein, that of insulin, was unraveled in 1955 by F. Sanger, and in 1963, W. H. Moore and S. Stein elucidated the first amino acid sequence of an enzyme, ribonuclease. Six years later, R. B. Merrifield reported the total synthesis of this enzyme by the solid-phase peptide synthesis. The first three-dimensional structures of protein molecules, myoglobin and hemoglobin, were determined by J. C. Kendrew and M. F. Perutz with the x-ray diffraction technique in 1960 (Florkin and Stotz, 1972).

Up to now, an overwhelming number of different proteins have been isolated and characterized from all types of organisms from bacteria and viruses to man. Proteins are essentially involved in every process occurring in living organisms, like reproduction of the genetic material; fertilization; development of cells and of whole organisms; maintenance of structures; selection, uptake, and metabolism of nutrients; energy generation; photosynthesis; muscle contraction; sensory functions like vision; nerve conduction, and brain function. Within a short review, it is impossible to give more than a superficial summary on proteins. At first, the structure of proteins is discussed, followed by a survey on some important functions. A broader space is given to the most significant proteins, the enzymes. The ability to accelerate chemical reactions by several orders of magnitude is one of the most fascinating inventions of nature and a fundamental prerequisite for life. As chemical catalysts enzymes obey the pertinent rules (cf. CHEMICAL KINETICS), but being proteins, they possess various possibilities to adapt their catalytical capacity to the special requirements of the cell and the organism, and they follow their own rules of enzyme kinetics.

The methods for isolation, characterization, and structure determination are similar both for proteins in general and for enzymes. Enzymes, however, possess the advantage of being detectable by specific, sensitive, enzyme tests even in tissue homogenates. The recently developed techniques of genetic engineering revolutionized the investigation of proteins. These methods not only allowed the unraveling of an immense number of primary structures from different proteins within a short time period. They also make possible the modification of proteins in any imaginable mode and open a broad field for altering functional domains like catalytic centers and binding sites to create new functions or to accept alternative ligands. The modifications of the protein molecule concerned are designed on a computer screen and realized by the methods of genetic engineering. Increasing interest is won also by the application of enzymes for industrial processes, e.g., in bioreactors and biosensors and enzyme therapy in medicine.

1. PROTEIN STRUCTURE

1.1 Primary Structure

Proteins are built up from amino acids. With rare exceptions of untypical examples (e.g., peptide antibiotics) all proteins so far described share 20 different amino acids, which are summarized in Fig. 1. They all carry the amino group at the α (or C2) position, creating an asymmetric center (with the exception of glycine) uniformly assuming the L conformation. With respect to their chemical character, the amino acids are classified as neutral, acid, basic, hydrophobic, and aromatic. Integrated in the protein molecule, the amino acids preserve their character. Most proteins possess polar amino acid residues on their surface, rendering the protein molecule soluble in the aqueous medium, while hydrophobic residues are buried to the inside and mediate also noncovalent contacts between different protein subunits.

In proteins, a large number of amino ac-

ids (mostly 100–500, sometimes more than 1000) are linked together in a strictly defined sequence. This *primary sequence* is constant and characteristic for each special protein. The amino acids are linked together by acid amide bonds between the carboxy group of the one and the α-amino group of the second amino acid, the *peptide bond* (Fig. 2). In this way, a covalent *polypeptide* chain is formed with a uniform backbone, the amino acid side chains sticking out. There exist also smaller chains, the *peptides*, consisting of 2–10 amino acids, and the *oligopeptides*, containing 11–100 amino acids. They differ in their functions from the large protein molecules and act mainly as hormones or antibi-

otics. Since the molecular mass of amino acids on the average is 110, most polypeptide chains have molecular masses between 10 000 and 60 000.

1.2 Secondary Structure

Native proteins cannot be regarded as flexible strings; rather, they assume defined stable three-dimensional structures. Three types of folding units, the secondary structure elements, are found in most proteins: α helix, β-pleated sheet, and random coil. In the *α helix,* the backbone of the peptide bonds is arranged in a right-handed spiral with 3.6 amino acid residues per turn and a pitch of 0.54 nm, stabilized by hydrogen bonds between the carboxy and the amino groups of the backbone (Plate 1). It has a rodlike structure with a diameter of about 0.5 nm and a maximum length of 4 nm, though α helices up to 100 nm occur in some structural proteins like myosin from muscle, keratin from hair, or fibrin from blood. The amino acid side chains point outward from the helix.

In *β-pleated sheets,* linear strands of the peptide backbone are arranged in a parallel or an antiparallel manner in a sheetlike structure, stabilized by hydrogen bonds between carboxy and amino groups from adjacent strands (Plate 1). Two to six strands form one sheet, but sometimes large structures up to 15 strands occur.

Native proteins are composed of various α-helix and β-pleated sheet elements. The regions between these elements appear more irregular and are designated as *random coil,* though they form also stable structures containing regular units like *β turns,* which often appear as a link between two antiparallel α helices. The β turns are hairpin turns where the polypeptide chain changes its direction by an angle of 180°. They are built from a sequence of four amino acids stabilized by hydrogen bonds. A special left-handed helix with 3.3 residues per turn is found in the structural protein collagen. This protein has a regular amino acid sequence with glycine at each third position, the following position frequently occupied by proline.

Which secondary structure element becomes realized at a defined region of the protein molecule is dictated by the amino acid sequence encoded in the primary structure. Both the angles of the peptide bonds and influences of the amino acid side chains determine the spatial arrangement of the polypeptide chain. Consequently, the amino acid sequence should allow the prediction of the secondary structure of a protein. However, because of an immense number of forces and restrictions governing macromolecular structures it has been impossible to deduce a convincing system for precise structure predictions. Out of numerous approaches, the most accepted one is that of Chou and Fasman (1978). A coefficient is ascribed to each amino acid for its probability to occur in one of the secondary structure elements, e.g., glutamic acid has a strong preference for α helices, while proline acts as a helix breaker. The coefficient was deduced empirically from a series of known protein structures. The Chou–Fasman rules give a high degree of correct predictions.

The secondary structure elements are arranged in proteins in *supersecondary structures,* like the $\beta\alpha\beta$ motif, where an α helix is embedded between two β strands. An extension of this motif is the eightfold $\alpha\beta$ barrel structure that appears in a series of enzymes like the triosephosphate isomerase and the pyruvate kinase. Eight alternating α helices and β strands are arranged like a barrel with a hole in its middle, which serves as a catalytic center of the enzymes. The Rossmann fold ($\beta\alpha\beta\alpha\beta$) is generated by fusion of two $\beta\alpha\beta$ units, while three antiparallel β strands connected by two β turns form a β meander (Rossmann and Argos, 1981).

1.3 Tertiary Structure

Larger proteins fold into distinct folding units, the *domains.* Each domain consists of 100–150 amino acid residues. Different domains are linked together by small peptide bridges. Domains are often functional units of proteins carrying binding sites, regulatory sites, or catalytic centers. One protein may fold into two or more domains, each contributing a special function that all together cooperate in the intrinsic physiological function of the native protein. It is assumed that in evolution larger proteins evolved by combination of domains with the proper functions.

Folding of polypeptide chains brings into close contact with one another distinct amino acid residues that are quite separate in the primary structure. In this way, stable three-dimensional centers are created, where the amino acid residues are kept in a precise spatial orientation in an optimum arrangement to allow specific interactions with ligands for specific binding, proper orientation, and activation for the catalytic conversion. These functional sites are often hydrophobic pockets, shielded from the surrounding aqueous phase and allowing the entry of the ligand molecule only through a narrow gap.

The outside surface of the protein is formed preferentially from hydrophilic amino acid residues that mediate the contacts to the hydrophilic environment and maintain the solubility of the protein molecule. Hydrophobic regions on protein surfaces serve as an anchor for integration into membranes of cells or cell organelles.

1.4 Quaternary Structure

Protein molecules with simple functions, like binding proteins (e.g., myoglobin) or degrading enzymes (e.g., proteases, ribonucleases), consist mainly of one single polypeptide chain (*monomer*). Most proteins, however, are aggregates of several polypeptide chains (*subunits*), which may be identical (homo-oligomers) or nonidentical (hetero-oligomers). Also, both identical and nonidentical subunits may occur in one protein molecule. The number of subunits of a distinct protein is strictly defined, and symmetrical structures are formed. Oligomers with a small, even number of subunits predominate: 2 (dimer), 4 (tetramer, assuming preferentially tetrahedral structures), or 6 (hexamer). Aggregation is important for stabilizing the protein structure (especially in the case of identical subunits), for regulatory mechanisms (e.g., allosteric enzymes, see Sec. 4.5), or to combine subunits with different functions. Aggregates of subunits with different catalytic functions are *multienzyme complexes,* like the pyruvate dehydrogenase complex or the membrane-associated respiratory chain. They contain several enzyme components, each catalyzing one step of a reaction sequence, so that intermediates formed by one enzyme component are channeled to the next enzyme component without diffusion into the surrounding fluid.

Protein subunits are usually attached to one another by strong, noncovalent forces, like salt bridges and hydrophobic bonds. The subunits can be separated by *p*H changes, high ionic strength, urea, or detergents. Sometimes subunits are connected by covalent dithiol bridges between cystein residues of different polypeptide chains. Such bonds are cleaved by reduction with thiol reagents like dithiothreitol.

1.5 Cellular Distribution of Proteins

Proteins are synthesized by a complicated machinery of the ribosomes in the cytosol of the cell, translating the genetic information encoded in the DNA sequence into the amino acid sequence (see NUCLEIC ACIDS). Since for many proteins the place of action is not in the cytosol, but in distinct cell compartments or membranes, they are synthesized originally as preforms carrying additional signal sequences of 15–35 amino acids at their amino terminus. This sequence directs the protein to its cell compartment (e.g., the mitochondria) and promotes its translocation through the membrane. At the final place, the signal sequence is split off, and the protein becomes activated (Pfanner and Neupert, 1990).

1.6 Posttranslational Modification of Proteins

Proteins are often modified after their synthesis (*processing*). Membrane proteins, antibodies, and other proteins are glycosylated by attachment of carbohydrates, branched oligosaccharide chains containing sugar components like glucose, mannose, or galactose, partially derivatized with amino and acetyl residues. The oligosaccharide residues cover the cell surface and mediate cell-cell recognition. The structural protein collagen is modified by hydroxylation of prolin and lysin residues. Protein modification serves also as a regulatory mechanism. Various enzymes are controlled by reversible phosphorylation of distinct serine or tyrosine residues. Several proteins, e.g., digestive enzymes (trypsin, chymotrypsin) or hormones (insulin), are modified by cleavage of peptide fragments, as described already for the signal sequences.

2. PROTEIN FUNCTIONS

Only a short survey on the major functions of proteins can be given here (enzymes will be treated separately in Sec. 3). The broad variety of protein functions is based on two intrinsic features of this class of compounds:

1. the ability of recognition and binding of a distinct ligand or substrate out of a large variety of compounds in the cell; and
2. the ability to undergo reversible conformational transitions, allowing the change of activity in answer to an external signal.

2.1 Structural and Contractile Functions

Proteins are structural determinants for cells and organisms. *Collagen,* which amounts to $\frac{1}{3}$ of all proteins in the human organism, is a major protein component of connective tissues, cartilage, tendons, and cornea. It has a special conformation, where three polypeptide chains are twisted in a helical manner, leading to stable elastic fibers. The *keratins* are the major components in hair, horn, silk, and skin and in epithelial sheets. They are fibrillar elastic proteins, which confer high flexibility to these substances. Together with neurofilaments in neurons and desmin filaments in muscle cells they belong to the family of intermediate filament (IF) proteins. They are components of the cytoskeleton, a cellular meshwork responsible for the shape and motility of the cell. Another component of the cytoskeleton is the microtubules, long cylindric structures about 30 nm in diameter and built up by the proteins α and β *tubulin.* These proteins form also the cilias of microorganisms. *Actin* and *myosin* are components of contractile microfilaments in the cytoskeleton. Together with *tropomyosin* they form the contractile elements of muscles.

2.2 Binding, Transport, and Storage

Proteins are responsible for transport and storage of substrates and metabolites. *Hemoglobin* in erythrocytes of the blood and *myoglobin* in muscle are both responsible for the binding and providing of oxygen for cellular respiration. Both these proteins have been intensely studied as models for metabolic regulation by proteins. Myoglobin, a monomeric protein, shows normal oxygen binding, while the tetrameric hemoglobin binds oxygen in a cooperative manner controlled by subunit-subunit interactions and was the first example for an allosteric protein (see Sec. 4.5). This cooperativity is influenced in a positive or negative manner by metabolic effectors, like the *p*H of the blood. Acid *p*H favors the dissociation of oxygen into the tissues while oxygen uptake in the lung releases protons from hemoglobin and liberates CO_2 from HCO_3^+. In both proteins, oxygen binds to a complex-bound Fe^{2+} ion of a porphyrin-ring system.

Iron is transported by *transferrin* in the blood and stored by *ferritin* in the liver. Ferritin binds iron up to one-quarter of its own molecular mass. Copper is transported in the blood by *ceruloplasmin.* Essential transport proteins for fatty acids and lipids in the blood are *serum albumin* and *lipoprotein.* Opsin, a membrane protein in the retina of the eye, combines with the light-absorbing chromophore retinal to form the eye pigment *rhodopsin.*

2.3 Infection Defense and Blood Clotting

Antibodies (*immunoglobulins*) protect the organisms against infections. They are of uniform structure consisting of two light and two heavy polypeptide chains linked together by disulfide bridges. Antigens, like viruses or bacteria, are inactivated by binding to highly variable regions on the immunoglobulins, which are able to adapt their amino acid sequence to the structure of the foreign substance. A large number of different proteins are involved in a complicated cascade mechanism of blood coagulation. The principle of this cascade is the activation of a series of inactive protein precursors after damage or trauma, by cleavage of small peptide fragments. This causes an amplification of the whole process. The final step is the cleavage of the fibrous protein fibrinogen to *fibrin,* which polymerizes to form the blood clot.

2.4 Membrane Proteins and Membrane Transport

Proteins integrated into membranes can be regarded as a special protein class. Though their general structure is similar to that of other proteins, they possess some remarkable features. Integration into the membrane is mediated by regions on the protein surface with a high content of hydrophobic amino acid residues. Biological membranes, which are essential components of the walls of cells and cell compartments, are lipid bilayers formed by fatty acids, cholesterol, and other lipid residues. These are amphiphilic compounds with both a hydrophobic hydrocarbon region and polar groups like carboxy residues or phosphates. They are arranged in thin layers, the polar groups oriented to the one, the hydrophobic residues to the other side. Two such layers form a membrane bilayer: the hydrophobic sites facing one another and the polar sides interacting with the polar surrounding liquid (Fig. 3). Hydrophobic regions of proteins dive into the lipid phase of the bilayer, the hydrophilic parts sticking outside. Membrane binding of proteins is very stable, and dissociation from the membrane as well as reorientation in the vertical direction through the membrane is quite improbable. In the lateral direction across the membrane, free flotation of the proteins occurs and allows different membrane proteins to come into direct contact. Because of their tight membrane integration, resolvation of the proteins from the membrane is difficult and results often in inactivation of the protein function. Membrane proteins are investigated either in membrane fragments or in the presence of lipids or detergents.

With respect to membrane binding of proteins, three types can be differentiated. Various proteins are only loosely associated with the membrane and can be resolved by applying mild conditions. The second class dip into the membrane with one part, while the other part looks outside, e.g., into the cytosolic fluid. This is the case for many membrane-bound enzymes like those from the respiratory chain. The third class is completely integrated into the membrane with a central hydrophobic region and with polar regions looking outside at both faces of the membrane (integral membrane proteins). These proteins can interact with components from both sides of the membrane and are able to transfer signals from the one to the other side. This is the principle of the receptor function, where hormones or transmitter substances bind to specific receptors outside the membrane, triggering a reaction inside of it. A characteristic example is the β-adrenergic hormone receptor. Its central part consists of seven parallel transmembrane helices, which are integrated into the mem-

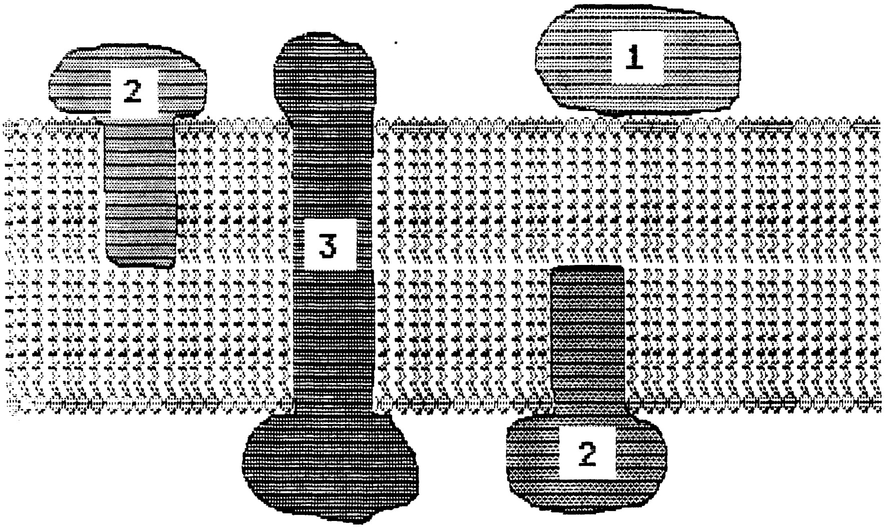

FIG. 3. Bilayer membrane with (1) loosely associated, (2) integral, and (3) transmembrane proteins.

brane. The hormone adrenaline binds to the receptor at the outside of the cell membrane. To the inside, a regulatory *G* protein is associated, which is an aggregate of three different subunits: G_α, G_β, and G_γ. Hormone binding triggers the dissociation of the G_α subunit, which binds to a membrane-bound enzyme, the adenylate cyclase. The binding activates this enzyme, and it catalyzes the synthesis of cyclic adenosine monophosphate (cAMP), a cell hormone or second messenger that regulates various processes in the cell. Also, for other peptide hormones and neurotransmitters like acetyl choline and γ aminobutyrate (GABA), there exist specific membrane-protein receptors. Neurotransmitters act by opening specific ion channels in the membrane.

Ion channels play an essential role in maintaining ion gradients between the two sides of the membrane. These gradients are important for various cellular processes like energy generation, signal transduction, cellular regulation, muscle contraction, and nerve conduction. The ion channels (ion pumps) consist of transmembrane proteins that bind the respective ions (Ca^{2+}, Na^+, Cl^-, H^+, etc.) with high specifity. The transport across the membrane against the concentration gradient occurs by a conformational change of the protein. The energy is provided by the breaking of an energy-rich phosphoric acid anhydride bond of adenosine triphosphate (ATP), the main energy mediator of the cell. Restoration of the energy-rich bond is brought about in the reverse process also by a transport system, the membrane-bound proton pump. The cellular respiration on the inner mitochondrial membrane generates a proton gradient by selective segregation of protons to the outside. To compensate the concentration gradient, protons migrate to the inside of the membrane through a specific proton channel, and the energy of this process is used to induce a conformational change of proteins of the system that mediates the ligation of energy-rich ATP bonds. Membrane-bound proteins, like the photosynthetic reaction center, are responsible for the photosynthetic fixation of carbon dioxide.

Transport of metabolites and other substances like amino acids or carbohydrates through membranes is achieved by integral membrane proteins. The metabolites are specifically recognized by receptor regions at the outside of the membrane. Translocation through the membrane occurs via a conformational change of the protein driven by breakage of energy-rich ATP bonds. Selective, energy-driven carrier systems that control the uptake of substances from the environment enable the organism to segregate only such compounds as are required for its metabolism and to concentrate them within the cell.

3. ENZYMES

3.1 Enzyme Catalysis

Enzymes, the most important group of proteins, have a twofold function for the living organism: they are the catalysts and also the regulators of all reactions of the cell metabolism. In comparison with chemical catalysts, enzymes are very efficient, enhancing the reaction rates by factors of more than 10^{10}. Thus even reactions that appear quite unfavorable become accessible to the metabolism. As true catalysts, however, enzymes can enhance the reaction rate, but cannot influence the thermodynamic equilibrium. If the state of the equilibrium of a reaction favors the substrate *A* instead of the product *B* (*endergonic reactions*—the free energy ΔG has a positive value):

$$A \overset{+\Delta G}{\rightleftharpoons} B,$$

it cannot be shifted by the enzyme in order to provide the cell with sufficient product. But even such reactions can become accessible by coupling them to one (or more) strongly *exergonic reactions* (negative ΔG values). The second reaction releases energy, which is taken to drive the first one. It is only essential that the net amount of free energy remains negative. The principle of this coupling is the fast removal of the product of the first enzyme reaction by the enzyme catalyzing the second one so that the reaction becomes *kinetically driven:*

$$A \overset{+\Delta G_1}{\rightleftharpoons} B \overset{-\Delta G_2}{\rightleftharpoons} C, \quad \Delta G_1 < -\Delta G_2.$$

In most cases, the cleavage of an energy-rich

ATP bond serves to supply unfavorable reactions with the necessary energy, and the main task of the energy metabolism of the cell is to regenerate ATP as a motor of the whole cell metabolism.

Each metabolic reaction is catalyzed by a special enzyme. This is true even for the same type of reactions if the substrates differ, e.g., dehydrogenation of compounds like ethanol and lactate. This apparently uneconomic principle makes possible independent regulation of each reaction and the realization of a complex network of hundreds of metabolic reactions occurring in parallel in the same cell compartment at the same time.

3.2 Catalytic Center

The catalytic conversion occurs at a distinct region of the enzyme molecule, the *catalytic center* or *active site.* It is a hydrophobic pocket inside of the enzyme molecule with an entry for the substrate. It is formed by a precise three-dimensional arrangement of functional amino acid residues of the protein chain. Often it is found in a cleft between different domains, and also elements from different subunits of a protein molecule can contribute to an active site. The active site is responsible for the recognition and discrimination of its substrate molecule out of a mixture of partly very similar compounds in the cell (*enzyme specificity*). For correct recognition, close interaction between substrate and catalytic site by proper positioning of charges and steric obstacles is important. This adaptation is supported by conformational changes at the active site, which are induced by the substrate upon binding (*induced fit*). Conformational changes cause further stabilization of the transition state, which initiates the catalytic process.

Besides different functional amino acid residues of the protein, frequently nonprotein components bound covalently (*prosthetic groups*) or noncovalently (coenzymes, cofactors) to the catalytic center are involved in enzyme catalysis. Many of these coenzymes or their precursors cannot be synthesized by the human organism itself and must be supplied by food (*vitamins*). Examples of such coenzymes are nicotinamide adenine dinucleotide (NAD) and flavins FMN (flavin mononucleotide) and FAD (flavin dinucleotide), both of which are involved in redox reactions; thiamine diphosphate (ThDP), taking part in decarboxylation reactions; and coenzyme A, mediating the acyl group transfer.

Many enzyme reactions use metal ions as cofactors. Magnesium occurs in all reactions with the energy mediator ATP, zinc is found in alcohol dehydrogenase, copper is found in the cytochrome oxidase of the respiratory chain, and molybdenum is found in MoFeS clusters that participate in the nitrogen fixation of the nitrogenase reaction. Iron is involved in a variety of reactions, either complex bound in a porphyrin ring system (e.g., in cytochromes of the respiratory chain and in the oxygen carrier hemoglobin) or as iron-sulfur clusters in redox reactions.

3.3 Mechanisms of Enzyme Catalysis

The principle of enzyme catalysis is the reduction of the activation energy by stabilizing the transition state. To achieve this, the reactants are brought into direct contact with one another by binding to the same catalytic center and by fixing them in a proper orientation. This effect results in a large increase of the efficient substrate concentration and is an entropic contribution to enzyme catalysis (Jencks, 1975).

In various enzyme reactions, covalent intermediates are formed by nucleophilic attack of functional groups of the enzyme to electrophilic regions at the substrate molecule. Nucleophilic groups in the catalytic site are carboxy, amino, hydroxy, imidazol, or thiol groups, and acyl, glycosyl, or phosphoryl intermediates can be formed from appropriate substrates. In a second step, the intermediate becomes transferred to a nucleophilic acceptor molecule, e.g., water in hydrolytic reactions.

Another principle for the acceleration of catalytic reactions is to exert strains or distortions on the substrate molecule upon binding to the enzyme. The substrate becomes destabilized to facilitate the switch into the transition state. This is achieved by twisting of bond angles, steric compression, or electrostatic repulsion between charged groups of the substrate molecule and the catalytic site (Walsh, 1979).

Many enzyme reactions proceed by general acid-base catalysis, e.g., proton transfer to or from the transition state. At neutral *p*H, the imidazol group of the amino acid histidine is a very efficient base, and it is often found in catalytic sites. An exceptional example of general acid-base catalysis is the chymotrypsin reaction. The catalytic site of this enzyme contains three functional residues in juxtaposed position: an imidazol group from histidine, a hydroxy group from serine, and a carboxy group from aspartate (*catalytic triad*). The reaction starts by a proton transfer from the hydroxy group to a nitrogen of the imidazol ring, which is stabilized by the carboxy group of aspartate. A nucleophilic attack of the hydroxy group on a carbonyl group of the substrate and a proton transfer from imidazol to the amino group of the substrate destabilizes the peptide bond. The amine product is released, and an acyl intermediate remains bound to the serine residue. Hydrolysis of this intermediate by a water molecule and release of product is a reversion of the acylation mechanism (Fig. 4).

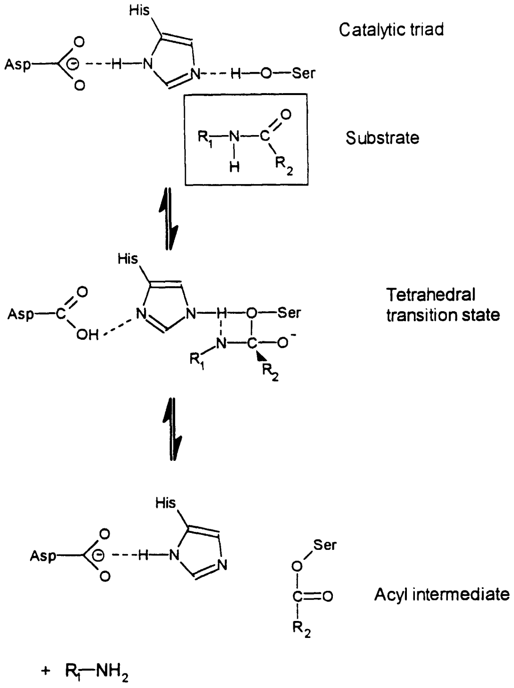

FIG. 4. Catalytic mechanism of chymotrypsin.

3.4 *p*H Dependence of Enzyme Reactions

The activity of enzymes is strongly dependent on the *p*H value of the solution. Optimum curves are obtained with a maximum mainly within the neutral range (*p*H 7.0–8.0) according to neutral *p*H of the cell, but there are examples of very extreme *p*H optima, like acid proteases, e.g., pepsin of the gastric juice, which has its highest activity at *p*H 2.0. Both at low *p*H (<3) and at high *p*H (>11), the enzyme activity declines to zero. The *p*H optimum is determined by two effects:

1. direct influences by ionized or protonated groups in the active center, and
2. indirect influences by residues essential for maintenance of the native structure.

The catalytic residues show sigmoidal *p*H titration curves in dependence of the enzyme activity. Their inflexion points correspond to the pK_a values, i.e., the *p*H value at which the residue is half protonated. While *p*H-dependent dissociation of active site residues is usually reversible, activity losses due to changes of the ionic state of structurally important residues often cause irreversible denaturation of the enzyme.

As a result of their protein nature, enzymes carry a large number of charged groups (amino, carboxy, thiol, hydroxy residues). Within the protein molecule, positive and negative charges are mutually neutralized, but usually there remains a residual amount of surplus charges at physiological *p*H. At a distinct *p*H value, the *isoelectric point* (*pI*), also this net charge becomes zero. The *pI* is a characteristic value for proteins, where they show their lowest solubility in water and tend to precipitate. At this *p*H value, the protein does not migrate in the electric field. Various preparative techniques, like isoelectric focusing and precipitation methods, make use of this fact. Generally, the surface charges of protein molecules are important for their solubility in polar solvents like water, and many analytical and preparative methods (e.g., electrophoresis, ion chromatography) are based on the polyionic nature of proteins.

3.5 Temperature Dependence and Arrhenius Theory

To convert substrate into product, the energy barrier of the transition state has to be overcome, and the reaction proceeds only if the system possesses sufficient energy to surmount the barrier. The principle of enzyme catalysis is to reduce the energy barrier by stabilizing the transition state. The activation energy E_a of the transition state is given by the Arrhenius equation:

$$k = Ae^{-E_a/RT}, \tag{1}$$

where k is the rate constant of the reaction, A is a pre-exponential factor containing the collision frequency and a steric component, R is the gas constant, and T is the absolute temperature (K). According to this equation, reaction rate is a logarithmic function of the reciprocal absolute temperature:

$$\ln k = \ln A - E_a/RT. \tag{2}$$

A plot of ln k against $1/T$ should yield a straight line with the slope of E_a/R.

Enzyme-catalyzed reactions, like chemical reactions, are accelerated by a factor of 2–3 if the temperature is raised by 10 °C. However, because of their metastable protein structure, enzymes denature irreversibly at higher temperatures, and the reaction velocity drops to zero. In this region, the straight line in an Arrhenius plot declines abruptly. In contrast to the pH optimum, the temperature maximum cannot be regarded as optimal for the enzyme activity, since denaturation occurs even at the maximum temperature. Individual enzymes differ considerably with respect to their temperature ranges of denaturation and their thermal stability. Most enzymes denature between 40 and 50 °C, but there exist extremely temperature-sensitive enzymes like alcohol dehydrogenase, which denatures already at 30 °C, while enzymes from thermophilic microorganisms living in hot volcanic springs remain stable up to 100 °C. Thermal denaturation is a complex, irreversible, multistep process. Usually, one initial step causes the loss of catalytic activity, followed by a series of processes leading to a successive unfolding of the native protein structure. Investigation of such processes is important for the understanding of the native enzyme structure.

3.6 Enzyme Regulation

In contrast to spontaneous chemical reactions, catalyzed reactions can be influenced by changing both the amount and the efficiency of the catalyst. Both these regulation principles are realized. There exist mechanisms for adaptation of the amount and the activity of enzymes to the actual metabolic requirements. The amount of the enzyme is regulated at the level of enzyme biosynthesis by control of gene expression (see NUCLEIC ACIDS). Specific metabolites that are directly or indirectly involved in the enzyme reaction, like substrate, products, or intermediates, either enhance (*induction*) or repress (*repression*) the gene expression. Usually, substrate molecules act as inducers, and their accumulation favors enzyme synthesis, while products are repressors signaling the stop of the synthesis. Many compounds and metabolites are synthesized in sequences of several reaction steps, each being catalyzed by a specific enzyme. Such *metabolic pathways* are regulated by interaction of their end product as a repressor and of their initial substrate as an inducer with a regulatory gene (operator) of the gene cluster (operon) containing the structural genes of the respective enzymes (Fig. 5). Too high amounts of enzymes already present in the cell are digested by specific degradative enzymes, the *proteases*.

The efficiency of the enzyme catalyst is controlled by binding and interaction of regulatory substances (*effectors*) to the enzyme. This regulation principle is similar to gene regulation: reaction substrates activate, products inhibit. Metabolic pathways are subject to a concerted regulation: The first enzyme is inhibited by the end product of the whole pathway (*feedback inhibition*) so that accumulation of intermediates is prevented. The inhibitors and activators react either by direct interaction, e.g., blocking of the active site of the enzyme, or by binding to a distinct regulatory site that transfers the regulatory signal to the active center by conformational changes and subunit-subunit interactions of the protein (*allosteric enzymes*, cf. Sec. 4.5). Another regulation principle is effector-induced covalent but reversible modification of the enzyme, frequently via phosphorylation of distinct serine or tyrosine residues. This effect causes either activation or inhibition depending on the special type of enzyme. Phosphorylation is further controlled by the regulatory metabolite cyclic adenosine monophosphate (cAMP), a *second messenger* of the cell. The cAMP level is itself

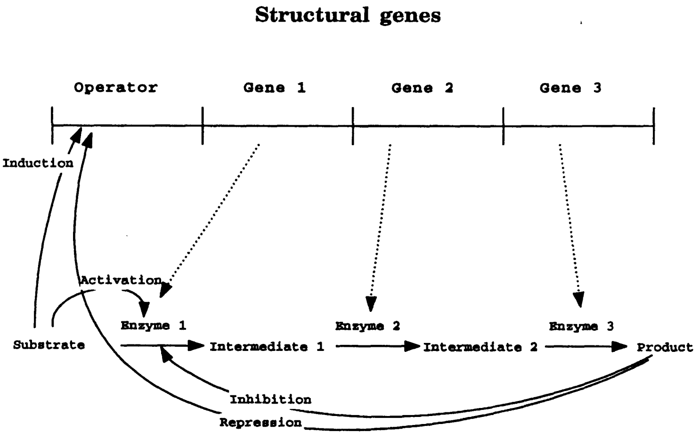

FIG. 5. Regulation of enzyme activity on the gene and the enzyme levels.

subject to hormonal control, thus connecting hormone action to enzyme activity.

3.7 Cellular Organization of Enzymes

In the cells, the enzymes are partitioned in various compartments to separate different pathways. In the cytosol, the metabolization of carbohydrates in the *glycolytic pathway* (Embdem–Meyerhof pathway) and the *pentose-phosphate pathway* occur and fatty acids are there synthesized. Degradation of fatty acids for energy generation and for disposition of precursors for metabolite synthesis occurs in the mitochondria, where it is coupled to the *citric acid cycle* (Krebs cycle) and the *respiration chain,* the main energy generating machinery of the cell. Lysosomes, small cell particles, contain enzymes for degradation of proteins, polysaccharides, and lipids, and the peroxisomes concentrate enzymes that form and destroy the highly toxic hydrogen peroxides.

Usually one reaction is catalyzed by one enzyme. The enzyme molecule either may consist of one polypeptide chain carrying one catalytic center or (more frequently) may be an oligomer consisting of some (about 2–6) identical polypeptide chains, each possessing the same catalytic site. The reasons for aggregation and for concentration of catalytic sites of the same type in one molecule may be the stabilization of the native structure and the reduction of particle volumes within the limited cell space. Also regulatory mechanisms are based on subunit-subunit interactions (cf. Sec. 4.5). Various enzymes possess more than one type of catalytic center and catalyze different, usually sequential reaction steps (*multienzyme complexes*). The reaction intermediates are directly transferred from one center to the next without dilution into the cell liquid. Different catalytic centers are usually located on different subunits so that multienzyme complexes consist of several nonidentical subunits, and each subunit type can appear in such complexes in several identical copies. The pyruvate dehydrogenase complex, the largest multienzyme complex of the cell, consists of three different enzyme components, two of them contributing 60 and the third one contributing 12 identical copies so that the total molecular mass amounts to 8×10^6 for the whole enzyme complex. Sometimes different catalytic sites are located on the same polypeptide chain (*multifunctional enzymes*), as in the case of the fatty acid synthase, where seven catalytical centers are arranged on one single subunit.

Higher organized structures are realized by membrane fixation of proteins and enzymes. An example is the respiratory chain, which consists of several functional protein complexes integrated into the inner mitochondrial membrane. It mediates the transport of reduction equivalents from various metabolites to molecular oxygen by formation of water. Segregation of this chemically simple reaction into several enzyme-controlled reaction steps allows conservation of the energy liberated by this process. Protons produced in the course of this reaction sequence are vectorially released into the intermembrane space between the inner and the outer mitochondrial membranes. A proton gradient is generated, and in order to equalize the concentration difference, protons migrate through specific proton channels, which converts the energy gained by this process into the chemical energy of acid anhydride bonds of ATP. Three such bonds are formed by one passage of reduction equivalents through the respiratory chain, corresponding to 40% efficiency.

4. KINETICS OF ENZYME REACTIONS

4.1 Michaelis–Menten Equation and Steady-State Relationship

The central law for enzyme analysis and enzyme kinetics is the equation formulated in 1913 by L. Michaelis and M. Menten in Berlin on the basis of earlier studies of A. J. Brown and V. Henry. It was originally derived for a single substrate reaction:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P,$$

where the reversible formation of the ES complex (*Michaelis complex*) between enzyme E and substrate S is followed by the catalytic conversion of substrate into product P and its dissociation from the enzyme in a quasi-irreversible process. Michaelis and Menten assumed the catalytic process to be very slow compared to the initial binding equilibrium; the rate constants should be related by $k_1 \sim k_{-1} \gg k_2$. Under these conditions, the reaction velocity v, which is proportional to the concentration of the ES complex ($v = k_2[ES]$), can be taken as a direct measure for the reversible binding equilibrium, which was thought to be not influenced by the following catalytic step. On the basis of this assumption, the *Michaelis–Menten equation* for the dependence of the enzyme velocity on the substrate concentration was derived:

$$v = V[S]/(K_m + [S]). \qquad (3)$$

The term V is the maximum velocity for the case that the total amount of enzyme in the sample $[E]_0$ is saturated with substrate and is involved in the reaction; $V = k_2[E]_0$. It can be attained only at infinite substrate concentration. According to the Michaelis–Menten assumption, the *Michaelis constant* K_m is identical to the dissociation constant of the ES complex, $K_d = k_{-1}/k_1$.

In 1923, G. E. Briggs and J. B. S. Haldane suggested a modification of the Michaelis–Menten equation that extends its general validity. They realized that the catalytic conversion may be fast enough to influence the binding equilibrium, for which v is no longer a direct measure. But even under these conditions, the concentration of the ES complex remains constant for a distinct time, where formation of ES and decomposition into E, S, and P are counterbalanced. In contrast to a real (time-independent) equilibrium, this state, which lasts only for a limited time period of several seconds to minutes, is designated as *steady state.* Equation (3) remains valid also for this modification, with the exception that the Michaelis constant is extended by the catalytic constant k_2: $K_m = (k_{-1} + k_2)/k_1$. It cannot be further regarded as a true thermodynamic dissociation constant. The steady-state range can only be observed if $[S] \gg [E]$ and is characterized by an initial linear zero-order product formation, which turns into nonlinear first-order kinetics after a considerable decrease of the initial substrate concentration. In this modified form, the Michaelis–Menten equation is valid also for more complicated enzyme reactions, including more than one substrate, enzyme inhibition or activation, and reversible reactions, if initial reaction rates are measured and all parameters besides the one under investigation are kept constant.

4.2 Graphical Representation of the Michaelis–Menten Equation

The dependence of the enzyme velocity on the substrate concentration according to the Michaelis–Menten Eq. (3) obeys a hyperbolic function [Fig. 6(a)] and approaches asymptotically the maximum velocity V since v becomes V for $[S] \rightarrow \infty$. At half saturation ($v = V/2$), the substrate concentration corresponds to the Michaelis constant K_m. Both K_m and V are characteristic enzyme constants. The Michaelis constant reflects the affinity of the substrate for the catalytic center, as long as k_2 is small. The K_m values range usually be-

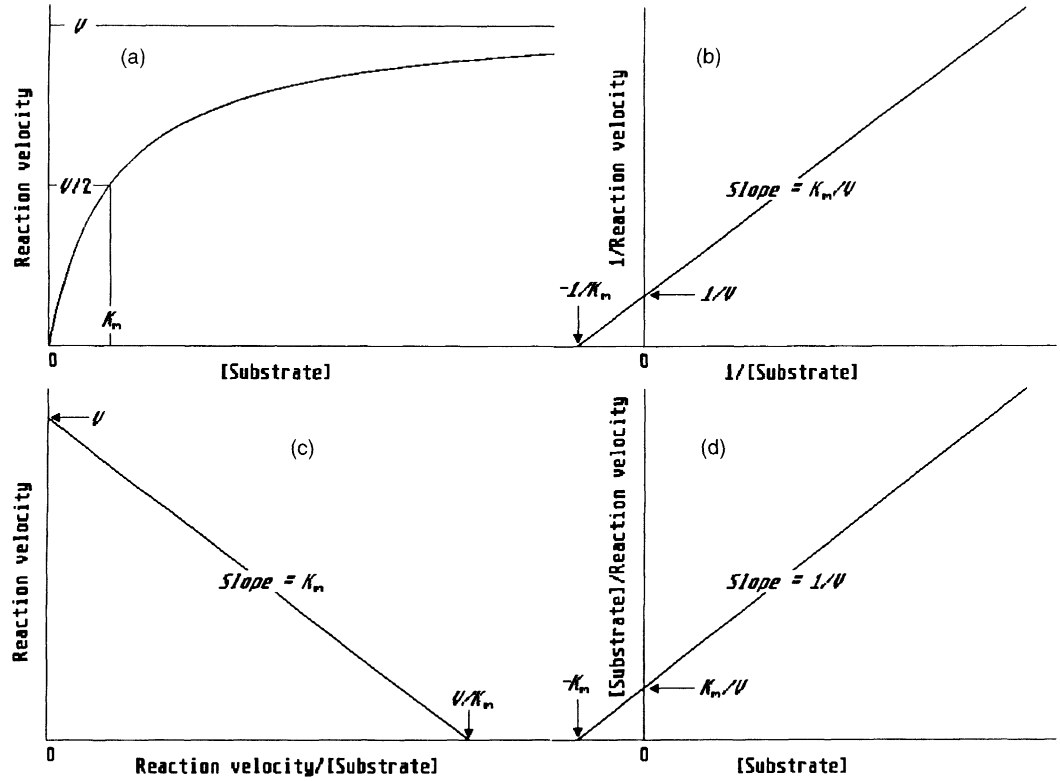

FIG. 6. Graphical representation of the Michaelis–Menten equation: (a) direct plotting; (b) Lineweaver–Burk diagram; (c) Eadie–Hofstee diagram; (d) Hanes diagram.

tween 10^{-6} and 10^{-3} mol/L. The term V is defined as the amount of substrate converted per time unit (mol/s). It is a measure of the catalytic efficiency of the enzyme and depends on the amount of enzyme and thus on the purity of the preparations. Of more general significance is the catalytical constant or turnover number k_{cat} [k_2 in Eq. (3)], which is obtained by dividing V by the enzyme concentration $[E]_0$. The k_{cat}/K_m ratio is a measure for the enzyme specificity, large values indicating high specificity.

Though both K_m and V can be obtained by direct plotting of v against $[S]$, as shown in Fig. 6(a), this procedure is often ambiguous because of the problems of fitting nonlinear curves to scattering data points. This can be overcome by transformation of the Michaelis–Menten equation into linearized forms. Three simple ways of linearization exist. In the double reciprocal *Lineweaver–Burk diagram* the variables are plotted reciprocally, $1/v$ against $1/[S]$ (Fig. 6(b)), according to the following equation:

$$\frac{1}{v} = \frac{K_m}{V}\frac{1}{[S]} + \frac{1}{V}. \tag{4}$$

The *Eadie–Hofstee diagram* plots v against $v/[S]$ [Fig. 7(c)]:

$$v = K_m \frac{v}{[S]} - V, \tag{5}$$

and $[S]/v$ against $[S]$ is plotted in the *Hanes diagram* [Fig. 7(d)]:

$$\frac{[S]}{v} = \frac{[S]}{V} + \frac{K_m}{V}. \tag{6}$$

The Lineweaver–Burk plot is used most frequently, though the reciprocal plotting distorts the error margins of the data points and prohibits application of linear regression. This problem is less important with the other plots, but there the two variables v and $[S]$ are not separated by the coordinates. The kinetic constants K_m and V are obtained from these diagrams from slopes and coordinate intercepts of the straight lines, as indicated in Fig. 6.

4.3 Enzyme Inhibition

Enzyme reactions can be specifically inhibited by distinct compounds, the inhibitors. Inhibition is of great physiological significance for the regulation of the cell metabolism. Inhibition is a valuable tool for the study of enzyme mechanisms. Selective blocking of enzyme reactions by specific inhibitors is also applied in medical therapy.

Three main inhibition types are differentiated. If the inhibitor binds directly to the substrate binding site at the catalytic center, the inhibition is *competitive*. This is the case if the inhibitor is structurally closely related to the substrate but does not participate in the catalytic reaction. Both substrate (S) and inhibitor (I) cannot bind simultaneously to the enzyme but compete for the same binding site:

$$\begin{array}{l} E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P \\ + \\ I \\ \downarrow\uparrow K_i \\ EI \end{array}$$

Here K_i, the binding constant of the inhibitor I, is the *inhibition constant*. The Michaelis-Menten Eq. (3) changes to

$$v = \frac{V[S]}{K_m(1 + [I]/K_i) + [S]}, \tag{7}$$

and the K_m value is extended by a term containing the inhibitor concentration $[I]$ and the inhibition constant. Here V remains unchanged, since very high amounts of the substrate displace the inhibitor completely from the binding site. In the Lineweaver–Burk plot, the competitive inhibition is characterized by a common ordinate intercept at $1/V$ of straight lines that are obtained by determination of the enzyme activity in the presence of different inhibitor concentrations [Fig. 7(a)]. The term K_i is obtained from the abscissa intercepts of the lines, which have the meaning $-1/K_m(1 + [I]/K_i)$.

The product of an enzyme reaction, if present already at the start of the reaction, behaves like a competitive inhibitor, since it shares the same binding site as the substrate (*product inhibition*).

If there is no direct competition between inhibitor and substrate, the inhibition is *noncompetitive*. The inhibitor may bind either to a second binding site at the catalytic center (e.g., for cofactor or cosubstrate) or to a distant regulatory site. An inactive ternary EIS complex appears:

$$\begin{array}{lll} E + S & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & ES \xrightarrow{k_2} E + P \\ + & & + \\ I & & I \\ \downarrow\uparrow K_i & & \downarrow\uparrow K_{ii} \\ EI + S & \rightleftharpoons & EIS \end{array} .$$

Two inhibition constants exist: K_i and K_{ii}. They are identical if both substrate and inhibitor bind independently of one another. In this case, V, but not K_m, becomes changed:

$$v = \frac{V[S]/(1 + [I]/K_{ii})}{K_m + [S]}. \tag{8}$$

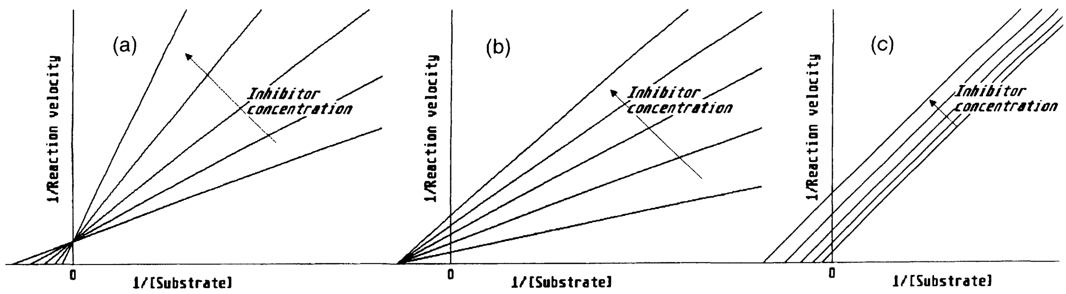

FIG. 7. Enzyme inhibition in the Lineweaver–Burk diagram: (a) competitive inhibition; (b) noncompetitive inhibition; (c) uncompetitive inhibition.

Indicative for this inhibition type is a common abscissa intercept of all lines in the Lineweaver–Burk plot [Fig. 7(b)]. The term K_{ii} is obtained from the ordinate intercept $(1 + [I]/K_{ii})/V$. If binding of inhibitor influences the binding of substrate and vice versa, then $K_i \neq K_{ii}$, and the rate equation reads

$$v = \frac{V[S]}{K_m(1 + [I]/K_i) + (1 + [I]/K_{ii})[S]}. \tag{9}$$

This case is sometimes designated as *mixed inhibition.* Now both K_m and V are changed, and the lines in the Lineweaver–Burk plot intersect at a common point to the left of the ordinate. Both K_i and K_{ii} are derived from abscissa and ordinate intercepts, as described above.

A rare type is *uncompetitive inhibition.* The inhibitor binds exclusively to the ES complex; thus, substrate binding is necessary for inhibitor action:

$$\begin{array}{l} E + S \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} ES \overset{k_2}{\rightarrow} E + P \\ \qquad\quad\;\; + \\ \qquad\quad\;\; I \\ \qquad\quad\;\; \downarrow\!\uparrow K_{ii} \\ \qquad\quad\;\; EIS \end{array} .$$

The rate equation is

$$v = \frac{V[S]}{K_m + (1 + [I]/K_{ii})[S]}. \tag{10}$$

Parallel lines appear in the Lineweaver–Burk plot; K_{ii} is obtained from the ordinate intercepts [Fig. 7(c)]. A special case of uncompetitive inhibition is *substrate inhibition.* A second substrate molecule binds to the ES complex, forming an inactive ESS complex. At high substrate concentrations, the reaction velocity slows down and characteristic deviations from the straight lines are observed in the linearized diagrams.

4.4 Multisubstrate Reactions

In most enzyme reactions, two and sometimes even three different substrates are involved. Three main mechanisms of multisubstrate reactions are differentiated with respect to the order of substrate binding: random, ordered, and ping-pong mechanisms. The numbers of substrates involved and of products released are added to the name of the mechanism (uni, bi, and ter for one, two, and three components), e.g., ordered bibi for an ordered mechanism with two substrates converted into two products. The Michaelis–Menten Eq. (3) and the linearization procedures remain principally valid as long as all substrates but one are kept constant (Cleland, 1970).

For the *random mechanism,* independent binding of the substrates ($S1$, $S2$), the following is assumed:

$$\begin{array}{lcl} E + S1 & \overset{K_{iS1}}{\rightleftharpoons} & ES1 \\ + & & + \\ S2 & & S2 \\ \downarrow\!\uparrow K_{iS2} & {\scriptstyle K_{mS1}} & \downarrow\!\uparrow K_{mS2} \\ ES2 + S1 & \rightleftharpoons & ES1S2 \end{array} .$$

For each substrate, there exist two types of constants, an *inhibition constant* (K_{iS1},K_{iS2}) for the binding to the free enzyme and a *Michaelis constant* (K_{mS1},K_{mS2}) for the formation of the active $ES1S2$ complex. The constants are related by the relationship $K_{iS1}/K_{iS2} = K_{mS1}/K_{mS2}$. Both the K_i and K_m values for the same substrate are identical if the different substrates bind independently, and they differ if the substrates mutually influence each other in the binding process. The rate equation is

$$v = \frac{V[S1][S2]}{K_{iS1}K_{mS2} + K_{mS2}[S1] + K_{mS1}[S2] + [S1][S2]}. \tag{11}$$

Multisubstrate reactions are analyzed by varying the amount of one substrate at constant cosubstrate concentrations. A series of straight lines with a common abscissa intercept is obtained for the random mechanism in the Lineweaver–Burk plot.

The different substrates bind in a strictly sequential mode, one after the other, in the *ordered mechanism:*

$$E \overset{+S1}{\rightarrow} ES1 \overset{+S2}{\rightarrow} ES1S2.$$

Equation (11) remains valid, and the inhibition constants for binding of a substrate differ considerably from its Michaelis constant. The lines in the Lineweaver–Burk plot intersect at a common point to the left of the ordinate.

In the *ping-pong mechanism,* the first substrate forms an intermediate with the enzyme E' while the first product becomes released. The second substrate reacts with the enzyme intermediate, forming the second product and restoring the original enzyme form E:

$$E \xrightarrow{+S1} ES1 \xrightarrow[-P1]{} E' \xrightarrow{+S2} E'S2 \xrightarrow[-P2]{} E.$$

Examples for a ping-pong mechanism are aminotransferases, an enzyme class with pyridoxal phosphate as a prosthetic group. They catalyze the transfer of an amino group from an amino acid to an α-oxo acid by formation of a covalent enzyme-pyridoxamine intermediate.

The rate equation for this mechanism is

$$v = \frac{V[S1][S2]}{K_{mS2}[S1] + K_{mS1}[S2] + [S1][S2]}. \qquad (12)$$

Parallel lines are obtained in the Lineweaver–Burk plot.

4.5 Allosteric Enzymes

Allosteric enzymes represent one of the major regulatory principles of the cell. Enzymes belonging to this group show three significant features:

1. composition of identical subunits;
2. sigmoidal saturation behavior of ligands, mainly the substrate (*homotropic effects*); and
3. regulatory centers (*allosteric sites*) for binding and action of effectors (inhibitors or activators) distant from the catalytic site (*heterotropic effects*).

The sigmoidal shape of the saturation curves is generally ascribed to cooperativity due to subunit-subunit interactions. The first ligand binding to a subunit increases the affinity for the following ones. The steepness of the sigmoidal saturation curves is a measure of the strength of cooperativity and of subunit-subunit interaction. Allosteric inhibitors strengthen the cooperative effects (though the enzyme activity is reduced), while activators weaken it and convert the sigmoidal curves to hyperbolic ones (Fig. 8).

Two models were proposed that are equally suited to describe the behavior of allosteric enzymes. According to the *concerted* or *symmetry model* of Monod *et al.* (1965), the enzyme molecule exists in at least two conformational states: an inactive T state (T = tense) and an active R state (R = relaxed). The transition between the two states occurs spontaneously in a symmetrical manner, all identical subunits of the enzyme molecule assuming the same conformation at the same time. In the absence of substrate, the T state predominates. Substrates and activators bind preferentially to the active R state, which becomes stabilized and is drawn out of the equilibrium between the free states. To restore this equilibrium, a corresponding amount of enzyme in the free T state changes into the R state. Conversely, inhibitors stabilize the T state and reduce the amount of the active R state.

Also, the *sequential model* of Koshland *et al.* (1966) assumes the enzyme to exist in an inactive state in the absence of substrate. Substrate binding induces a change to the active conformation, but only of those enzyme subunits to which the substrate actually binds, while free subunits remain in their inactive state. It is further assumed that interactions between active and inactive subunits facilitates binding of substrate molecules to the inactive states and their transition into the active form. Activators act in

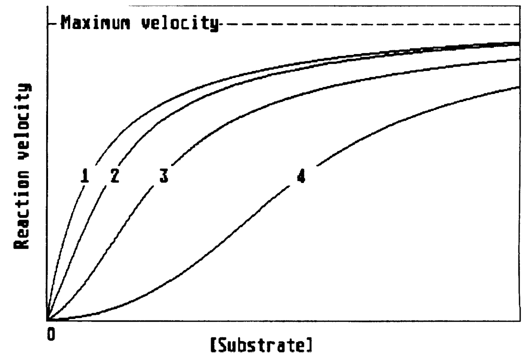

FIG. 8. Sigmoidal saturation behavior of allosteric enzymes: (1) normal hyperbolic curve; (2–4) sigmoidal curves: (2) in the presence of an activator; (3) without effector; (4) in the presence of an inhibitor.

the same way, while inhibitors impede the transition.

Allosteric enzymes control the initial steps of metabolic pathways (*key enzymes*) and are regulated by the end product of the pathway (*feedback inhibition*). One of the well-documented allosteric enzymes is aspartate transcarbamoylase, which possesses catalytic and regulatory centers on different subunits. It catalyzes the initial step of the biosynthetic pathway of pyrimidines, one of the two central building blocks for nucleic acids. The enzyme is inhibited by the end product of the pathway, cytidine triphosphate. ATP, the end product of the biosynthetic pathway of purines, the second building block for nucleic acids, acts as an activator. This regulation guarantees that both building blocks are synthesized in the same ratio as is needed for nucleic acid synthesis. Other examples for allosteric enzymes are phosphofructokinase, the main regulatory enzyme of the glycolytic pathway of carbohydrate degradation, and glycogen phosphorylase, which controls the mobilization of glycogen, the glucose (and energy) storage of the cell. Hemoglobin, a protein without catalytic activity, was the first example of an allosteric protein and is up to now the most thoroughly investigated representative of this group. Oxygen binding shows sigmoidal saturation behavior, which is allosterically influenced by 2,3-bisphosphoglycerate and by the Bohr effect, i.e., the regulation of oxygen binding by interaction with CO_2 and the proton concentration. The allosteric mechanism has been resolved by the brilliant work of Perutz (1989). Oxygen binds to the sixth coordination of an iron complex bound in a porphyrin ring system and causes a transition from the high-spin to the low-spin state of the iron. This transition is accompanied by movement of the iron into the plane of the porphyrin ring, which in turn triggers a conformational change of the whole protein molecule.

5. ISOLATION AND PURIFICATION OF PROTEINS

5.1 Cell Disintegration and Fractionation

The methods applied for the isolation of proteins or enzymes depend on the respective organism and tissue from which a particular protein should be extracted and also on its localization in the cell. Material must be available in sufficient quantities and must contain considerable amounts of the pertinent protein. Microorganisms are easy to cultivate. Their proteins can be specifically modified by mutation, which is very helpful for the investigation of protein functions. Microbial proteins are often closely related to corresponding proteins from higher organisms with respect both to structure and to function and can serve as valuable models. Genetic engineering allows the transfer of genes from higher organisms into microorganisms to isolate the respective proteins. For direct isolation of proteins from higher organisms, plants, laboratory animals like mice, rats, and guinea pigs, or tissues like heart, brain, kidney, or liver from the slaughter are taken. The preparation must be performed in *p*H-stabilized buffered solution with defined ionic strength in the cold room to prevent denaturation or degradation of the protein.

The initial isolation step is the disintegration of the tissue to obtain crude extracts. Tissues from higher organisms like liver, muscle, or kidney are minced into small particles with mincing machines, homogenizers, or fast blenders. The cell walls, especially of microorganisms, are disintegrated also by ultrasonication, digestion with degradative enzymes, detergents, or osmotic shock. Cell compartments like mitochondria, ribosomes, or nuclei are separated from cell homogenates by differential centrifugation. Membrane-bound proteins must be solubilized with detergents (Harris and Angal, 1989).

5.2 Precipitation and Concentration

The principle of protein precipitation is the disorganization of the hydration shell around the protein molecule. Ammonium sulfate or polyethylene glycol are efficient precipitants. Proteins precipitate at characteristic concentrations of the precipitant (*fractional precipitation*). Precipitation by *p*H changes makes use of the fact that proteins possess their lowest solubility at their isoelectric point (cf. Sec. 3.4). Precipitation at higher temperature is applied to separate thermostable proteins from the thermosensitive bulk proteins, especially after cloning of the gene of a thermophilic protein into a mesophilic microbial host. Ammonium sulfate and polyethylene glycol precipitation is also a method for concentrating proteins.

Dialysis of protein solutions against semipermeable membranes, which can be penetrated only by small molecules and not by macromolecules like proteins, is used to remove small impurities like metabolites, salts, or precipitants or to exchange buffer systems. The protein solution is included into a dialysis bag consisting of a cellulose membrane. The bag is transferred into a vessel containing a large volume of the desired buffer solution and gently stirred for several hours during which the outside solution is exchanged several times to remove traces of the contaminants. Special apparatus for dialysis of small volumes have been developed. Dialysis can also be used for protein concentration whereby the dialysis bag is embedded into hygroscopic substances (e.g., aquacide), which draws the water out of the bag.

Ultrafiltration is a technique for concentration of dilute protein solutions. The solutions are pressed through semipermeable membranes either mechanically or applying the pressure of compressed gasses, centrifugal force, or vacuum. Membranes of different materials (cellulose, nitrocellulose, etc.) and pore sizes are used and serve also for a rough separation of proteins. To concentrate large proteins, sedimentation in the gravitational field of an *ultracentrifuge* can be taken. Applying differential gradient centrifugation allows separation of proteins according to their size (cf. Sec. 6.5).

5.3 Chromatographic Techniques

The principle of column chromatography is the separation of protein mixtures on matrices in long columns. The column dimensions depend on the amount of protein to be separated, the binding capacity of the material, and the accuracy of separation of different protein bands (Scopes, 1987).

Ion-exchange chromatography is a powerful method for protein isolation. It makes use of the fact that the protein surface carries a large number of charged groups. DEAE (diethylaminoethyl) and QAE (diethyl-[2-hydroxypropyl]aminoethyl) groups as anion exchangers and CM (carboxymethyl) or SP (sulfopropyl) groups as cation exchangers fixed to cellulose, dextran, agarose, or synthetic polmer matrices are applied. Protein adsorbed to the exchangers is eluted by buffer or salt gradients with increasing ionic strength or *p*H change.

Adsorption chromatography is related to ion chromatography. It relies mainly on nonspecific dipole-dipole interactions between protein and the matrix. Inorganic materials like calcium phosphate or hydroxy-apatite serve as matrices.

Affinity chromatography makes use of the fact that proteins and especially enzymes possess specific binding sites for substrates and cofactors (Jakoby and Wilchek, 1974; Dean *et al.*, 1985). Such ligands are covalently attached to matrices like dextrans, agarose, cellulose, or polyacrylamide. The matrix has to be activated beforehand with cyanogen bromide or epoxide and the ligand is fixed either directly or via spacer molecules like 1,6-diaminohexane to confer high mobility onto the fixed ligand for the interaction with the protein. Besides enzyme substrates and coenzymes, also binding proteins like antibodies or lectins are used. Affinity chromatography is a very efficient purification method since only proteins that specifically interact with the fixed ligand are retarded. Elution is achieved with a solution of the unbound ligand.

Hydrophobic chromatography with alkyl (e.g., octyl), aminoalkyl, or aryl (e.g., phenyl) residues immobilized to matrices like agarose is based on interactions of these groups with hydrophobic regions on the protein surface. Polar conditions like high ionic strength favor binding while a decrease in polarity (lowering of ionic strength, nonpolar solvents) promote elution (Ochoa, 1978).

Gel filtration is a method to separate macromolecules according to their size. The dextran, agarose, or polyacrylamide matrices consist of porous particles with defined pore diameters. Smaller molecules penetrate the particles and are retarded on their way across the column while larger molecules pass the column directly. With this method, molecular masses of proteins also can be estimated.

The efficiency of column chromatography has been highly improved with respect both to the speed and to the quality of separation by the high performance liquid chromatography (HPLC) and the fast protein liquid chromatography (FPLC) techniques. The principle of both methods is the operation of column chromatography at high pressure (up to 400 bar for HPLC). HPLC has a broad spectrum of applications from small compounds to macromolecules, while the FPLC technique has been developed especially for purification of sensitive compounds like enzymes. The separation principles (ion exchange, gel filtration, hydrophobic chromatography) are equivalent to those of conventional chromatography, only the matrices are stabilized to endure the high-pressure conditions. One column run lasts some minutes compared to hours and days for conventional chromatography. Very sharp bands are obtained with high reproductivity (Rossomando, 1987; Mant and Hodges, 1991).

6. TECHNIQUES FOR ANALYSIS AND STRUCTURE DETERMINATION OF PROTEINS AND ENZYMES

6.1 Electrophoretic Techniques

Electrophoresis serves mainly as a control for the purity of protein preparations and for molecular mass determinations. Preparative electrophoresis is rarely used because of its complicated manipulation. The migration velocity of proteins in the electrical field depends on their net number of charges and, inversely, on their size (Stokes radius). Electrophoresis is performed with buffered protein solutions on matrices like agarose or polyacrylamide. Frequently, the electrophoresis is carried out in the presence of sodium dodecyl sulfate (SDS). This detergent associates to the protein molecule and unravels its secondary and tertiary structure so that it dissociates into its subunits. The negative charge of the bound SDS molecules exceeds the net charge of the protein, and migration to the anode is determined essentially by the protein size because of retardation within the matrix network (Hames and Rickwood, 1990).

Isoelectric focussing makes use of the fact that the net charge and thus the migration of a protein at its isoelectric point (*pI*) is zero. A *p*H gradient is created in an electric field by special amphoteric polymeric compounds, the ampholytes. Proteins migrate to the position of their respective *pI*'s, which can be determined by this method (Righetti, 1975; Chrambach, 1985).

Isotachophoresis is a type of electrophoresis that is performed at weakly alkaline *p*H where most proteins are negatively charged and migrate to the anode. The proteins migrate between a leading anion with fast mobility like phosphate and a terminator anion with low mobility like glycine in a high electric field. The anions in the sample arrange in the order of their mobility (Everaerts *et al.*, 1976; Righetti, 1975).

6.2 Protein Determination and Enzyme Tests

A large number of methods exist for the determination of the amount of protein in extracts and solutions. They are mainly based on the formation of colored complexes as in the biuret and the Lowry assay. The Bradford method makes use of the adsorption of the dye Coomassie brilliant blue to proteins. The absorption of aromatic amino acids, especially of tryptophan at 280 nm, is used both for quantitative protein determination and for detection of protein bands in chromatographic techniques.

Enzymes in extracts, solutions, or eluates from columns are identified by specific enzyme tests based on their catalytic reactions. The amount of product formed or of substrate converted as a function of time is measured, and the enzyme activity is expressed in katal (kat) as the amount of enzyme forming 1 mol product within 1 s (according to the SI nomenclature) or in enzyme units (U), the amount of enzyme producing 1 μmol product per minute. Enzyme activity divided by the protein concentration of the sample, the *specific enzyme activity*, is a measure for the purity of enzyme preparations. Enzyme tests must be performed at distinct standard conditions with respect to temperature, *p*H value, and ionic strength. Since enzymes differ considerably in their features, general standard conditions cannot be defined. Usually, enzymes are tested at 25 °C and at neutral *p*H (7.0–7.6), stabilized by a buffer system with moderate ionic strength (~0.1 M).

Enzyme reactions are preferentially followed spectrophotometrically or fluorimetrically if there is any detectable spectroscopic difference between substrate and product. Representative examples are the nicotinamide adenine dinucleotide (NAD) dependent dehydrogenases. The reduced form of this cofactor, NADH, possesses an additional absorption peak at 340 nm compared with the oxidized form and shows also considerable fluorescence emission. Reactions that proceed without spectral changes may be coupled with photometrically detectable reactions. In other cases, the reaction is stopped after a defined time, and the product produced or the remaining substrate is determined by chemical analysis. Also, the HPLC method is taken for the quantitative identification of the reactants.

6.3 Amino Acid Analysis and Protein Sequencing

The amino acid composition is determined after acid or basic hydrolysis of the respective protein or after its enzymatic hydrolysis with specific proteases. The amino acids from the hydrolysate are separated by chromatographic techniques, e.g., ion-exchange chromatography, HPLC, or gas-liquid chromatography. They are detected after conversion into colored derivatives (e.g., with ninhydrine or fluorescamine). Automatic amino acid analyzers have been developed (Needleman, 1970).

Some information about the occurrence of special amino acids and especially about their functional and structural roles in distinct proteins can be obtained from specific amino acid modifications. There exist different reagents reacting with distinct amino acids, like the sulfhydryl reagent 5,5′-dithio-bis-2-nitrobenzoic acid (DTNB, Ellman's reagent), the fluorescent amino group reagent 5-dimethylaminonaphthalene-1-sulfochloride (DANSYL chloride), or the tryptophan reagent 2-hydroxy-5-nitrobenzyl bromide (Koshland's reagent). In native proteins, only such amino acid residues react as are accessible by the reagent, and from this, information about their localization in the protein molecule can be gained.

Proteins from microorganisms can be modified by mutation. These are induced by special mutagens like bromouracil, diethylsulfate, or UV and x-ray radiation. With this method, amino acid exchanges, breaks, or deletions of parts of the polypeptide chain are created, and the changes in protein structure and function can be studied. Defined exchanges of special amino acids, e.g., in binding regions or catalytic centers, are obtained by the method of site-directed mutagenesis. Short oligonucleotides with the nucleotide sequence of the respective gene region including the desired mutation are synthesized with an automatic DNA synthesizer. This fragment hybridizes with a single-stranded DNA vector containing the original gene, and a DNA polymerase completes the oligonucleotide to the complementary DNA strand. The resulting mutant gene is transformed into a microbial host like *Escherichia coli* that expresses the modified protein. Site-directed mutagenesis allows introduction of any desired amino acid exchange. In combination with computer modeling, predicted changes—e.g., altering of binding specificity or functions of proteins—can be realized.

The amino acid sequences of proteins are resolved by successive splitting and determination of the terminal amino acids. There exist several methods for determination of both the amino terminal and the carboxy terminal residues of polypeptides, such as the conversion with phenylisothiocyanate (PITC, Edman's reagent) or fluorodinitrobenzene (Sanger's reagent). Specific enzymes, the aminopeptidases and the carboxypeptidases, cleave amino acid residues from the amino and the carboxy terminus, respectively (Needleman, 1970; Hugli, 1989). Protein sequences can be derived also from the DNA sequence of the respective genes. After cloning and isolation by methods of genetic engineering (e.g., the polymerase chain reaction, PCR), the gene is sequenced according to the Sanger or Maxam–Gilbert technique (Alberts *et al.*, 1989).

6.4 Determination of the Three-Dimensional Structure

The most powerful method to resolve the three-dimensional structure of a protein is x-ray crystallography. Electron-density maps are obtained from scattering of x rays or of synchrotron radiation by a protein crystal. For the interpretation of the density maps, a strongly scattering atom like a heavy-metal atom should be introduced into the protein molecule, e.g., by modification of side chains with mercurials. The density data are treated by Fourier transformation, and, in combination with the amino acid sequence, spatial arrangement of the polypeptide chain and association of protein subunits can be constructed (Cantor and Schimmel, 1980).

With other physical methods, only fragmentary information rather than a complete picture of the protein structure is obtained. However, such methods allow the study of proteins in solutions and especially of dynamic processes such as interaction with ligands and conformational changes. α helix, β-pleated sheet, and random coil, the major elements of the secondary structure of proteins, show characteristic circular dichroism (CD) spectra. CD spectroscopy serves to estimate the relative portion of these structures in proteins and allows the observation of changes of these structures. Information about secondary structure elements is revealed also from far-UV absorption spectra (200–220 nm). Especially aromatic amino acids contribute to the UV spectra of proteins in the range between 200 and 340 nm. Thus, the UV spectra of proteins give information about amino acid content, structure, and interaction with ligands. More sensitive is fluorescence spectroscopy, where the intrinsic protein fluorescence of aromatic amino acids can be taken as a specific signal from distinct positions of the protein molecule. Furthermore, amino acid residues can be labeled with fluorescent chromophores like fluorescein or dimethylaminonaphthalene as probes. With the method of fluorescence energy transfer, distances between different sites at a protein molecule can be estimated by introducing a pair of chromophores as donor and acceptor at the respective sites. The excitation energy of the donor is nonradiatively transferred to the acceptor, and the transfer efficiency is a measure of the distance. The size and shape of macromolecules can be obtained by fluorescence polarization and anisotropy measurements. Fluorescence is excited with linearly polarized light, and the polarization of the emitted light is measured as a ratio of the fluorescence intensities in and perpendicular to the plane of polarization. Depolarization occurs in dependence on molecular motion and thus the size of the molecule. Independent movements of distinct regions or groups on the protein surface can be detected (Brand, 1967).

Valuable information about the protein structure is obtained from electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR) spectroscopy. EPR is an extremely selective technique to detect unpaired, paramagnetic electrons, whose magnetic moment orients in an external magnetic field, and the resonance absorption of a microwave radiation is measured as a function of the magnetic field. Proteins themselves are not paramagnetic and give no EPR signal. Paramagnetic electrons appear in oxidative processes, e.g., in iron-sulfur clusters in the respiratory chain. Metal ions bound as cofactors to various proteins, like manganese, copper, or cobalt, give signals in the EPR spectroscopy. A large number of stable spin labels are available, which can be covalently attached to specific groups of the protein molecule and which act as reporter groups giving information about interactions in the environment of this region. Most frequently, the nitroxide radical stabilized as tetramethylpiperidinyl-1-oxyl (TEMPO) and coupled to a site-specific reactive group is used.

The NMR spectroscopy deals with the orientation of the nuclear magnetic moment in an external magnetic field. Transitions between distinct energy levels are induced by a perturbing field of a microwave oscillator, and the absorption of the energy of this field is determined. NMR signals in proteins are observed mainly with the isotopes ^{1}H, ^{13}C, and ^{31}P. Proton NMR gives information about H–C, H–N, and H–O bonds. Because of the large number of such bonds in a protein molecule, the picture is very complex and hard to unravel. Measurements must be performed in D_2O to eliminate the strong H_2O resonance. More specific signals are obtained by ^{13}C NMR. The intensities, however, are lower than with proton NMR, and the isotope must be incorporated into the protein (Freifelder, 1976).

6.5 Molecular Mass Determination

Molecular masses of polypeptide chains and protein subunits can be calculated from their amino acid sequences or from the DNA sequence of the respective genes. This gives, however, no information about the subunit composition of the protein. Similar information is obtained, in the absence of sequence data, from electrophoresis in the presence of the detergent sodium dodecylsulfate on polyacrylamide or agarose gels. The detergent adsorbs the protein, which dissociates into its subunits, and the negative charge of the detergent determines the migration rate of the protein subunits. In the narrow network of the gel, the protein becomes retarded according to its size, and in comparison to known standard proteins, the relative molecular masses of the protein subunits can be estimated.

A simple, but not very accurate, method for the determination of molecular masses of native proteins in their aggregated state is gel filtration chromatography (see Sec. 5.3). A more accurate technique is the analytical ultracentrifuge. Large proteins migrate in the gravitational field of an ultracentrifuge. The sedimentation velocity v depends on the molecular mass M_r, the partial specific volume $\bar{v}$ of the protein, the frictional coefficient f, and the density ρ of the solution:

$$\frac{M_r(1 - \bar{v}\rho)}{Nf} = \frac{v}{\omega^2 r} = s,$$

where N is Avogadro's number, ω is the angular velocity, and r is the distance from rotation center. The sedimentation coefficient s (usually expressed in Swedberg units $S = 1 \times 10^{13}$ s) is a characteristic value for the macromolecule from which the molecular mass can be deduced. The sedimentation behavior of the protein is followed during the centrifugation run with special ultracentrifugation cells equipped with observation windows. The sedimentation of the sample is observed by UV absorption, or Schlieren or interference optics. Two different ultracentrifugation techniques are applied. The *sedimentation velocity method* registers the velocity v of the particle in the gravitational field. From v, r, and the angular velocity ω, the sedimentation coefficient s is obtained. More accurate is the *sedimentation equilibrium method*. During sedimentation, the particles form a boundary moving to the bottom of the ultracentrifugation cell. This migration is opposed by diffusion. The two effects are counterbalanced at equilibrium, and the boundary remains at a constant position. From the steepness of the boundary, the molecular mass can be calculated.

Molecular masses of proteins and enzymes even in crude preparations can be estimated by the technique of differential gradient centrifugation. In the ultracentrifuge tube, a linearly increasing concentration gradient of a dense medium like sucrose is prepared before centrifugation and the protein sample is applied onto the top of the gradient. In the gravitational field, the protein migrates according to its mass as a single band. From the migration distance of the protein band to the top of the gradient, the sedimentation coefficient and the molecular mass of the sample can be calculated in relation to known standard proteins.

During recent years, mass spectroscopy (MS) has become increasingly important also for proteins. The protein is ionized by fast-atom bombardment, and molecular masses are determined with high accuracy up to 400 000 without need for reference proteins for calibration. The structure of fragments from the protein produced by collisions with small neutral molecules can be analyzed in tandem mass spectrometers and gives information about structural aspects of the protein. Bombarding is done with argon or xenon atoms or cesium ions with kinetic energies of 8–35 keV for peptides and smaller proteins. For larger proteins, the fission products of ^{252}Cf with kinetic energies of 80 MeV are taken. The proteins are adsorbed on a nitrocellulose layer (plasma-desorption MS) and the time of flight (TOF-MS) of the ions is determined. For laser-desorption MS, the protein is embedded in an ultraviolet-absorbing matrix and ionized by a pulsed ultraviolet laser. With the electrospray method ionization is achieved by spraying the protein solution across an electrostatic field gradient. Besides molecular masses of proteins, changes due to mutations or modifications like glycosylation can be detected. Collision-induced decomposition (CID) by helium, argon, or xenon is used for sequencing of peptides and proteins with a tandem MS. The peptides are scanned in a first mass spectrometer, a selected beam passes a collision cell, and the resulting fragments are analyzed in a second mass spectrometer (Biemann, 1992).

Information about the size and the structure of proteins can be obtained also by electron microscopy. Especially for large protein molecules and aggregates like multienzyme complexes, the overall molecular shape and the subunit composition become visible. To create contrasts for the electron beam, the proteins must be pretreated with heavy metals like uranyl acetate or phosphotungstate, which, however, may cause some damage to the native conformation of the protein. A more gentle treatment is the shadowing of freeze-dried samples with platinum and carbon, though the resolution is poorer. An improvement of the resolution of electron micrographs and the elimination of artifacts are achieved by computer-aided image reconstruction, where a series of images of the molecule in the same projection is superimposed.

6.6 Measurement of Fast Reactions

For the study of extremely fast processes in catalysis, ligand binding, and conformational mobilities of proteins and enzymes, special techniques have been developed: flow or rapid mixing techniques and relaxation methods (Hiromi, 1979). The principle of the flow techniques, which have been developed by Chance (1974), is the minimization of the mixing time of the reactants, which is usually the time-limiting process for conventional measurements. Plungers of two syringes containing the reactant solutions are simultaneously compressed by hydraulic or mechanical forces, and the solutions are forced through narrow nozzles into a mixing chamber. In the *continuous-flow apparatus,* the reaction mixture flows at constant rate through an observation tube. During the flow, the reaction proceeds, and its age becomes proportionally to the distance from the mixing chamber. To follow the reaction course, the absorption or the conductivity of the reaction mixture is measured at different points of the observation tube. The disadvantage of this method is the need of large sample volumes.

For the *stopped-flow apparatus,* the observation tube is replaced by a reaction cell, and the drive of the plungers is stopped when the cell is filled with the reaction mixture (Fig. 9). Simultaneously, a trigger is released to start the detection. Most frequently, optical methods like absorption or fluorescence spectroscopy are applied. The signal is registered by a storage oscillograph or fast computer storage. The resolution time of the flow methods lies within the range of 1 ms.

The principle of the relaxation methods, developed by M. Eigen (Eigen and De Mayer, 1974), is the disturbance of an equilibrium by a rapid change of environmental parameter and the observation of the relaxation of the system to the new equilibrium conditions. Since the equilibrium constants depend on temperature, pressure, and field strength, distinct apparatus for each parameter have been constructed. For biological studies, the *temperature-jump apparatus* is most convenient. An observation cell contains the sample solution between two platinum electrodes. A high tension is applied and discharged by a spark gap. A current surge crosses the observation cell and ele-

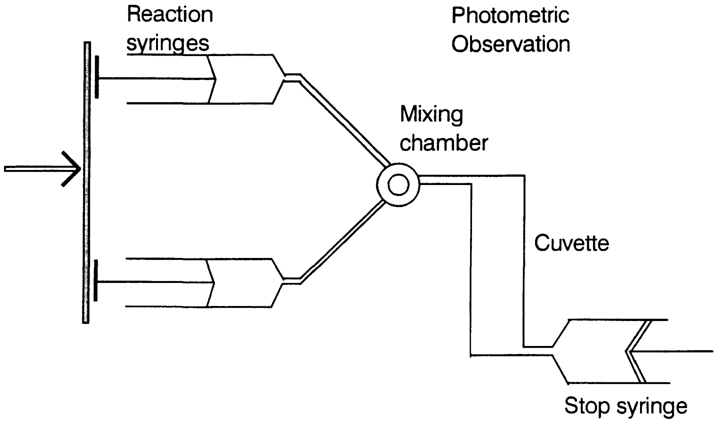

FIG. 9. Schematic drawing of a stopped-flow apparatus.

vates the temperature by some degrees by Joule heating within about 1 μs. A trigger starts the optical detection.

Instantaneous expansion of high pressure in the sample solution is the principle of the *pressure-jump technique.* Up to 100 atm are applied to the sample through compressed air. Rupture of a metal diaphragm with a steel needle allows the air to escape and releases the trigger. The time resolution is between 20 and 100 μs. Since high reactant concentrations are needed to obtain detectable signals, the method is less suited for enzymatic studies. Nearly no application for protein and enzyme studies is made of the *electric field-jump technique.* High electric fields are alternately applied and removed to the observation cell within short time intervals, and the relaxation of the sample to equilibrium is observed. Because of the considerably high field strength, the sample warms up within a short time, causing denaturation of proteins.

6.7 Peptide and Protein Synthesis

For the synthesis of a distinct protein, the amino acids must be arranged and combined in a defined sequence. The first step is the protection of amino acid side chains, which should not take part in the reaction, by selective protection groups. N-Benzyloxycarbonyl (cbo, cbz, Z), N-*tert*-butoxycarbonyl (boc), 4-toluenesulfonyl (tosyl), and triphenylmethyl (trityl) residues are protection groups for amino residues, and benzyl and *tert*-butyl residues for carboxy groups. These groups must be removed from the protein after the synthesis without impairing the peptide bonds and other amino acid side chains. A second prerequisite for protein synthesis is an extremely high degree of purity of the amino acids used, since even minute contaminations accumulate during the synthesis cycles of the growing protein molecule and cause incorrect incorporation of amino acids. For the same reason, completion of the reaction at each step must be assured. These problems limit the length of artificially synthesized polypeptide chains. Larger proteins must be constructed by combination of shorter fragments.

Two different principles for peptide synthesis exist: the conventional peptide synthesis in solution and the solid-phase technique. Synthesis in solution has the disadvantage that the reaction intermediate must be isolated after each cycle. Therefore, the development of the *solid-phase technique* by R. B. Merrifield in 1963 was a valuable improvement (Erickson and Merrifield, 1976). The growing peptide chain is fixed to solid matrices like polystyrene, and the amino acids are linked to it in standardized reaction cycles. Automatic synthesizers are constructed for this technique. A disadvantage is that purification of intermediates is impossible.

7. TECHNICAL APPLICATIONS OF PROTEINS AND ENZYMES

7.1 Immobilization of Proteins and Enzymes

Enzymes as very efficient catalysts are highly recommended for technical applications. A serious obstacle, however, is their instability and the fact that the extremely valuable enzyme material becomes lost within the reaction batch, and reisolation from there is unprofitable. This problem can be overcome at least for some special enzymes of industrial interest by immobilization to solid supports. These can be removed from the reaction batch and regenerated for the next process. Immobilization is also applied for proteins with other functions like antibodies. Different immobilization techniques are used: entrapment into microcapsules, fixation to solid supports, and cross-linking.

Entrapment is the most gentle immobilization technique since the proteins retain their native structure. Proteins have been included into microcapsules formed by polymerization of nylon or nitrocellulose in an organic phase of an emulsion with the aqueous protein solution. Also, microcapsules consisting of phospholipid or cholesterol liposomes are applied. Protein entrapment is also possible in hollow fibers. These are long narrow tubes (about 1-mm diameter) of semipermeable cellulose or synthetic polymer membranes. They provide large surfaces for the exchange of the entrapped protein with the surrounding solution. Polymer lattices like polyacrylamide or agarose are further used for protein entrapment. A disadvantage of protein entrapment, however, is the limitation of free diffusion of the reaction components from the outside solution to the entrapped protein. Steric obstacles, charges, or polarity may limit both the diffusion of the substrate to its enzyme and that of the product outside, so that inside the microcapsule, a region of substrate depletion and product accumulation will be generated. Since most enzyme reactions are inhibited by larger product concentrations, this effect may cause a severe activity decline.

Fixation to *solid supports* can be achieved by noncovalent adsorption of the polyionic proteins to anion or cation exchangers under defined conditions of ionic strength and *p*H value. The proteins keep their native structure and can be stripped off from the matrix by change of *p*H or ionic strength after the reaction process. Covalent attachment of proteins to solid matrices yields stable adducts but may influence the native protein structure and function. As matrices dextrans, cellulose, synthetic polymers, silanized glass, and ceramics are used. They must be activated to introduce reactive groups for the covalent protein fixation. Cyanogen bromide, epoxide, or transition-metal salts like $TiCl_4$ or $SnCl_4$ are applied for activation. The protein is linked to the activated matrix either directly or via spacer molecules like hexamethylene diamine or glutardialdehyde to prevent steric hindrance between support and protein.

Cross-linking of proteins with bifunctional reagents like glutardialdehyde without supports yields large, insoluble aggregates, which can easily be separated from the solution after reaction. The cross-linking can be done either with homogeneous proteins or by co-immobilization between the sample and an inert stabilizing protein, like serum albumine.

If instability of an enzyme allows no immobilization, whole cells containing considerable activities of the pertinent enzyme are immobilized. An example is the transformation of steroids by bacterial cells used for synthesis and modification of drugs. Entrapment techniques or covalent linkage are applied in this case. Mammalian cells immobilized as monolayer cultures to solid supports with glycoproteins are used for hormone detection.

7.2 Enzyme Reactors

To perform reaction processes with immobilized enzyme on industrial scales, special reactors have been constructed. In the *stirred-tank reactor,* the immobilized enzyme particles are stirred in a vessel together with the substrate. After the reaction, the enzyme particles are collected by filtration or centrifugation. The procedure is laborious, but it is applicable to viscous and particulate substrates, which may block membranes of other reactor types. The stirred-tank reactor can be run continuously by constant pumping of the substrate solution into the reaction vessel and withdrawing the reaction product through a membrane. The efficiency of such reactions can be increased by packing the immobilized enzyme into columns. The substrate solution flows up or down the column (*fixed-* or *packed-bed reactor*). The *fluidized-bed reactor* is a combination of the two principles. The flow rate of the upward stream of the substrate solution balances the sedimentation of the enzyme particles.

Enzyme reactors are applied for amino acid synthesis, isomerization of glucose to fructose, production of wort from unmalted barley in brewing, antibiotic processing, and drug synthesis and modification. Immobilized systems have been developed for the regeneration of coenzymes that are involved in the reactions, which may otherwise be lost during the process (Woodward, 1985).

7.3 Biosensors

Biosensors (enzyme electrodes) gain increasing importance in industrial processes like fermentation and bioreactors, where they control the reaction progress. In medicine, biosensors are used for distinct diseases to detect metabolites in serum and urine. Biosensors consist of a biological system, usually an enzyme, entrapped or fixed to a support and shielded from the surrounding liquid by a membrane permeable for the enzyme substrate. This compartment is connected to a transducer. The transducer is an electrode sensitive for oxygen, carbon dioxide, ions, or *p*H, or an optoelectrical detector combined with a field-effect transistor. It transduces the enzyme reaction, e.g., oxygen formation or *p*H change, into an electrical signal, which is monitored after amplification. Biosensors are used to determine glucose (e.g., in the blood), urea (in the urine), amino acids, cholesterin, antibiotics, and peroxides (Turner, 1987). Enzyme thermistors monitor the heat generated in the course of an enzyme reaction. The substrate solution passes a column containing the immobilized enzyme, and the temperature of the eluate is measured with a thermistor. Enzyme thermistors allow the detection of extremely small metabolite concentrations.

7.4 Medical Applications

Proteins and especially enzymes play an important role in medicine. In the course of different diseases and metabolic disorders, the level of distinct enzymes in the organism changes. The variation of enzyme and metabolite levels is tested in enzyme diagnostics in the blood or in tissue samples to gain information about the type and course of the disease and also for prophylaxis. Inborn errors like phenylketonuria or glycogen storage diseases can be identified in this way. Inhibition of enzymes by specific inhibitors acting as substrate analogs is widely used in therapy, e.g., the reduction of cholesterol synthesis to prevent formation of arterial plaques. Various drugs and toxic substances like heavy metals and cyanide block specifically enzyme reactions or other protein functions like hormone receptors (e.g., beta blockers). In special cases, direct administration of enzymes, especially into the blood, serves in therapy (*enzyme therapy*) to remove toxic substances. Blood clots are dissolved by the administration of the enzymes streptokinase and urokinase. In tumor therapy, the enzyme asparaginase is used, which cleaves asparagine, a metabolite essential for some tumours.

7.5 Protein Engineering and Artificial Enzymes

Site-directed mutagenesis allows the exchange of special amino acids in proteins. In combination with computer modeling, this is a powerful tool to create proteins and enzymes with modified features with respect to substrate specifity, inhibitor sensitivity, thermal stability, etc. With special computer programs, the three-dimensional structure of an enzyme (so far as known from x-ray crystallography or other methods) can be visualized on a screen, and distinct amino acid residues can be exchanged and adapted to the overall protein structure, like bulky or charged residues. For example, catalytic centers can be constructed to accept alternative substrates. These predictions are tested and verified by site-directed mutagenesis, which realizes the projected amino acid exchanges. In this way, the substrate specificity of the enzyme xylose isomerase has been changed from xylose to glucose (Meng *et al.,* 1991).

A recently developed method to create artificial enzymes is the construction of catalytic antibodies. This technique is based on the assumption that the principle of enzyme catalysis is the stabilization of the transition state of a reaction. Monoclonal antibodies are raised against stable transition-state analogs to form complementary structures at its antigen binding sites. Several examples of reactions catalyzed by catalytic antibodies have already been demonstrated (Benkovic, 1992).

Less promising are attempts to construct artificial enzymes by chemical synthesis (synzymes). As models of binding sites for substrate molecules, cyclic compounds with a hole in their middle are chosen, like cyclodextrines and crown ethers with different diameters. Functional groups to perform general acid/base catalysis and other mechanisms are introduced. Reactions like hydrolysis, proton transfer, acyl transfer, proceeding partially stereospecific, could be demonstrated. The reaction rates of artificial enzymes, however, remain far behind those of natural enzyme reactions (Komiyama and Bender, 1984; Stoddart, 1984).

GLOSSARY

Cell Compartments: Particles and organelles within the living cell representing distinct functional regions: the nucleus as carrier of the genetic information, the mitochondria responsible for energy generation and cell respiration, the chloroplasts as the place of photosynthesis, and the lysosomes, which concentrate degradative activities.

Cellular Respiration: Process of energy generation in the cell. Hydrogen from various reductive processes is transmitted to molecular oxygen in a multistep reaction by the mitochondrial respiratory chain. The energy released by this reaction is stored in the form of energy-rich phosphoric acid anhydride bonds.

Coenzymes (Cofactors): Nonprotein portion of enzymes that supports the catalytic process. Coenzymes are often vitamins or metal ions.

Cytoplasm: Total cell contents besides the cell organelles. Many essential cell functions like protein biosynthesis and various metabolic pathways occur in the cytoplasm. The soluble fraction of the cytoplasm is the cytosol.

Enzymes: Biocatalysts controlling all reactions within living organisms. Enzymes are protein molecules, partly associated with a nonprotein portion, the coenzyme or prosthetic group.

Hormones: Biologically active substances produced by distinct organs and acting specifically on other organs, tissues, or cells. Hormones are important regulators of development, growth, and metabolism of organisms.

Immobilized Enzymes: Enzymes fixed to solid supports or entrapped in microcapsules. They serve as catalysts in biotechnical processes.

Ligands: Compounds, mainly of low molecular mass, that specifically interact with macromolecules, e.g., enzyme substrates or hormones binding to receptors.

Metabolism: Sum of all (usually enzyme-catalyzed) reactions occurring in the living cell.

Metabolites: Compounds that participate in the cell metabolism as substrates and products of enzyme reactions, as intermediates of metabolic pathways, and as precursors of biological active substances. Metabolites act often as regulators of metabolic pathways or related processes like gene regulation.

Mitochondria: Large organelles of eukaryotic cells executing various essential functions of the cell. Mitochondria possess an outer and an inner membrane. The inner membrane carries the major components of the respiratory chain. The inner mitochondrial space, the matrix, contains important enzymes for energy metabolism and fatty acid degradation.

Nucleotides: Building units of the nucleic acids consisting of a heterocyclic base, a sugar (ribose or deoxyribose), and phosphoric acid.

Nucleic Acids: Large nucleotide polymers, which act as carriers of the genetic information and are responsible for the translation of this information into functional components of the cell like proteins.

Oligosaccharides: Polymeric molecules consisting of sugar units, like glucose. Oligosaccharides serve as energy storage (starch, glycogen) and have structural functions (cellulose, cell wall components).

Prosthetic Groups: Nonprotein components covalently bound to catalytic centers of enzymes and essentially involved in the catalytic mechanisms.

Proteins: Macromolecules consisting of polymeric chains from different α-amino acids arranged in distinct sequences. Proteins are involved in all essential functions of living organisms like cell metabolism, energy generation, gene reproduction, and translation, motility, sensory, and structural functions. The most important group of proteins are the enzymes.

Reaction Order: Classification of chemical reactions according to the number of reactants involved; e.g., reaction of two substances is second order.

Receptors: Regions at the surfaces and membranes of cells that interact with specific signal substances like hormones or neurotransmitters and transduce the signal into the cell. Receptors are mainly built from membrane proteins.

Ribosomes: Cellular particles that are responsible for the translation of the genetic information encoded in nucleic acids into the primary sequence of proteins (protein biosynthesis). Ribosomes consist of proteins and nucleic acids.

Second Messengers: Cellular substances accepting signals from hormones and neurotransmitters from the outside of the cell and causing the transformation of the messages into cellular functions. The most important second messenger is cyclic AMP.

INTRODUCTION

Quantum electrodynamics is a natural generalization of quantum mechanics that satisfies the requirement of relativity. It is applicable without restriction to all phenomena involving the electromagnetic interaction. Its validity has been confirmed up to a few parts in 10^{12} in precision and down to the length scale of about 10^{-17} m.

In order to understand quantum electrodynamics, it is useful to recall what was wrong with classical electrodynamics, which after all was one of the most successful theories in the history of physics. Classical electrodynamics is applicable to most electromagnetic phenomena and describes them quite accurately. However, it is found to disagree with observations on a microscopic scale, the spectrum of the blackbody radiation and the photoelectric effect being two such phenomena discovered around the end of the nineteenth century. Furthermore, it is incapable of providing a satisfactory explanation for the structure of atomic spectra or the stability of atoms and molecules. From a more fundamental point of view, it suffers from internal inconsistencies such as the infinite energy of self-interaction of charged particles.

As is well known, efforts to resolve some of these difficulties led to the discovery of quantum mechanics. Quantum mechanics has been extremely successful. Through it, the structure of the spectra of atoms and molecules is understood for the first time. It describes qualitatively the emission and absorption of photons by atoms and molecules, although the proper quantitative treatment of the photon had to wait for the development of a quantum theory of photons. It has become the foundation of modern physics and of most modern technologies including lasers, semiconductors, and superconductors. Even in the seemingly macroscopic domains such as establishing practical standards of electricity and magnetism, high-precision re-

alization of such standards now depends on quantum effects such as the ac Josephson effect of superconductors and the quantum Hall effect of semiconductors at very low temperature (Cohen and Taylor, 1987).

Insofar as practical applications are concerned, there seems to be no need to go beyond the conventional quantum mechanics. However, this is not completely satisfactory. First of all, quantum mechanics cannot possibly be exactly correct since it does not incorporate special relativity, which is one of the cornerstones of modern physics. It is not capable of explaining why electrons obey the Pauli exclusion principle. Furthermore, its predictions often diverge if one tries to calculate beyond lowest-order approximations. The first defect was recognized as soon as quantum mechanics was formulated around 1925, and efforts were made to make quantum mechanics compatible with relativity. However, this task turned out not to be so trivial, and it took more than 20 years before a theory that satisfies the requirement of relativity and incorporates the exclusion principle was formulated successfully. The renormalized quantum electrodynamics (hereafter abbreviated as QED) is the outcome of this effort.

QED has turned out to be much more than a mere marriage of quantum mechanics and relativity. The wave/particle duality is now fully incorporated in the theory, and electrons and photons are treated on the same footing, viz., as quantized fields. It enables us to handle not only the motion of particles dynamically but also the creation and destruction of photons and electron-positron pairs.

What makes QED particularly intriguing is that, for the first time in the history of physics, we have found a theory that has no obvious intrinsic limitations and enables us to calculate physical phenomena from first principles to any accuracy we need in terms of a few measurable parameters such as the elementary electric charge e and the electron mass m_e. Predictions of QED have been confirmed by extensive experiments without exception. In recent years, it has become the prototype of a more general theory, called the standard model, that unifies the electromagnetic force with the weak and strong forces found in nuclear and elementary particle physics.

Throughout this article, only more recent works not found in standard textbooks will be cited. Others may be found in textbooks quoted in Further Reading.

1. DEVELOPMENT OF QED

1.1 Brief Review of Quantum Mechanics

Since QED is nothing but a relativistic extension of ordinary quantum mechanics, it will be useful to begin by recalling the basic features of the latter. Quantum mechanics was discovered in the efforts to make sense out of various observations of atomic scale that contradicted predictions of classical physics. Experiments showed convincingly that classical waves behave like particles (e.g., in the photoelectric effect) and classical particles behave like waves (e.g., in the diffraction of electrons by a crystal lattice) at the atomic scale. A crucial step from classical physics to quantum physics is to accept this wave/particle duality as the fundamental experimental fact. As was noted by A. Einstein and L. de Broglie, the energy E and the momentum p carried by a particle are then related to the frequency ν and the wavelength λ of the associated wave by

$$E = h\nu, \quad p = h/\lambda, \tag{1}$$

where $h = 6.626\,075\,5\,(40) \times 10^{-34}$ J s is Planck's constant. The quantity enclosed in the parentheses represents the measurement uncertainty in the final digits of the numerical value.

One of the characteristic features of a wave is that the peak of its oscillation cannot be located much more precisely than its wavelength. This is translated in quantum theory to the statement that the position x and the corresponding momentum p_x cannot be measured precisely at the same time. Mathematically, p_x can be expressed as a differential operator

$$p_x = \frac{\hbar}{i}\frac{\partial}{\partial x}, \quad \text{where } i = \sqrt{-1}. \tag{2}$$

As is easily checked, the products xp and px, acting from the left on a function of x, are not equal but related to each other by the "commutation relation"

$$xp_x - p_x x = i\hbar \quad \text{or}\ [x,p_x] = i\hbar,$$

where $[x,p_x] \equiv xp_x - p_x x$ is called a commutator. This leads to the Heisenberg uncertainty relation

$$\Delta x \Delta p_x \geq \hbar,$$

where Δx and Δp_x are uncertainties in the position x and the momentum p_x when they are measured simultaneously. Similar commutation relations and uncertainty relations hold for the y and z axes, too. In addition, the energy E becomes an operator

$$E = -\frac{\hbar}{i}\frac{\partial}{\partial t}, \tag{3}$$

leading to another uncertainty relation,

$$\Delta t \Delta E \geq \hbar.$$

In classical physics, the energy E of a free particle of mass m and momentum p is described by the equation

$$E = p^2/2m. \tag{4}$$

If one applies the substitution rules [Eqs. (2) and (3)] to Eq. (4) and supplies a "wave function" $\psi(t,x)$ on which the differential operators operate, one obtains the wave equation

$$i\hbar \frac{\partial}{\partial t}\psi(t,x) = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi(t,x).$$

This is the Schrödinger equation, which gives a complete quantum description of the motion of a free particle in one space dimension. The square of the absolute value of the wave function $\psi(t,x)$ gives the probability for finding the particle at the location x at the time t. Generalizations to three space dimensions and to several particles, and inclusion of the potential energy, are straightforward.

1.2 Quantization of a Free Electromagnetic Field

Shortly after the birth of quantum mechanics, P. A. M. Dirac, W. Heisenberg, and W. Pauli attempted to quantize the energy contained in the electric field $\mathbf{E}(t,\mathbf{x})$ and magnetic field $\mathbf{B}(t,\mathbf{x})$—as required by quantum mechanics for the energy of any physical system. This is not simple because $\mathbf{E}$ and $\mathbf{B}$ are not only functions of time t but also of position $\mathbf{x}$ and hence have infinitely many degrees of freedom. Nevertheless, they managed to quantize it by requiring that $\mathbf{E}$ and $\mathbf{B}$ satisfy a commutation relation analogous to that of x and p_x. The actual form of commutation relations for $\mathbf{E}$ and $\mathbf{B}$ is fairly complicated. It is simpler to write them for the four-vector potential A^μ.

In dealing with relativity, it is convenient to treat the position $\mathbf{x}$ and ct, where c is the speed of light in vacuum and t is the time, together as a vector in four-dimensional space-time. This combination is called a four-vector and denoted as x^μ, $\mu = 0, 1, 2, 3$, where $x^0 = ct$, $x^1 = x$, $x^2 = y$, $x^3 = z$. If one introduces another four-vector $x_\mu \equiv \Sigma_{\nu=0}^3 g_{\mu\nu} \times x^\nu$, where $g_{00} = 1$, $g_{11} = g_{22} = g_{33} = -1$, $g_{\mu\nu} = 0$ otherwise, the principle of relativity can be reduced to the geometrical statement that the "scalar product" of four-vectors x^μ and y_μ, $x^\mu y_\mu \equiv x^0 y^0 - \mathbf{x}\cdot\mathbf{y}$, has the same value in any inertial frame; in other words, it is invariant under the Lorentz transformation. Here and elsewhere in this article, we drop the summation symbol following the convention. Some important four-vectors are the energy-momentum four-vector $p^\mu = (E/c,p_x,p_y,p_z)$ and the four-vector potential $A^\mu = (\phi,A_x,A_y,A_z)$ mentioned already, where ϕ and $\mathbf{A}$ are the scalar and vector potentials in the conventional sense. When there is no danger of confusion, p^μ is often written as p and $p_\mu p^\mu$ as $p\cdot p$ or p^2. Another convention we adopt hereafter is natural units, in which $\hbar = c = 1$ where $\hbar$ is Planck's constant h divided by 2π, instead of SI units. This is done to avoid unnecessary complication of notation. It is not difficult to reconstruct SI units from natural units.

The actual form of A^μ depends on the choice of gauge (see Glossary). In the gauge called "Feynman gauge," it can be written, if A_μ and A_ν have equal time t, as

$$[\dot{A}_\mu(t,\mathbf{x}),\dot{A}_\nu(t,\mathbf{y})] = 0,$$

$$[A_\mu(t,\mathbf{x}),A_\nu(t,\mathbf{y})] = 0,$$

$$[\dot{A}_\mu(t,\mathbf{x}),A_\nu(t,\mathbf{y})] = ig_{\mu\nu}\delta^3(\mathbf{x}-\mathbf{y}), \tag{5}$$

where $\dot{A}_\mu \equiv \partial A_\mu/\partial t$ and $\delta^3(\mathbf{x}) \equiv \delta(x^1)\delta(x^2)\delta(x^3)$,

δ being Dirac's delta function. Reflecting the infinite degrees of freedom of the electromagnetic field, the quantized energy, which can be obtained by applying the action principle to the Lagrangian

$$\mathcal{L}_M = -\tfrac{1}{4} F_{\mu\nu}F^{\mu\nu}$$

and using the commutation relation (5), can be expressed as a superposition of an arbitrary number of quanta. Here, $F_{\mu\nu} \equiv \partial A_\mu/\partial x^\nu - \partial A_\nu/\partial x^\mu$ is the covariant form of the electromagnetic field. This quantum can be identified with Planck's photon, the fundamental carrier of light and electromagnetic radiation. The quantized form of Maxwell's equation requires that the photon be a particle of zero mass, with constant velocity c ($\sim 3 \times 10^8$ m/s) and one unit of angular momentum $\hbar$—directed either along or against its direction of motion. The field amplitudes **E** and **B** [and the four-vector potential $A^\mu(x)$] are now quantum-mechanical operators that have nonzero matrix elements only between states that differ by exactly one photon. This enables us to describe correctly the emission and absorption of radiation in atomic systems.

1.3 Quantization of a Free Electron Field

During this exciting period in which developments in quantum theory came at an incredible rate, Dirac was trying to find a relativistic generalization of the (nonrelativistic) Schrödinger equation for a particle of mass m. Starting from Einstein's energy-momentum relation

$$E^2 = p^2c^2 + m^2c^4,$$

which reduces to the well-known formula "$E = mc^2$" for $p = |\mathbf{p}| = 0$, he was led to the equation

$$[i\gamma_\mu(\partial^\mu + ieA^\mu) - m]\psi(x) = 0, \tag{6}$$

which describes the motion and spin (internal angular momentum) of an electron in an (unquantized) electromagnetic potential A^μ. Here, $\partial_\mu \equiv \partial/\partial x^\mu$, ψ is a one-column four-row matrix, and γ_μ are a set of noncommuting 4×4 matrices satisfying the commutation relation

$$\gamma_\mu\gamma_\nu + \gamma_\nu\gamma_\mu = 2g_{\mu\nu}, \quad \mu, \nu = 0, 1, 2, 3.$$

The application of Eq. (6) to an electron bound in a Coulomb field led to the successful prediction of the fine structure of the energy levels of the hydrogen atom caused by the interaction between spin and orbital motion of the electron. The ratio of the fine-structure separation to the Rydberg is of the order of

$$\alpha \equiv e_0^2/4\pi\hbar c \sim 1/137.$$

This dimensionless number, called the fine-structure constant, characterizes the nature of the electromagnetic interaction and plays the central role in the theory of QED described in the following.

Unfortunately, Dirac's equation had some paradoxical features and defied simple probabilistic interpretation. P. Jordan and E. P. Wigner realized that this difficulty can be resolved if Dirac's ψ is treated not as a probability amplitude for finding a particle at **x** but as a dynamical wave similar to the electromagnetic field and is quantized accordingly. The only new feature is that a product of two ψ's must satisfy a different commutation relation, called (equal-time) anticommutation relation:

$$\{\psi_\xi(t,\mathbf{x}),\psi^\dagger_\eta(t,\mathbf{y})\} = \delta_{\xi\eta}\delta^3(\mathbf{x} - \mathbf{y}), \quad \xi, \eta = 1, 2, 3, 4, \tag{7}$$

where $\psi^\dagger$ is the Hermitian conjugate of ψ, $\{A,B\} \equiv AB + BA$, and $\delta_{\xi\eta} = 1$ if $\xi = \eta$, $= 0$ otherwise. The quanta of the ψ field can be identified with the physical electrons and positrons—particles (antiparticles) that have charge $\mp|e|$, mass m, and angular momentum $\frac{1}{2}\hbar$ directed along or against their motion and obey the Pauli exclusion principle. More specifically, the Dirac ψ field becomes a quantum-mechanical operator that destroys an electron or creates a positron. Conversely, $\bar{\psi}(\equiv \psi^\dagger\gamma^0)$ destroys a positron or creates an electron. Note that electron and positron are described symmetrically by ψ and $\bar{\psi}$ (charge-conjugation symmetry). These properties follow from the Lagrangian

$$\mathcal{L}_D = \tfrac{1}{2} i[\bar{\psi}\gamma^\mu\partial_\mu\psi - (\partial_\mu\bar{\psi})\gamma^\mu\psi] - \tfrac{1}{2} m_0[\bar{\psi},\psi] \tag{8}$$

and the anticommutation relation [Eq. (7)].

1.4 Interaction of the Electron Field and the Electromagnetic Field

Classical electrodynamics suggests (by the "correspondence principle") a quantum form of interaction energy density between the electron, positron, and photon, namely,

$$e_0 j_\mu(x) A^\mu(x), \quad \text{where } j_\mu(x) = \tfrac{1}{2}\,[\bar{\psi}(x), \gamma_\mu \psi(x)]. \tag{9}$$

(Note $j_\mu A^\mu \equiv j^0 A^0 - \mathbf{j}\cdot\mathbf{A}$.) If one accepts Eq. (9), the dynamics of the interacting photon, electron, and positron can be described by the Lagrangian density

$$\begin{aligned}\mathscr{L} = {} & \tfrac{1}{2}\, i[\bar{\psi}\gamma^\mu \partial_\mu \psi - (\partial_\mu \bar{\psi})\gamma^\mu \psi] - \tfrac{1}{2}\, m_0[\bar{\psi}, \psi] \\ & - \tfrac{1}{4}\, F_{\mu\nu}F^{\mu\nu} + \tfrac{1}{2}\, \mu_0^2 A_\mu A^\mu \\ & - \tfrac{1}{2}\, \lambda_0(\partial_\mu A^\mu)^2 - \tfrac{1}{2}\, e_0[\bar{\psi}, \gamma^\mu \psi]A_\mu.\end{aligned} \tag{10}$$

Here μ_0 and λ_0 are a (vanishingly) small photon mass and an arbitrary (gauge) parameter, respectively, introduced for technical reasons. (We must put $\mu_0 = 0$ after the calculation is finished. The final answer should not depend on the value of λ_0.)

If the electric charge e_0 is zero, $\mathscr{L}$ reduces to $\mathscr{L}_M + \mathscr{L}_D$. Upon quantization, the fields ψ, $\bar{\psi}$, and A_μ become operators, each creating or destroying an electron, a positron, or a photon at a time. The energy operator derived from $\mathscr{L}_D + \mathscr{L}_M$ has a structure such that, if a state has given numbers of photons, electrons, and positrons initially, the state remains the same at any later times. Change in the state can occur only if the interaction term is taken into account. An exact solution including this term, which makes the theory nonlinear, has not been obtained thus far.

A common method to find an approximate solution is to expand the solution into a power series in e_0 and determine the expansion coefficients. This method, called perturbation theory, works very well for QED if one restricts oneself to the lowest-order terms, the expansion parameter e_0 being rather small. The results of such calculations are in good agreement with experiment, unless the energy of the photon is too low.

In lowest-order perturbation theory, because of quantization of ψ and A_μ, the interaction term has nonzero matrix elements only between states that differ by one photon or one electron-positron pair. This may be represented graphically by the "vertex" diagrams shown in Fig. 1, where the upper and lower parts correspond to the final state and initial state, respectively. Note that the vertex conserves charge and is "local", i.e., it describes the creation or absorption of a photon at the same point $x = (t,\mathbf{x})$ in time and space where an electron (or positron) scatters or where an electron-positron pair is created or destroyed. The corresponding matrix elements are proportional to (a) $e_0\bar{u}(q)\gamma_\mu u(p)\epsilon^\mu(k)$, (b) $-e_0\bar{v}(q)\gamma_\mu v(p)\epsilon^\mu(k)$, (c) $e_0\bar{u}(q)\gamma_\mu v(p)\epsilon^\mu(k)$, (d) $e_0\bar{v}(q)\gamma_\mu u(p)\epsilon^\mu(k)$. Here $u(p)$, $v(p)$ are one-column, four-row matrices satisfying $(\gamma^\mu p_\mu - m)u(p) = 0$, $(\gamma^\mu p_\mu + m)v(p) = 0$, and $\bar{u}(p)$, $\bar{v}(p)$ are one-row, four-column matrices satisfying $\bar{u}(p)(\gamma^\mu p_\mu - m) = 0$, $\bar{v}(p)(\gamma^\mu p_\mu + m) = 0$, respectively. The term $\epsilon^\mu(k)$ represents the polarization state of a photon of four-momentum k.

The transition amplitude for more complicated physical processes can be obtained from the iteration of the basic interaction (i.e., higher-order terms of perturbation expansion in powers of e_0). In the order e_0^2, new diagrams appear in which some lines connect vertices. Such solid lines are called internal electron lines while wavy lines are called internal photon lines. Other lines are called "external." For example, the order-e_0^2 amplitude for the electron-positron collision can be computed from the "Feynman diagram" shown in Fig. 2(a). It is proportional

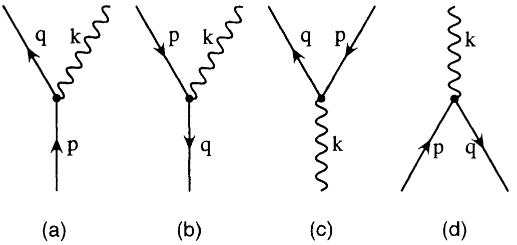

FIG. 1. These "vertex" diagrams are graphic representations of the basic interaction between electron, positron, and photon. (a) Emission of a photon (represented by a wavy line) by an electron (represented by a solid line with an upward arrow) that recoils to a different four-momentum state. (b) Emission of a photon by a positron (represented by a solid line with a downward arrow). (c) Creation of an electron-positron pair by a photon, and (d) its reverse. There are four more diagrams. Each diagram must conserve energy, momentum, and charge. The corresponding matrix elements vanish because of energy-momentum conservation if the electron, positron, and photon are free.

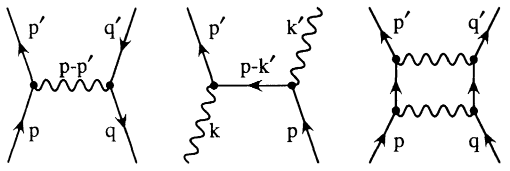

(a) (b) (c)

FIG. 2. Examples of second-order diagrams. (a) Scattering of a positron and an electron caused by an exchange of a virtual photon. (b) Scattering of a photon on an electron caused by an exchange of a virtual electron. (c) An example of higher-order diagrams in which more than one photon is exchanged.

to

$$ie_0^2\bar{u}(p')\gamma_\mu u(p)\,\frac{1}{(p-p')^2}\,\bar{v}(q)\gamma^\mu v(q'),$$

where the factor $1/(p-p')^2 \equiv [(E-E')^2 - (\mathbf{p}-\mathbf{p}')^2]^{-1}$, called a photon propagator, represents propagation of the photon carrying momentum $\mathbf{p}-\mathbf{p}'$ and energy $E-E'$ between the electron and the positron. A similar propagator $[\gamma_\nu(p^\nu - k'^\nu) - m]^{-1}$ occurs in diagrams such as Fig. 2(b) for the propagation of the internal electron or positron. The corresponding amplitude is of the form

$$ie_0^2\bar{u}(p')\epsilon_\mu(k')\gamma^\mu[\gamma_\nu(p^\nu - k'^\nu) - m]^{-1} \times \epsilon_\sigma(k)\gamma^\sigma u(p).$$

The diagram of Fig. 2(c) is an example of the e_0^4 term. These diagrams give contributions to the collision cross section that are smaller than that of Fig. 2(a) by a factor of order α. Because of the smallness of α, it is usually sufficient to calculate the lowest-order terms in order to compare with experiments.

The absolute square of the sum of all the possible amplitudes for the process gives the quantum-mechanical probability, or, in the case of a collision process, the cross section.

1.5 Divergence Difficulty

Despite the apparent correctness of the basic structure of the interaction between the photon and the electron, the good agreement with experiment is completely destroyed as soon as one tries to improve the theory by including higher-order terms of perturbation theory. The correction terms are infinitely large!

For example, the calculation of the energy shift of a free electron due to its emission and subsequent absorption of a single photon, shown in Fig. 3, gives an infinite result. This divergence difficulty can be traced to the basic interaction being pointlike (local). Attempts to solve this problem by giving a finite size to the electron have not been successful.

A breakthrough on this problem was brought forward by an extraordinary experiment performed by W. E. Lamb and R. C. Retherford in 1947. The Dirac equation for an electron bound in a Coulomb field predicted that the energy levels with the same principal quantum number n and total angular momentum j should be degenerate, i.e., they should not depend on other quantum numbers such as that of orbital angular momentum. In particular, there should be no energy separation between $2P_{1/2}$ and $2S_{1/2}$ excited levels in atomic hydrogen. Lamb's experiment, however, demonstrated conclusively that the levels were in fact separated by ~1000 MHz, a full tenth of the fine-structure separation of the $n = 2$ levels.

Then, in a historic paper of 1947, H. A. Bethe showed that the "Lamb shift" can be explained by a proper reinterpretation of the theory (inspired by H. A. Kramers's attempt to solve the self-mass divergence difficulty). He pointed out that when one calculates the

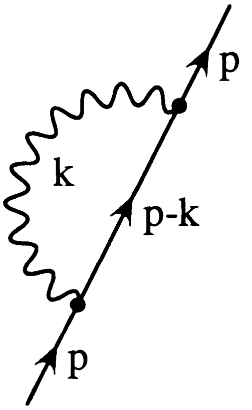

FIG. 3. Second-order electron self-energy diagram describing an electron emitting and reabsorbing a photon.

self-energy correction to a bound-state electron resulting from the emission and reabsorption of a photon, part of the energy shift—in fact, the divergent part—should be identified with the "self-energy" or "self-mass" of the electron itself. Now, the energy shifts for two bound-state levels contain the same self-mass term and hence their difference should be finite. In fact, his calculations showed that the $2S_{1/2}$ level is displaced above the $2P_{1/2}$ level by about 1080 MHz. This can be understood physically by the observation that the emission and reabsorption of the photon causes the position of the electron to fluctuate over a distance of the Compton wavelength of the electron ($\hbar/m_e c$) a fraction α of the time. The degeneracy predicted by the Dirac equation is a consequence of the strict $1/r$ behavior of the electron-nucleus Coulomb potential. This is destroyed by the orbital dependence of the effective spreading of the electron's position.

Bethe's calculation is in good agreement with the Lamb–Retherford experiment if one includes the "vacuum polarization" effect, which increases the binding of the electron and reduces the $2S_{1/2} - 2P_{1/2}$ separation by 27 MHz. This effect, found by R. Serber and E. A. Uehling in 1935, is caused by the modification of the nuclear Coulomb potential due to the presence of virtual electron-positron pairs. (The phenomenon is analogous to the polarization of dielectric matter in the presence of charge.) In fact, because two charged particles always see each other through a cloud of virtual particle-antiparticle pairs, the charge e_0 that appears as a parameter in the Lagrangian [Eq. (10)] is not precisely the physical charge e of the electron (as defined classically for an electron scattering at large distances from a test electric field). Attempts to calculate e in terms of e_0 lead to another divergent correction unrelated to that of the electron self-mass.

1.6 Renormalized Quantum Electrodynamics

Within a few years after Bethe's work, J. Schwinger, S. Tomonaga, R. P. Feynman, and F. J. Dyson demonstrated that all the divergences in quantum-electrodynamic calculations could be eliminated order by order in perturbation theory. This procedure, called the renormalization program, was shown to be covariant (independent of Lorentz frame), and despite the presence of infinite quantities in intermediate expressions, the calculations were shown always to lead to unambiguous finite results.

Briefly, one starts from the observation that the "bare charge" e_0 and "bare mass" m_0 that appear as parameters in the Lagrangian [Eq. (10)] or the equations of QED are not the physical charge and mass of the electron. To any given order in perturbation theory, one must adjust the values of m_0 and e_0 so that after calculation of all the contributing terms, electron-electron scattering at large distances will agree with classical Coulomb scattering for two particles of charge e, and that Compton scattering (elastic photon-electron scattering) at zero photon frequency will agree with the Thomson limit that defines the ratio e^2/m. After this adjustment is made, calculations not only of these but also of all *physical* quantities give finite results, although the values in perturbation theory for the quantities e_0 and m_0 are mathematically divergent.

Let me now sketch the Feynman-diagram technique for computing the transition amplitudes of QED. (For details, consult the textbooks listed in Further Reading.) For this purpose, it is useful to introduce a free-field Lagrangian $\mathscr{L}^0$ whose solution is known completely:

$$\begin{aligned}\mathscr{L}^0 = {} & \tfrac{1}{2} i[\bar{\psi}^0\gamma^\mu\partial_\mu\psi^0 - (\partial_\mu\bar{\psi}^0)\gamma^\mu\psi^0] \\ & - \tfrac{1}{2} m[\bar{\psi}^0,\psi^0] - \tfrac{1}{4} F^0_{\mu\nu}(F^0)^{\mu\nu} \\ & + \tfrac{1}{2} \mu_0^2 A^0_\mu(A^0)^\mu - \tfrac{1}{2} \lambda_0[\partial_\mu(A^0)^\mu]^2, \end{aligned} \tag{11}$$

where A^0_μ and ψ^0 are free-field operators satisfying the "initial" condition

$$\begin{aligned} A^0_\mu(0,\mathbf{x}) &= \sqrt{Z_3}A_\mu(0,\mathbf{x}), \\ \psi^0(0,\mathbf{x}) &= \sqrt{Z_2}\psi(0,\mathbf{x}), \end{aligned} \tag{12}$$

at $t = 0$, Z_2 and Z_3 being some constants to be fixed later. Note that ψ^0 has the physical mass m.

We want to express the solution of $\mathscr{L}$ in terms of the solution of $\mathscr{L}^0$, treating the difference $\mathscr{L} - \mathscr{L}^0$, which can be written

$$-\mathscr{H}_{\text{int}} \equiv -\tfrac{1}{2} e_0[\bar{\psi}^0,\gamma^\mu\psi^0]A^0_\mu + \tfrac{1}{2}\,\delta m[\bar{\psi}^0,\psi^0], \tag{13}$$

as a small perturbation, where $\delta m = m -$

m_0. The probability amplitude for the transition from a state at $t \to -\infty$ to a state at $t \to +\infty$ can then be written as a matrix element of the operator

$$S = \frac{T\left(\exp\left[-i\int \mathcal{H}_{\text{int}}(x)d^4x\right]\right)}{\left\langle 0\left|T\left(\exp\left[-i\int \mathcal{H}_{\text{int}}(x)d^4x\right]\right)\right|0\right\rangle},$$

where $|0\rangle$ means the vacuum state (state of lowest energy) and T means that all products of operators (obtained by expanding the exponential function in a power series) are ordered from left to right in the descending order of their time variable t.

It can be shown that matrix elements of S correspond one-to-one to figures called Feynman diagrams. Some examples were shown in Figs. 1 through 3. The rules for calculating the matrix element, called the Feynman–Dyson rules, have been given in a very elegant and simple form by R. P. Feynman in 1949.

Let $|i\rangle$ be the initial state containing several particles of given four-momenta and spins and $\langle f|$ be the final state similarly specified. Draw all diagrams (of given order) that connect the initial state to the final state, excluding those containing disconnected pieces and also those with self-energy insertions on external lines. Let P_i and P_f be the total four-momenta of the initial and final states. Let us introduce a matrix R by

$$\langle f|S - 1|i\rangle = -(2\pi)^4 i\delta^4(P_f - P_i)\langle f|iR|i\rangle.$$

Then the matrix element $\langle f|iR|i\rangle$ can be obtained by assigning the following factors to each diagram:

1. $-ie_0\gamma_\mu$ for each three-point vertex ($e_0 < 0$);
2. $i\delta m$ for each mass counterterm vertex;
3. $\sqrt{Z_2}u(p,s)$ or $\sqrt{Z_2}v(p,s)$ for each electron line entering the graph in the initial or final state; likewise, for each electron line leaving the graph a factor $\sqrt{Z_2}\bar{u}(p,s)$ or $\sqrt{Z_2}\bar{v}(p,s)$, where p,s are the four-momentum and spin state of the electron;
4. $\sqrt{Z_3}\epsilon^\mu(k)$ for each external photon line carrying four-momentum k;
5. $i/(\gamma_\mu p^\mu - m + i\epsilon)$ for each internal electron line with four-momentum p^μ, where ϵ is an infinitesimally small positive number;
6. $-ig_{\mu\nu}/(q^2 + i\epsilon)$ for each internal photon line with four-momentum q (in Feynman gauge only);
7. Four-dimensional integration

   $$\int \frac{d^4k}{(2\pi)^4}$$

   for each internal momentum k not fixed by momentum-conservation constraints at vertices (note that four-momentum is conserved at each vertex);
8. -1 for each closed electron loop.

Finally, renormalize the charge with $e = Z_2 Z_1^{-1}\sqrt{Z_3}e_0$. (Actually, $Z_1 = Z_2$ according to an identity proved by J. Ward.)

The quantities δm, Z_1, Z_2, and Z_3 are defined as values of $\langle f|R|i\rangle$ for some special states $\langle f|$ and $|i\rangle$. In the lowest order, $\delta m = 0$, $Z_1 = Z_2 = Z_3 = 1$. In addition, some normalization factors are needed to obtain an exact R. See Bjorken and Drell (1965) for details.

In each $\langle f|R|i\rangle$ thus constructed, infinite quantities appear during the calculation. However, as a consequence of renormalization, they all disappear in the final result expressed in terms of observed charge and mass.

In 1948, Feynman proposed an alternative formulation of quantum mechanics called the path-integral method. This method, applied to the electromagnetic interaction, provides an alternative formulation of QED. In fact, this is how Feynman was led to his diagrammatic method. The path-integral approach is useful in formulating more complicated theories such as quantum chromodynamics and the standard model.

Finally, we note that the electromagnetic interaction is invariant under the operation of space reflection P, time-reversal T, or charge conjugation C. In contrast, the weak interaction is not invariant under P or C separately, although it is invariant under the combined operation PC. All known interactions are invariant under the combined CPT operation.

2. EXPERIMENTAL TESTS OF QED

Over the history of physics, various theories have been formulated, tested, and revised by experiment. In a similar manner, QED has been tested extensively. High-energy collisions of electrons and positrons examine the validity and limitation of the theory in the region of very short distance scales, or, equivalently, very large momentum transfer. On the other hand, higher-order QED corrections are tested in various high-precision measurements of atomic energy levels and transitions.

2.1 High-Energy Tests

Very high-energy (short-distance) tests of the predictions of QED for electron-positron scattering have been performed at colliding electron-positron beam facilities at Stanford, Cornell, Orsay, Novosibirsk, Frascati, Tsukuba, Hamburg, and Geneva. The main processes studied are those in which colliding positron (e^+) and electron (e^-) produce an e^+e^- pair, two photons (γ's), or a positive-muon (μ^+), negative-muon (μ^-) pair:

$$\begin{aligned} &e^+ + e^- \rightarrow e^+ + e^-, \\ &e^+ + e^- \rightarrow \gamma + \gamma, \qquad (14) \\ &e^+ + e^- \rightarrow \mu^+ + \mu^-. \end{aligned}$$

Here the muon is an elementary particle that behaves exactly like an electron except for its heavier mass: $m_\mu/m_e = 206.768\,262\ (30)$.

QED predicts that the cross sections for the processes of Eqs. (14) fall inversely with the square of the center-of-mass energy and have a certain angular dependence. The measurements have confirmed these predictions at center-of-mass energies as high as 9×10^{10} eV (denoted 90 GeV). This means that the measurements rule out breakdown of QED down to distances of $\sim 10^{-17}$ m.

Actually, above center-of-mass energies of several hundred million eV (MeV), the e^+e^- collision is dominated by non-QED processes such as production of pions and kaons. (These particles are called "hadrons.") Nevertheless, for the processes of Eqs. (14), the prediction of QED holds precisely. At energies around 90 GeV, the contribution of the weak boson Z^0, predicted by the electroweak theory of Glashow, Weinberg, and Salam and recently confirmed at CERN experiments, dominates those of QED and production of hadrons. This does not mean, however, that QED fails at short distances but simply that the real world has forces besides electromagnetism. Indeed QED must be regarded as an integral part of a more comprehensive theory, the so-called standard model, that accommodates strong and weak forces in addition to the electromagnetic force.

2.2 High-Precision Tests of QED at Low Energies

Experiments at low energies are not very sensitive to short-distance behavior of QED. Instead, these experiments are useful in examining higher-order terms of perturbation theory and nonperturbative features of QED associated with bound states. QED has been applied to the Lamb shifts and fine and hyperfine structures of hydrogenlike atoms, as well as to more complex atoms such as helium and high-Z muonic atoms. Recent progress in the measurement of various energy levels of stripped heavier atoms has provided further confirmation of QED. The agreement of theory and experiment is excellent if all relevant higher-order corrections are included. In the following, let us review some of the high-precision results.

2.2.1 Anomalous Magnetic Moment of the Electron The classic and most basic test of QED is provided by the measurement of the anomalous magnetic moment a_e of the electron. According to the Dirac equation [Eq. (6)], the electron gyromagnetic factor g_e, the ratio of spin and rotation frequencies, must be exactly equal to 2. However, it was found by P. Kusch and H. M. Foley in a 1947 experiment that g_e is larger than 2 by about 0.1%. J. Schwinger showed that this is due to the emission and reabsorption of a photon by the electron in a magnetic field. The agreement of the experiment with his calculation of $a_e = (g_e - 2)/2$ was one of the crucial successes of the (then) newly developed theory of QED.

A more accurate measurement of the electron anomalous magnetic moment utilizes electrons that move in a helical orbit with a rotational frequency $\omega_L = eB/mc$ in a uniform magnetic field. If the electron's magnetic interaction conformed to the simple Dirac equation, the directions of its momentum and intrinsic spin would precess with exactly the same frequency. Any deviation from Dirac's prediction would then be detected by measuring the spin precession. Wilkinson and Crane (1963) have shown that the electron anomalous magnetic moment can be measured very accurately in this manner. The best result obtained by this technique is (Wesley and Rich, 1971)

$$a_e^{\text{exp}} = 0.001\,159\,6577\,(35). \tag{15}$$

More recently, based on an entirely different technique that utilizes rf resonance transitions between quantized levels of an electron in a magnetic field, Van Dyck *et al.* (1987) have improved the value of a_e by three orders of magnitude over Eq. (15). Their results for the electron and positron are

$$a_{e^-}^{\text{exp}} = 0.001\,159\,652\,1884\,(43),$$

$$a_{e^+}^{\text{exp}} = 0.001\,159\,652\,1879\,(43), \tag{16}$$

respectively. This experiment verifies the predicted invariance of QED under the combined operation of *TCP* to the level of 10^{-12}:

$$a_{e^-}^{\text{exp}} - a_{e^+}^{\text{exp}} = 0.5(6.1) \times 10^{-12}. \tag{17}$$

Thus far, the theory of a_e has been extended to the emission and reabsorption of up to four photons by the electron, which means that terms of up to eighth order in perturbation theory have been calculated (Kinoshita and Lindquist, 1990). Such a calculation requires the help of algebraic and numerical computation techniques on the fastest computers. The result can be written as

$$\begin{aligned} a_e^{th} &= 0.5\alpha/\pi - 0.328\,478\,965 \cdots (\alpha/\pi)^2 \\ &\quad + 1.176\,11(42)(\alpha/\pi)^3 \\ &\quad - 1.434(138)(\alpha/\pi)^4 + 4.4 \times 10^{-12} \\ &= 0.001\,159\,652\,1409\,(43), \end{aligned} \tag{18}$$

in good agreement with experiment. The last term (4.4×10^{-12}) consists of the effects of muon and hadrons on the photon propagator and the weak-interaction contribution. The value of α used in Eq. (18) is obtained from Eq. (22). The gyromagnetic ratio of the electron g_e is thus correctly predicted by QED to 12 significant figures!

2.2.2 Anomalous Magnetic Moment of the Muon The anomalous magnetic moment of the muon is another quantity measured very accurately. The most precise value obtained at CERN, Switzerland, based on a muon spin-precession technique similar to that of Wilkinson and Crane (1963) for the electron, is (Farley and Picasso, 1990)

$$a_\mu = 1\,165\,923(8.5) \times 10^{-9} \quad (7\text{ ppm}).$$

This is in agreement with the theoretical calculation (Kinoshita and Marciano, 1990)

$$a_\mu^{\text{theory}} = 1\,165\,919.2(1.8) \times 10^{-9}.$$

In this result, the roles of the photon-hadron interaction and the weak interaction are much more important than in Eq. (18). Thus, an accurate measurement of a_μ provides an important test of the theory of weak interaction (or the standard model). A new experiment for a more accurate measurement of a_μ is in progress.

2.2.3 Hyperfine Structure of One-Electron Atoms Other precision tests of QED involve the hyperfine splitting of the ground-state energy level of fundamental atoms such as hydrogen, muonium (atom consisting of a positive muon and an electron), and positronium (positron-electron atom). The hyperfine splitting results because of the difference in energy that occurs when the electron and nuclear magnetic moments are parallel and antiparallel. Measurements (based on the properties of the hydrogen maser) by Helwig *et al.* (1970) and Essen *et al.* (1971) have determined this separation to 13 significant figures in atomic hydrogen:

$$\Delta\nu(\text{hydrogen}) = 1420.405\,751\,7667(9)\text{ MHz}.$$

The results agree with the theoretical prediction to six significant figures. Unfortunately, the theory is sensitive to the structure of the proton at the level of a few parts per million, and cannot be improved further until the proton structure is known better.

Muonium is similar to the hydrogen atom in many ways, except that it does not share the difficulty of the hydrogen atom that arises from the finite size of the proton: The muon is structureless as far as we have been able to measure. In this sense, the muonium is a better system to test the validity of QED.

Very accurate measurement of the hyperfine splitting in muonium by Mariam *et al.*

(1982) gives

$$\Delta\nu(\text{muonium}) = 4463\,302.88(16)\ \text{kHz}. \quad (19)$$

Recent theoretical efforts (Eides *et al.*, 1991) have led to

$$\Delta\nu^{th}(\text{muonium}) = 4463\,303.63(1.34) \times (0.21)(1.0)\ \text{kHz},$$

where the first and second errors reflect the uncertainties in the measurements of the muon mass m_μ and α from Eq. (22), and the third is an order-of-magnitude estimate of the uncalculated higher-order contributions. Comparison of these results pushes the test of QED to a precision of 0.17 ppm. Further improvements in theory and measurement of $\Delta\nu$(muonium) are in progress at present.

The present experimental value for the hyperfine splitting in the ground state of positronium is (Ritter *et al.*, 1984)

$$\Delta\nu(\text{positronium}) = 203\,389.10(74)\ \text{MHz}.$$

The theory is similar to that for the muonium hyperfine structure, with the additional complications coming from the facts that the electron and positron have the same mass and that the electron and positron can annihilate each other. The latest theoretical result is (Adkins *et al.*, 1993)

$$\Delta\nu^{th}(\text{positronium}) = 203\,389.0(6)\ \text{MHz}.$$

The agreement between theory and experiment is very good, but the precision is not yet as high as that of the muonium hyperfine structure.

2.2.4 The Hydrogen Lamb Shift The most recent measurements of the hydrogen Lamb shift are

1057 862(20) kHz, (Andrews and Newton, 1976),

1057 845(9) kHz, (Lundeen and Pipkin, 1981),

1057 851(2) kHz. (Pal'chikov *et al.*, 1983). (20)

The latest theoretical values are (Sapirstein and Yennie, 1990)

1057 853(13) kHz,

1057 871(13) kHz, (21)

depending on which measured value of the proton radius is used. Although the Lamb-shift experiment played a crucial role in the development of QED, it is at present not the best system to test QED because of its dependence on the proton structure, which is hard to measure accurately. However, new experiments based on laser technology promise to give much more accurate data before long.

3. HIGH-PRECISION DETERMINATION OF α

Since the fine-structure constant α is the most important parameter of QED, let us review here how α is determined precisely. At present, the most accurate non-QED methods are those based on macroscopic quantum effects discovered in the realm of condensed-matter physics, namely the quantum Hall effect and the ac Josephson effect. Note, however, that the accuracy of these effects implicitly assumes the full validity of QED.

3.1 α Determined by the Quantum Hall Effect

Currently, the most accurate value of α outside of pure QED is one obtained using the quantum Hall effect. With the use of the exactly defined constants μ_0 (the permeability of the vacuum) and c (the speed of light), the quantum Hall resistance R_H (in SI units) is related to the fine-structure constant by

$$\alpha^{-1} = 2R_H/\mu_0 c.$$

The best result obtained thus far by the quantum Hall effect is (Cage *et al.*, 1989)

$$\alpha^{-1}(\text{QHE}) = 137.035\,9979(32)\ (0.024\ \text{ppm}). \quad (22)$$

3.2 α Determined by the ac Josephson Effect

Another way to obtain a very accurate α is to rely on a chain of four separate precision measurements, making use of the formula

$$\alpha^{-2} = \frac{c}{4R_\infty \gamma_{p'}} \frac{\mu_{p'}}{\mu_B} \frac{2e}{h}.$$

The most critical two are the ac Josephson effect, which gives a precise value for the combination $2e/h$, and the gyromagnetic ratio of the proton in water (called $\gamma_{p'}$), which is the spin-flip frequency of the proton divided by the magnetic field. This frequency can be measured very precisely. The magnetic field is obtained by constructing a precision coil with a current known from a precision current standard. The Rydberg constant, R_∞, and the proton's magnetic moment (in water) in units of the Bohr magneton, $\mu_{p'}/\mu_B$, are very accurately measured (Cohen and Taylor, 1987). The best result obtained thus far by the ac Josephson effect is (Williams *et al.*, 1989)

$$\alpha^{-1}(\text{acJ}) = 137.035\,9770(77)\ (0.056\ \text{ppm}). \tag{23}$$

3.3 α Determined by QED

If one assumes (with ample justification) that QED is valid to the precision examined, one can calculate the value of α from various QED processes. The most accurate value obtained thus far is one from the electron anomalous magnetic moment. Comparing Eqs. (16) and (18), one finds

$$\alpha^{-1}(a_e) = 137.035\,992\,22(94)\ (0.0069\ \text{ppm}). \tag{24}$$

A less accurate value is obtained from the theory and measurement of the muonium hyperfine structure (Kinoshita and Yennie, 1990):

$$\alpha^{-1}(\text{muonium}) = 137.035\,9930(224) \times (0.164\ \text{ppm}). \tag{25}$$

Very good agreement between the values of α given by Eqs. (24) and (25) shows that QED is valid to the level of 0.17 ppm. However, Eq. (25) must be improved by a factor of 20 to reach the precision of Eq. (24). Once that is accomplished, one can test the internal consistency of QED at the level of 0.01 ppm or better.

The uncertainty in Eq. (25) comes mainly from the muon mass and the theory of muonium hyperfine structure. A new experiment for a more accurate measurement of the muon mass is in progress. The same experiment will also improve $\Delta\nu$ of Eq. (19).

3.4 High-Precision Test of Condensed-Matter Physics

It is generally believed that the α determined by the quantum Hall effect and the ac Josephson effect are exact and need no theoretical correction, although this has never been proven. The difference of 21×10^{-6} between Eqs. (22) and (23), which is about three times larger than the error in Eq. (23), might be the first indication that this belief is open to question. A small discrepancy between these α's and $\alpha(a_e)$ obtained from QED also points to the possibility that small corrections might have to be applied to the predictions of condensed-matter physics.

4. CONCLUSIONS

As far as we know, QED provides a mathematically exact description of the electromagnetic properties of the electron and muon. To the extent that the electromagnetic properties of the nucleus are known, QED also provides the fundamental dynamical theory of the relativistic atom, including its external electromagnetic interactions. At present, there is no outstanding discrepancy with any of its predictions, provided that the experimental data are corrected for effects due to weak and hadronic interactions, despite our pursuing the limits of the theory to very high accuracy and very small distances. In addition, the invariance of QED under charge conjugation C, space reflection P, and time reversal T, various conservation laws, the constancy in time of α, c, etc., have all been checked to various degrees. The great success of QED is rooted deeply in the fact that it is a logical and natural extension of the classical electrodynamics and the conventional quantum mechanics, both supported strongly by experiments within their own applicabilities.

Nevertheless, it must be kept in mind that QED still has aspects that have been taken as arguments against its adequacy as a satisfactory theory, such as the following:

1. The expansion in powers of α is only asymptotic, and
2. The very presence of infinities, even though there is an internally consistent means of eliminating them, is a symptom of a deeper problem.

Besides these concerns, the adequacy of QED at shorter distances or at higher precision will have to be questioned if any of the following exist: intrinsic lepton size, nonlocal currents, heavy leptons, heavy photons, magnetic charge, or anomalous constants not given by the renormalization procedure, although these possibilities have been ruled out to some extent by the various tests discussed in this article.

More importantly, QED has served as a prototype for the development of various non-Abelian gauge theories. There is now strong evidence that one of these theories, called the standard model, can account for the properties of the strong and weak interactions observed in nuclear and elementary particle physics. Some of the particles predicted by the standard model, the W and Z bosons, which mediate the weak force, have been confirmed experimentally. Nevertheless, the standard model, of which QED is a part, is generally regarded as far from an ultimate theory. For instance, at present the mass and charge of an electron are just input parameters and not an outcome of the theory itself. To calculate them theoretically would require a deeper understanding of physics. It is not clear whether one of the (super-)string theories, which are being investigated vigorously at present, is a candidate of such a theory.

GLOSSARY

ac Josephson Effect: A phenomenon in which a pair of electrons tunnel back and forth with the frequency ν determined by the equation $h\nu = 2eV$ through a junction which separates superconductors at potential difference V.

Gauge and Gauge Invariance: The Lagrangian [Eq. (10)] is unchanged under the transformation (called gauge transformation)

$$A_\mu \rightarrow A_\mu + \frac{1}{e_0}\partial_\mu \Lambda,$$

$$\psi \rightarrow e^{i\Lambda}\psi,$$

$$\bar{\psi} \rightarrow \bar{\psi}e^{-i\Lambda}, \qquad (26)$$

where $\Lambda(x)$ is an arbitrary function of x^μ. This invariance is a consequence of masslessness of the photon and is a characteristic feature of QED. Gauge invariance of QED means that physics must be independent of the choice of the gauge function. The choice is dictated by convenience or other desirable features.

Quantum Hall Effect: When the electrons participating in a Hall-effect measurement are confined to a very thin, almost two-dimensional, layer with a strong perpendicular magnetic field and at very low temperatures, the Hall resistance tends to be quantized at certain particular values. That is, as some external parameter such as the magnetic field or a gate voltage is varied (depending on the type of device), one observes certain "plateaus" in the Hall resistance, which is defined as the ratio of the voltage (V_H) across the sample to the current (I_H) flowing along the sample.

INTRODUCTION

In formulating and studying principles of valid reasoning, logicians have been guided not only by introspection and philosophical reflection, but also by an analysis of various rational procedures commonly employed by mathematicians and scientists. Because these principles have a multitude of disparate sources, efforts to consolidate them in a single coherent system have been unsuccessful. Instead, philosophers, logicians, and mathematicians have created a panoply of competing logical formalisms, each with its own domain of applicability. Among these formalisms are Boolean-based propositional and predicate calculi, modal and multivalued logics, intuitionistic logic, and quantum logic.

Our purpose in this article is to outline the history and present some of the main ideas of quantum logic. In what follows, it will be helpful to keep in mind that there are four levels involved in any exposition of logic and its relation to the experimental sciences.

1. *Philosophical:* Addresses the epistemology

of the experimental sciences. Guides and motivates the activities at the remaining levels while assimilating and coordinating the insights gained from these activities.
2. *Syntactic:* Emphasizes the formal structure of a general calculus of experimental propositions.
3. *Semantic:* Focuses on the construction of classes of mathematical models for a logical calculus.
4. *Pragmatic:* Concentrates on a specific mathematical model pertinent to a particular branch of experimental science.

For instance, studies regarding the logics associated with classical physics could be categorized as follows:

1. Philosophical writings extending back at least to Aristotle.
2. Propositional and predicate calculi.
3. The class of Boolean algebras.
4. The Boolean σ algebra of all Borel subsets of the phase space of a mechanical system.

Likewise, for quantum logic, we have

1. Philosophical writings beginning with Schrödinger, von Neumann, Bohr, Einstein, *et al.*
2. Quantum-logical calculi.
3. The class of orthoalgebras.
4. The lattice of projection operators on a Hilbert space.

For expository reasons, our survey proceeds roughly in the order **1, 4, 3, 2.** Thus, we give a brief history of quantum logic in Sec. 1, outline the standard quantum logic of projections on a Hilbert space in Sec. 2, introduce orthoalgebras as models for quantum logic in Sec. 3, and discuss a general quantum-logical calculus of propositions in Sec. 4.

1. BRIEF HISTORY OF QUANTUM LOGIC

1.1 The Origin of Quantum Logic

The publication of John von Neumann's *Mathematische Grundlagen der Quantenmechanik* (1932) was the genesis of a novel system of logical principles based on propositions affiliated with quantum-mechanical entities.

According to von Neumann, a quantum-mechanical system $\mathcal{S}$ is represented mathematically by a separable (i.e., countable dimensional) complex Hilbert space $\mathcal{H}$, observables for $\mathcal{S}$ correspond to self-adjoint operators on $\mathcal{H}$, and the spectrum of a self-adjoint operator is the set of all numerical values that could be obtained by measuring the corresponding observable. Hence, a self-adjoint operator with spectrum consisting at most of the numbers 0 and 1 can be regarded as a *quantum-mechanical proposition* by identifying 0 with "false" and 1 with "true." Since a self-adjoint operator has spectrum contained in $\{0,1\}$ if and only if it is an (orthogonal) projection onto a closed linear subspace of $\mathcal{H}$, von Neumann (1955, p. 253) observed that

> . . . the relation between the properties of a physical system on the one hand, and the projections on the other, makes possible a sort of logical calculus with these.

1.2 The Work of Birkhoff and von Neumann

In 1936, von Neumann, now in collaboration with Garrett Birkhoff, reconsidered the matter of a logical calculus for physical systems and proposed an axiomatic foundation for such a calculus. They argued that the experimental propositions regarding a physical system $\mathcal{S}$ should band together to form a lattice L (Birkhoff, 1967) in which the meet and join operations are formal analogs of the *and* and *or* connectives of classical logic (although they admitted that there could be a question of the experimental meaning of these operations). They also argued that L should be equipped with a mapping carrying each proposition $a \in L$ into its negation $a' \in L$. In present-day terminology, they proposed that L forms an *orthocomplemented lattice* with $\wedge$, $\vee$, and $a \rightarrow a'$ as meet, join, and orthocomplementation, respectively (Kalmbach, 1983; Pták and Pulmannová, 1991).

Birkhoff and von Neumann observed that the experimental propositions concerning a classical mechanical system $\mathcal{S}$ can be identified with members of a field of subsets of the phase space for $\mathcal{S}$, (or, more accurately, with elements of a quotient of such a field by an ideal). In any case, for a classical mechanical system $\mathcal{S}$, they concluded that L forms a *Boolean algebra.*

An orthocomplemented lattice L is a Boolean algebra if and only if it satisfies the *distributive law:*

$$x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z). \qquad (1)$$

An example in which $a \in L$ denotes the observation of a wave packet on one side of a plane, $a' \in L$ its observation on the other side, and $b \in L$ its observation in a state symmetric about the plane shows that

$$b = b \wedge (a \vee a') \neq (b \wedge a) \vee (b \wedge a') = 0,$$

so that the distributive law of classical logic breaks down even for the simplest of quantum-mechanical systems. As Birkhoff and von Neumann observed,

> . . . whereas logicians have usually assumed that properties of negation were the ones least able to withstand a critical analysis, the study of mechanics points to the *distributive identities* as the weakest link in the algebra of logic.

Invoking the desirability of an *"a priori* thermo-dynamic weight of states," Birkhoff and von Neumann argued that L should satisfy a weakened version of Eq. (1), called the *modular law,* and having the following form:

$$\text{If } z \leq x, \quad \text{then } x \wedge (y \vee z) = (x \wedge y) \vee z. \qquad (2)$$

If Eq. (1) holds, then so does Eq. (2) in view of the fact that $z \leq x$ implies $x \wedge z = z$. However, Eq. (2) is weaker than Eq. (1) since the projection operators for a Hilbert space of finite dimension $n \geq 2$ form a modular, but nondistributive, lattice. Thus, Birkhoff and von Neumann proposed an *orthocomplemented modular lattice* as a model for a quantum-mechanical calculus of logic, although they admitted that it would be satisfying if one could interpret the modular law in Eq. (2) "by simpler phenomenological properties of quantum physics."

Birkhoff and von Neumann also gave an example to show that the projection operators on an infinite-dimensional Hilbert space fail to satisfy the modular law. Evidently, von Neumann considered this to be a possible serious flaw of the Hilbert-space formulation of quantum mechanics as proposed in his own *Grundlagen.* Much of von Neumann's work on continuous geometries (1960) and rings of operators (Murray and von Neumann, 1936) was motivated by his desire to construct concrete complemented modular lattices carrying an *"a priori* thermo-dynamic weight of states," that is, a continuous dimension or trace function.

1.3 The Orthomodular Law

Although the projection lattice of an infinite-dimensional Hilbert space fails to satisfy the modular law in Eq. (2), it was discovered by Husimi (1937) that it does satisfy the following weaker condition, now called the *orthomodular law:*

$$\text{If } z \leq x, \quad \text{then } x = (x \wedge z') \vee z. \qquad (3)$$

If Eq. (2) holds, then so does Eq. (3) in view of the fact that $x = x \wedge (z' \vee z)$. The same condition was rediscovered independently by Loomis (1955) and Maeda (1955) in connection with their work on extension of the Murray–von Neumann dimension theory of rings of operators to orthocomplemented lattices. An orthocomplemented lattice satisfying Eq. (3) is called an *orthomodular lattice.*

In 1957, Mackey published an expository article on quantum mechanics in Hilbert space based on notes for lectures that he was then giving at Harvard. These notes were later published in the form of a monograph (Mackey, 1963) in which the basic principles of quantum mechanics were introduced in terms of a function

$$p = \text{Prob}(A,\psi,E) \qquad (4)$$

interpreted as the probability p that a measurement of the observable A in state ψ results in a value in a set of E of real numbers. The square A^2 of A is then defined by the condition

$$\text{Prob}(A^2,\psi,E) = \text{Prob}(A,\psi,F),$$

where F is the set of all real numbers x such that $x^2 \in E$. If $A = A^2$, then A is called a *question*. Under certain more or less reasonable hypotheses, it can be shown that the set of all questions forms an orthomodular lattice L.

The generality of Mackey's formulation and the natural way in which Mackey's questions give rise to an orthomodular lattice engendered the heady idea of a universal logical calculus for all of the experimental sciences. Such a calculus would be based on the class of all orthomodular lattices—including the Boolean algebras that would serve as models for the logics affiliated with classical mechanical systems. Would this be the realization of Leibniz's dream of a *calculus ratiocinator?* This captivating thought helped to motivate an ongoing study of the theory of orthomodular lattices by a relatively small but devoted group of researchers. An authoritative account of the resulting theory of orthomodular lattices as developed up to about 1983 can be found in Kalmbach (1983).

1.4 The Interpretation of Meet and Join

In spite of the appeal of a general scientific logic based on orthomodular lattices, a nagging question raised in the 1936 paper of Birkhoff and von Neumann was still unresolved. If, for a quantum-mechanical system, most pairs of observations are incompatible and cannot be made simultaneously, what experimental meaning can one attach to the meet $p \wedge q$ of two propositions? Two and a half decades after his initial paper with von Neumann, Birkhoff returned to this question (Birkhoff, 1961), calling for an autonomous quantum logic that draws its authority directly from experiments. (A similar question arises in connection with the logic of relativistic physics where the traditional notion of simultaneity is meaningless for spatially separated events.) After all, simultaneity is an indispensable constituent of classical propositional conjunction.

An obvious way to avoid the interpretation issue for $p \wedge q$ is to replace the assumption that $p \wedge q$ always exists with the weaker assumption that it exists if p and q are *compatible* in the sense that they can be *simultaneously tested* by means of a single experiment. In this connection, Birkhoff and von Neumann were careful to point out that "... one may regard a set of compatible measurements as a single composite 'measurement'."

Thus, for compatible propositions, experimental meaning can be bestowed upon the meet and join by regarding these connectives as the conjunction and disjunction in the usual sense of classical logic.

Although the mainstream effort to develop a viable quantum logic has concentrated on the use of orthomodular lattices as the basic models (Jauch, 1968; Piron, 1976; Mittelstaedt, 1978; Beltrametti and Cassinelli, 1981), alternative models have been introduced that avoid the interpretation issue for meet and join by invoking the notion of compatibility. Among these are the *orthomodular posets* introduced in the early 1960s (Foulis, 1962) and the *orthoalgebras* proposed in the late 1970s (Randall and Foulis, 1978; Hardegree and Frazer, 1981; Lock and Hardegree, 1984a,b). Thus, the evolution of quantum logic from the 1930s to the present has been the story of a slow retreat from Boolean-algebra–based logic and the concurrent development of more and more general mathematical models.

2. STANDARD QUANTUM LOGIC

2.1 The Orthomodular Lattice of Projections on a Hilbert Space

As a mathematical model for a calculus of quantum logic, the orthomodular lattice L of projection operators on a Hilbert space $\mathcal{H}$ is called a *standard quantum logic*. Wilbur (1977) has given a purely lattice-theoretic characterization of the standard quantum logics.

In the present section, we sketch the theory of standard quantum logics, considering only the special case in which $\mathcal{H}$ is a separable Hilbert space of dimension at least three over the complex number field $\mathbb{C}$. Thus, we leave aside real or quaternionic Hilbert spaces as well as the generalized Hilbert spaces of Gross and Keller (Keller, 1980). We regard $\mathcal{H}$ as the Hilbert space corresponding to a quantum-mechanical system $\mathcal{S}$. (For the time being, we do not consider superselection rules.)

If A is a bounded operator on $\mathcal{H}$, we denote by A^* the adjoint of A. Thus, $\langle A\psi|\phi\rangle = \langle\psi|A^*\phi\rangle$ for all $\psi, \phi \in \mathcal{H}$. A bounded operator

P on $\mathcal{H}$ is called a *projection* if $P = P^* = P^2$, and we define $L = L(\mathcal{H})$ to be the set of all such projection operators. If $P \in L$ and

$$\mathcal{M} = P(\mathcal{H}) = \{P(\psi) | \psi \in \mathcal{H}\} \tag{5}$$

is the range of P, then $\mathcal{M}$ is a closed linear subspace of $\mathcal{H}$; conversely, every closed linear subspace $\mathcal{M}$ of $\mathcal{H}$ is of the form given in Eq. (5) for a uniquely determined $P \in L$. If P and $\mathcal{M}$ are related as in Eq. (5), we say that P is the *projection onto* $\mathcal{M}$. The zero operator $\mathbb{0}$ is the projection onto $\{0\}$ and the identity operator $\mathbb{1}$ is the projection onto $\mathcal{H}$.

If P is the projection onto $\mathcal{M}$ and Q is the projection onto $\mathcal{N}$, we write $P \leq Q$ if and only if $\mathcal{M}$ is a linear subspace of $\mathcal{N}$. Thus, L is a partially ordered set (poset) under $\leq$. If $\mathcal{M}$ is a closed linear subspace of $\mathcal{H}$, we write $\mathcal{M}^\perp$ for the set of all vectors in $\mathcal{H}$ that are orthogonal to every vector in $\mathcal{M}$. Then $\mathcal{M}^\perp$ is again a closed linear subspace of $\mathcal{H}$. If P is the projection onto $\mathcal{M}$, we write the projection onto $\mathcal{M}^\perp$ as P'. Note that

$$P' = \mathbb{1} - P, \quad (P')' = P, \quad \mathbb{0}' = \mathbb{1}, \quad \text{and } \mathbb{1}' = \mathbb{0}.$$

Furthermore, if $P, Q \in L$ with $P \leq Q$, then $Q' \leq P'$.

If $\mathcal{M}$ and $\mathcal{N}$ are closed linear subspaces of $\mathcal{H}$, then so is the set-theoretic intersection $\mathcal{M} \cap \mathcal{N}$. If P is the projection onto $\mathcal{M}$ and Q is the projection onto $\mathcal{N}$, we define $P \wedge Q$ to be the projection onto $\mathcal{M} \cap \mathcal{N}$, noting that $P \wedge Q$ is the meet of P and Q in the poset L. If we define $P \vee Q = (P' \wedge Q')'$, we find that $P \vee Q$ is the join of P and Q in L. Also, $P \wedge P' = \mathbb{0}$ and $P \vee P' = \mathbb{1}$, and so L forms a lattice that is orthocomplemented by $P \to P'$. Furthermore, L satisfies Eq. (3), and hence it is an orthomodular lattice.

If P is the projection onto $\mathcal{M}$ and Q is the projection onto $\mathcal{N}$, then $\mathcal{M}$ is a linear subspace of $\mathcal{N}^\perp$ if and only if $P \leq Q'$. If $P \leq Q'$, we say that P and Q are *orthogonal* to each other and write $P \perp Q$. It can be shown that $P \perp Q$ if and only if $P + Q$ is again a projection operator, in which case, $P + Q = P \vee Q$.

If $(\mathcal{M}_\alpha)$ is a family of closed linear subspaces of $\mathcal{H}$, then the set-theoretic intersection $\cap_\alpha \mathcal{M}_\alpha$ is again a closed linear subspace of $\mathcal{H}$. If P_α is the projection onto $\mathcal{M}_\alpha$ for all α and P is the projection onto $\cap_\alpha \mathcal{M}_\alpha$, then P is the *greatest lower bound* in L of the family (P_α), and we write $\wedge_\alpha P_\alpha = P$. Likewise, $(\wedge_\alpha (P_\alpha)')'$ is the *least upper bound* on L of the family (P_α), and we write $\vee_\alpha P_\alpha = (\wedge_\alpha (P_\alpha)')'$. Consequently, the standard quantum logic L is actually a *complete* orthomodular lattice.

The interpretation of L as a model for a logic of quantum mechanics is based on the following premise:

> *The two-valued (true/false), experimentally testable propositions for the quantum-mechanical system* $\mathcal{S}$ *are represented by the projections in the standard quantum logic* L *for the Hilbert space* $\mathcal{H}$ *corresponding to* $\mathcal{S}$.

Furthermore, if each experimental proposition for $\mathcal{S}$ is identified with its corresponding projection $P \in L$, it is assumed that

> *if* P, Q ∈ L, *then* P ≤ Q *holds if and only if* P *and* Q *are simultaneously testable and, whenever they are both tested and* P *is found to be true, then* Q *will also be true.*

2.2 Observables

As is customary, we assume that an *observable* or *dynamical variable* for the quantum-mechanical system $\mathcal{S}$ is represented by a (not necessarily bounded) self-adjoint operator A on the Hilbert space $\mathcal{H}$. In particular, then, each projection operator $P \in L$ represents an observable that, when measured, can only produce the values 1 (true) or 0 (false). As we shall see, the connection between general observables and projection observables is effected by the celebrated *spectral theorem*.

The smallest collection of subsets of the real numbers $\mathbb{R}$ that contains all open intervals and is closed under the formation of complements and countable unions is called the σ field of *real Borel sets*. A *spectral measure* is a mapping $E \to P_E$ from real Borel sets into projections such that $P_\varnothing = \mathbb{0}$, $P_\mathbb{R} = \mathbb{1}$, and, for every pairwise disjoint sequence $E_1, E_2, E_3, \ldots$ of real Borel sets,

$$\bigvee_{k=1}^{\infty} P_{E_k} = P_{E_1 \cup E_2 \cup E_3 \cup \cdots}$$

If $E \to P_E$ is a spectral measure, $\lambda \in \mathbb{R}$, and J

$= (-\infty,\lambda]$, define $P_\lambda = P_J$. Then, by the *spectral theorem* there is a one-to-one correspondence between observables A and spectral measures $E \rightarrow P_E$ such that

$$A = \int_{-\infty}^{\infty} \lambda dP_\lambda.$$

The projections in the family (P_E) are called the *spectral projections* for the observable A.

We can now be quite explicit about the connection between observables in general and projection observables in particular. Suppose that A is an observable and that (P_E) is the corresponding family of spectral projections. Then

> $\mathrm{P_E}$ *represents the experimental proposition asserting that a measurement of the observable* A *yields a result* r *that belongs to the real Borel set* $\mathrm{E} \subseteq \mathbb{R}$.

In quantum mechanics it is understood that a family of observables (A_α) is *compatible* (that is, *jointly* or *simultaneously observable*) if and only if $A_\alpha A_\beta = A_\beta A_\alpha$ for all α,β (that is, if and only if the observables commute with each other). On the basis of this understanding, we can state the following:

> *A family of projections* $(\mathrm{P}_\alpha) \subseteq \mathrm{L}$ *is compatible (that is, simultaneously testable) if and only if* $\mathrm{P}_\alpha \mathrm{P}_\beta = \mathrm{P}_\beta \mathrm{P}_\alpha$ *for all projections in the family.*

It can be shown that two observables commute with each other if and only if their spectral projections commute with each other.

It is interesting to note that the question of whether or not two projections commute can be settled in *purely lattice-theoretic terms.* Indeed, for $P,Q \in L$,

$$PQ = QP \quad \text{if and only if} \quad P = (P \wedge Q) \vee (P \wedge Q').$$

The equation stating the condition is a special case of the distributive law in Eq. (1); hence, in a standard quantum logic, the failure of the distributive law is a direct consequence of the fact that there are incompatible pairs of quantum-mechanical ·observables.

2.3 States

A bounded self-adjoint operator W on $\mathcal{H}$ is said to be *nonnegative* if $\langle W\psi|\psi\rangle \geq 0$ for all $\psi \in \mathcal{H}$. A nonnegative operator W belongs to the *trace class* if the series

$$\mathrm{tr}(W) = \sum_{\psi \in B} \langle W\psi|\psi\rangle$$

converges for an orthonormal basis $B \subseteq \mathcal{H}$. Convergence on any one orthonormal basis implies convergence on all orthonormal bases.

A *(von Neumann) density operator* on $\mathcal{H}$ is a bounded, self-adjoint, nonnegative, trace-class operator W on $\mathcal{H}$ such that $\mathrm{tr}(W) = 1$. Denote by $\Omega = \Omega(\mathcal{H})$ the set of all density operators on $\mathcal{H}$. One of the basic assumptions of statistical quantum mechanics is the following:

> *There is a one-to-one correspondence between the possible states of the system* $\mathcal{S}$ *and the density operators* $\mathrm{W} \in \Omega$ *such that, for every experimental proposition* $\mathrm{P} \in \mathrm{L}$, *tr(*WP*) is the probability that* P *will be true when tested in the state corresponding to* W.

In accordance with this assumption, we shall identify each possible state of the system $\mathcal{S}$ with the corresponding density operator W. In particular, if A is an observable with spectral family (P_E), the probability function, Eq. (4) in Mackey's formulation, is realized as

$$\mathrm{Prob}(A,W,E) = \mathrm{tr}(WP_E). \tag{6}$$

Equation (6), one of the fundamental equations of quantum mechanics, says that

> *the probability that a measurement of the observable* A *in the state* W *yields a result* r *in the Borel set* E *is given by tr(*$\mathrm{WP_E}$*).*

By a *countably additive probability measure* on the orthomodular lattice L is meant a function $\omega{:}L \rightarrow [0,1] \subseteq \mathbb{R}$ such that, for every sequence $P_1, P_2, P_3, \ldots$ of pairwise orthogonal projections in L,

$$\omega(\vee_k P_k) = \sum_k \omega(P_k).$$

By a celebrated theorem of Gleason (1957),

ω is a countably additive probability measure on L if and only if there is a (uniquely determined) density operator $W \in \Omega$ such that

$$\omega(P) = \mathrm{tr}(WP) \quad \text{for all } P \in L.$$

2.4 Superposition of States

If $W_1, W_2, W_3, \ldots \in \Omega$ is a sequence of density operators and $t_1, t_2, t_3, \ldots$ is a corresponding sequence of nonnegative real numbers such that $\Sigma t_k = 1$, then $W = \Sigma_k t_k W_k$ is again a density operator, which is referred to as a *mixture* or an *incoherent superposition* of the states W_k. For instance, W could be regarded as the state of a statistical ensemble of systems for which t_k is the fraction of the systems that are in the state W_k.

A state W is called a *pure state* if it cannot be obtained as a mixture of other states. It is customary to assume that individual physical systems are always in a pure state and that mixed states apply only to statistical ensembles of systems each of which is in a pure state, or to physical systems that are interactively coupled with other physical systems.

It can be shown that $W \in \Omega$ is a pure state if and only if it is a projection onto a one-dimensional linear subspace $\mathcal{M}$ of $\mathcal{H}$. Thus, any normalized vector $\psi \in \mathcal{H}$ determines a unique pure state, namely the projection onto the linear subspace of complex multiples of ψ. Such a state is called a *vector state*, and two normalized vectors determine the same vector state if and only if each can be obtained from the other by multiplying by a complex number of modulus 1 (a *phase factor*). Every state W is a mixture of pure (that is, vector) states.

We define the *support* of $W \in \Omega$, in symbols supp(W), to be the set of all $P \in L$ such that $\mathrm{tr}(WP) \neq 0$. This is the same as the set of all $P \in L$ for which $WP \neq 0$. If $W = \Sigma_k t_k W_k$ is an incoherent superposition of the sequence (W_k), then it is clear that supp(W) is contained in the set-theoretic union $\cup_k \mathrm{supp}(W_k)$.

More generally, if (W_α) is a family of states, we say that the state W is a *superposition* of the states W_α if and only if

$$\mathrm{supp}(W) \subseteq \cup_\alpha \mathrm{supp}(W_\alpha)$$

(Bennett and Foulis, 1990). If W as well as every W_α is a pure state, then W is said to be a *coherent superposition* of the states W_α. For instance, if W is the vector state determined by $\psi \in \mathcal{H}$, each W_α is the vector state determined by $\psi_\alpha \in \mathcal{H}$, and ψ differs from a normalized linear combination of the ψ_α by a phase factor, then W is a coherent superposition of the W_α.

2.5 Dynamics

By *dynamics* is meant a study of the way in which the states (*Schrödinger picture*) or the observables (*Heisenberg picture*) of a system change or evolve in time. The Schrödinger and Heisenberg pictures are mathematically equivalent. For definiteness, we adopt the Schrödinger picture. Thus, if the space Ω of density operators represents the state space of the quantum-mechanical system $\mathcal{S}$, then the dynamical evolution of the system is represented by a function $f(t,W)$ of the time $t \in \mathbb{R}$ and the state $W \in \Omega$ such that

$$f(t,W) \in \Omega, \quad f(0,W) = W \quad \text{and} \quad f(t+s,W) = f(t,f(s,W)). \tag{7}$$

The understanding in Eq. (7) is that $f(t,W)$ represents the state of the system after a time interval t if it is in state W at time 0. The function f is called the *dynamical law* for the system $\mathcal{S}$.

If the dynamical law f in Eq. (7) preserves superpositions, and is continuous in a suitable sense, it can be shown (Mackey, 1963) that there is a family (U_t) of unitary operators continuously indexed by real numbers such that

$$f(t,W) = U_t W U_t^{-1}$$

holds for all $t \in \mathbb{R}$. Hence, by a celebrated representation theorem of Stone (1932), it follows that there is a self-adjoint operator H on $\mathcal{H}$ such that

$$U_t = e^{-itH} \tag{8}$$

for all $t \in \mathbb{R}$. Equation (8) is the operator form of the *Schrödinger equation* and H is the *Hamiltonian operator* for the system.

2.6 Combinations of Standard Quantum Logics

Suppose that $\mathcal{H}_1$ and $\mathcal{H}_2$ are complex separable Hilbert spaces with corresponding standard quantum logics L_1 and L_2. There are two natural ways to combine $\mathcal{H}_1$ and $\mathcal{H}_2$ to form a composite Hilbert space $\mathcal{H}$ with its own standard quantum logic L: We can form either the direct sum $\mathcal{H} = \mathcal{H}_1 \oplus \mathcal{H}_2$ or the tensor product $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$ (Foulis, 1989). In neither case is the structure of the resulting standard quantum logic L easy to describe in terms of the structures of L_1 and L_2.

If $\mathcal{S}_1$ and $\mathcal{S}_2$ are quantum-mechanical systems represented by corresponding Hilbert spaces $\mathcal{H}_1$ and $\mathcal{H}_2$, it is customary to regard the tensor product $\mathcal{H} = \mathcal{H}_2 \otimes \mathcal{H}_2$ as the Hilbert space corresponding to the "combined system" $\mathcal{S} = \mathcal{S}_1 + \mathcal{S}_2$ (Jauch, 1968). If this is so, then in the combination $\mathcal{S}_1 + \mathcal{S}_2$ the systems can be tightly correlated, but they cannot exert instantaneous influences on each other (Kläy *et al.*, 1987).

If W is a state for the combined system $\mathcal{S} = \mathcal{S}_1 + \mathcal{S}_2$, there exist uniquely determined states W_1 for $\mathcal{S}_1$ and W_2 for $\mathcal{S}_2$ such that for all $P_1 \in L_1$ and all $P_2 \in L_2$

$$\mathrm{tr}(W_1P_1) = \mathrm{tr}(W(P_1 \otimes \mathbb{1})) \quad \text{and}$$
$$\mathrm{tr}(W_2P_2) = \mathrm{tr}(W(\mathbb{1} \otimes P_2)).$$

The states W_1 and W_2 are called *reduced states*. In general, W is not determined by W_1 and W_2, but depends on the details of the coupling between $\mathcal{S}_1$ and $\mathcal{S}_2$. However, if W is a pure state and either W_1 or W_2 is pure, then both W_1 and W_2 are pure and $W = W_1 \otimes W_2$. Therefore, if $\mathcal{S} = \mathcal{S}_1 + \mathcal{S}_2$ is in a pure state and if $\mathcal{S}_1$ and $\mathcal{S}_2$ are correlated in any way, then neither $\mathcal{S}_1$ nor $\mathcal{S}_2$ can be in a pure state.

If $\mathcal{H} = \mathcal{H}_1 \oplus \mathcal{H}_2$, a *superselection rule* (Wick *et al.*, 1952) may be imposed, in which case the quantum logic L associated with $\mathcal{H}$ is understood to consist only of projections that commute with the projections P_1 and P_2 of $\mathcal{H}$ onto the subspaces $\mathcal{H}_1 \oplus \{0\}$ and $\{0\} \oplus \mathcal{H}_2$, respectively. In this case, L is isomorphic to the Cartesian product $L_1 \times L_2$ of the standard quantum logics L_1 and L_2, but L is no longer a standard quantum logic. If such a superselection rule is imposed, it is assumed that the superselected observables are those with spectral projections in L and the superselected states are represented by density operators W that commute with both P_1 and P_2.

3. ORTHOALGEBRAS AS MODELS FOR A GENERAL QUANTUM LOGIC

3.1 Orthoalgebras

In this section, we present an axiomatic mathematical structure called an *orthoalgebra* (Foulis *et al.*, 1992), which generalizes the standard quantum logics. The idea is to endow a generic orthoalgebra with an *absolute minimum of mathematical structure* so that it becomes possible to investigate the meaning and consequences of the special features that distinguish particular orthoalgebras—for instance, Boolean algebras, orthomodular lattices, or standard quantum logics—as models for a calculus of experimental propositions.

By definition, an *orthoalgebra* is a set L containing two special elements 0 and 1 and equipped with a relation $\perp$ called *orthogonality* such that, for each pair $p,q \in L$ with $p \perp q$, an *orthogonal sum* $p \oplus q$ is defined in L and subject to the following four axioms:

(*Commutativity*) If $p \perp q$, then $q \perp p$ and $p \oplus q = q \oplus p$.

(*Associativity*) If $p \perp q$ and $(p \oplus q) \perp r$, then $q \perp r$, $p \perp (q \oplus r)$, and $p \oplus (q \oplus r) = (p \oplus q) \oplus r$.

(*Orthocomplementation*) For each $p \in L$ there is a unique $p' \in L$ such that $p \perp p'$ and $p \oplus p' = 1$.

(*Consistency*) If $p \perp p$, then $p = 0$.

We note that every orthomodular lattice L becomes an orthoalgebra if we define $p \oplus q = p \vee q$ whenever $p \leq q'$. In particular, every Boolean algebra and every standard quantum logic is an orthoalgebra.

If L is an orthoalgebra and $p,q \in L$, we define $p \leq q$ to mean that there exists $r \in L$ with $p \perp r$ such that $p \oplus r = q$. It can be shown that L is partially ordered by $\leq$; $0 \leq p \leq 1$ and $p = p''$ hold for all $p \in L$; and, if $p \leq q$, then $q' \leq p'$. Also, if $p \perp q$, then with respect to $\leq$, $p \oplus q$ is a *minimal* upper bound for p and q; that is,

$$p,q \leq p \oplus q \text{ and there exists no } r \in L \text{ with } p,q \leq r < p \oplus q.$$

However, $p \oplus q$ may not be the *least* upper bound for p and q; that is, the conditions $r \in L$ and $p, q \leq r$ do not necessarily imply that $p \oplus q \leq r$.

If $x,y \in L$ have a least upper bound (respectively, a greatest lower bound), we write it as $x \vee y$ (respectively, as $x \wedge y$). By definition, an *orthomodular poset* is an orthoalgebra L satisfying the condition that $p \oplus q = p \vee q$ whenever $p \perp q$. An orthomodular lattice is the same thing as an orthoalgebra in which every pair of elements x, y has a meet $x \wedge y$ and a join $x \vee y$. A Boolean algebra is the same thing as an orthomodular lattice satisfying the condition that $x \wedge y = 0$ only if $x \perp y$.

By a *subalgebra* of the orthoalgebra L, we mean a subset $S \subseteq L$ such that $0, 1 \in S$ and, if $p, q \in S$ with $p \perp q$, then $p \oplus q \in S$ and $p' \in S$. Evidently, a subalgebra of an orthoalgebra is an orthoalgebra in its own right under the operations inherited from the parent orthoalgebra. If, as an orthoalgebra in its own right, a subalgebra B of L is a Boolean algebra, we refer to B as a *Boolean subalgebra* of L. If $p \perp q$ in L, then

$$B = \{0,1,p,q,p',q',p \oplus q,(p \oplus q)'\}$$

is a Boolean subalgebra of L, so L is a set-theoretic union of Boolean subalgebras.

3.2 Compatibility, Conjunction, and Disjunction in an Orthoalgebra

We say that a subset of an orthoalgebra L is a *compatible* set if it is contained in a Boolean subalgebra of L. A compatible set of pairwise orthogonal elements is called an *orthogonal* subset of L. If L is a standard quantum logic, then a subset of L is compatible if and only if the projections in the subset commute with one another.

Let $A = \{a_1,a_2,a_3, \ldots ,a_n\}$ be a finite orthogonal subset of L. Then, it can be shown that the least upper bound

$$\vee_B A = a_1 \vee_B a_2 \vee_B a_3 \vee_B \cdots \vee_B a_n$$

as calculated in any Boolean subalgebra B of L that contains A is independent of the choice of B. Thus, we define the *orthogonal sum*

$$\oplus A = \vee_B A$$

as calculated in any such B. If C and D are finite orthogonal subsets of L, then $\oplus C \perp \oplus D$ if and only if $C \cap D \subseteq \{0\}$ and $C \cup D$ is an orthogonal set, in which case $\oplus C \oplus \oplus D = \oplus(C \cup D)$. If $A = \{a_1,a_2\}$, then $\oplus A = a_1 \oplus a_2$. Thus, if $A = \{a_1,a_2,a_3, \ldots ,a_n\}$, is an orthogonal set, we can define

$$a_1 \oplus a_2 \oplus a_3 \oplus \cdots \oplus a_n = \oplus A$$

without notational conflict.

If $p,q \in L$ and both p and q belong to a Boolean subalgebra B of L, then the greatest lower bound $p \wedge_B q$ and the least upper bound $p \vee_B q$ of p and q as calculated in B may well depend on the choice of B. If $p \wedge_B q$ is independent of the choice of B, we define the *conjunction* p & q of p and q by

$$p \,\&\, q = p \wedge_B q.$$

Likewise, if $p \vee_B q$ is independent of the choice of B, we define the *disjunction* $p + q$ of p and q by

$$p + q = p \vee_B q.$$

It can be shown that the compatible elements p and q have a conjunction if and only if they have a disjunction. Furthermore, if $p \,\&\, q$ and $p + q$ exist, then $p \,\&\, q$ is a maximal lower bound and $p + q$ is a minimal upper bound for p and q in L. If p and q are compatible and at least one of $p \wedge q$ or $p \vee q$ exists in L, then $p \,\&\, q$ and $p + q$ exist, $p \,\&\, q = p \wedge q$, and $p + q = p \vee q$. If $p \,\&\, q$ exists, then so do $p' \,\&\, q'$ and $p' + q'$, and we have $p + q = (p' \,\&\, q')'$ and $p \,\&\, q = (p' + q')'$. If $p \perp q$, then $p + q = p \oplus q$ and $p \,\&\, q = 0$.

If L is an orthomodular poset, then any two compatible elements $p, q \in L$ have a conjunction $p \,\&\, q = p \wedge q$ and a disjunction $p + q = p \vee q$; however, there are orthoalgebras containing compatible pairs of elements that do not admit conjunctions or disjunctions. There are non-Boolean orthoalgebras in which every pair of elements forms a compatible set. There exist orthomodular posets containing three elements that are pairwise compatible, but that do not form a compatible set; however, in an orthomodular poset, every pairwise orthogonal subset is an orthogonal subset. There exist orthoalgebras containing three elements that are pairwise orthogonal, but do not form an orthogonal set.

3.3 Probability Measures on and Supports in an Orthoalgebra

By a *probability measure* on an orthoalgebra L, we mean a mapping $\omega{:}L \to [0,1] \subseteq \mathbb{R}$ such that, for $p,q \in L$, with $p \perp q$,

$$\omega(p \oplus q) = \omega(p) + \omega(q). \tag{8}$$

It is possible to define *σ-complete* orthoalgebras and *countably additive* probability measures thereon, and thus extend Eq. (8) to sequences in L, but we do not do so here. The set of all probability measures on L is denoted by $\Omega = \Omega(L)$. Evidently, Ω is a convex subset of the vector space of all real-valued functions on L.

If the elements of L are regarded as representing two-valued experimental propositions concerning a physical system $\mathcal{S}$, then a probability measure $\omega \in \Omega$ may be interpreted in any of the following ways:

(*Frequency*) ω is a *complete stochastic model* for $\mathcal{S}$ in the sense that $\omega(p)$ is the "long-run relative frequency" with which the proposition $p \in L$ will be true when repeatedly tested (D'Espagnat, 1971).

(*Subjective*) ω is a *model for coherent belief* encoding all of our current information about the system $\mathcal{S}$. Thus, if $p \in L$, then $\omega(p)$ measures our current "degree of belief," on a scale from 0 to 1, in the truth of the proposition p (Jaynes, 1989).

(*Propensity*) $\omega(p)$ is a measure on a scale from 0 to 1 of the "propensity" of the system $\mathcal{S}$ to produce the outcome 1 (= true) when the proposition p is tested (Popper, 1959).

(*Mathematical*) ω is a mathematical artifact that may be of use in making inferences about $\mathcal{S}$ using data secured by making measurements on $\mathcal{S}$ (Kolmogorov, 1933).

For $\omega \in \Omega$, we define the *support* of ω by

$$\text{supp}(\omega) = \{p \in L \mid \omega(p) > 0\}.$$

If $S = \text{supp}(\omega)$, then $1 \in S$ and, for all $p, q \in L$ with $p \perp q$,

$$p \oplus q \in S \quad \text{if and only if } p \in S \text{ or } q \in S. \tag{9}$$

A subset S of L such that Eq. (9) holds is called a *support* in L. In general, there are supports $S \subseteq L$ that are not of the form $\text{supp}(\omega)$ for $\omega \in \Omega$; those that are of this form are called *stochastic supports.* The set-theoretic union of supports is again a support, and it follows that the collection of all supports in L forms a complete lattice under set-theoretic inclusion.

3.4 Cartesian and Tensor Products of Orthoalgebras

If L_1 and L_2 are orthoalgebras, the Cartesian product $L_1 \times L_2$ becomes an orthoalgebra under the obvious componentwise operations. If L_1 is identified with $L_1 \times \{0\}$ and L_2 is identified with $\{0\} \times L_2$ in $L_1 \times L_2$, then every element in $L_1 \times L_2$ can be written uniquely in the form $p \oplus q$ with $p \in L_1$ and $q \in L_2$. This construction generalizes the superselected direct sum of standard quantum logics. Just as is the case for standard quantum logics, $\Omega(L_1 \times L_2)$ is isomorphic in a natural way to the convex hull of $\Omega(L_1)$ and $\Omega(L_2)$.

A construction for the tensor product $L_1 \otimes L_2$ of orthoalgebras based on Foulis and Randall (1981) can be found in Lock (1981). The factors L_1 and L_2 are embedded in the orthoalgebra $L_1 \otimes L_2$ by mappings $p \to p \otimes 1$ and $q \to 1 \otimes q$ for $p \in L_1$, $q \in L_2$ in such a way that $p \otimes 1$ and $1 \otimes q$ are compatible and have a conjunction $(p \otimes 1)$ & $(1 \otimes q) = p \otimes q$. Furthermore, elements of the form $p \otimes q$ generate $L_1 \otimes L_2$. If $\alpha \in \Omega(L_1)$ and $\beta \in \Omega(L_2)$, there is a unique $\gamma = \alpha\beta \in \Omega(L_1 \otimes L_2)$ such that $\gamma(p \otimes q) = \alpha(p)\beta(q)$ for all $p \in L_1$, $q \in L_2$. A probability measure on $L_1 \otimes L_2$ of the form $\alpha\beta$ is said to be *factorizable,* and a convex combination of factorizable probability measures is said to be *separable* (Kläy, 1988). The existence of probability measures on $L_1 \otimes L_2$ that are not separable seems to be a characteristic feature of the tensor product of non-Boolean orthoalgebras.

3.5 The Logic of a Physical System

We are now in a position to summarize the *quantum logic approach* to the study of *physical systems* (quantum-mechanical or not). The *basic postulate of quantum logic* for a physical system $\mathcal{S}$ is as follows:

> *(Logic postulate) The set* L *of all two-valued, experimentally testable propositions for* $\mathcal{S}$ *has the structure of an orthoalgebra such that every simultaneously testable set of propositions forms a compatible subset of* L *and every finite compatible subset of* L *is a simultaneously testable set of propositions. If* p,q $\in$ L *with* p $\perp$ q, *and if* p, q, *and* p $\oplus$ q *are tested simultaneously, then at most one of the propositions* p,q *will be true, and* p $\oplus$ q *will be true if and only if either* p *or* q *is true.*

We refer to L as the *logic* of the system $\mathcal{S}$.

It is customary to assume that there is a *state space* Ψ associated with the physical system $\mathcal{S}$. The elements $\psi \in \Psi$ are called *states,* and, at any given moment, $\mathcal{S}$ is presumed to be *in* one and only one state $\psi \in \Psi$. A state is supposed to encode all available information about the consequences of performing tests or making measurements on $\mathcal{S}$ when $\mathcal{S}$ is in that state.

Whereas the truth or falsity of an experimental proposition $p \in L$ can be determined by a suitable test, it may or may not be possible to determine the current state $\psi \in \Psi$ of $\mathcal{S}$ by a test or measurement; however, it may be possible to bring $\mathcal{S}$ into a state ψ by means of a suitable *state-preparation procedure.* The state of the system $\mathcal{S}$ can change under the action of a *dynamical law,* under a *state collapse* when an observer tests a proposition or measures an observable, because a *state-preparation procedure* is executed, or simply by virtue of a spontaneous *state transition.*

A connection between the state space Ψ for $\mathcal{S}$ and its logic L is effected as follows:

> *(Stochastic postulate) Each state* $\psi \in \Psi$ *determines a corresponding probability measure* ω_ψ *on* L *in such a way that, for* p $\in$ L, ω_ψ(p) *is the probability that the proposition* p *is true when tested with the system* $\mathcal{S}$ *in the state* ψ.

In the stochastic postulate, the probability measure ω_ψ can be interpreted in any of the four ways (frequency, subjective, propensity, mathematical) suggested in Sec. 3.3. In what follows, we denote by Σ the subset of $\Omega(L)$ consisting of all probability measures of the form ω_ψ for $\psi \in \Psi$, and we refer to each $\omega_\psi \in \Sigma$ as a *probability state* for the system $\mathcal{S}$. It is customary to identify the state ψ with the corresponding probability state ω_ψ and to speak of the elements in Σ as *states* for $\mathcal{S}$. Although this custom can lead to philosophical and mathematical difficulties (what if $\phi,\psi \in \Psi$, $\phi \neq \psi$, and yet $\omega_\phi = \omega_\psi$?), we shall follow it in the interests of simplicity.

Let $\omega \in \Sigma$ be a state and let $p \in L$ be an experimental proposition for the physical system $\mathcal{S}$. We say that p is *possible, impossible,* or *certain* in the state ω if $p \in \text{supp}(\omega)$, $p \notin \text{supp}(\omega)$, or $p' \notin \text{supp}(\omega)$, respectively. If both p and p' are possible, we say that p is *contingent* in the state ω. The state space Σ is said to be *unital* if every nonzero $p \in L$ is certain in at least one state $\omega \in \Sigma$.

If $\Lambda \subseteq \Sigma$ is a set of states, then a state $\omega \in \Sigma$ is said to be a *superposition* of the states in Λ if

$$\text{supp}(\omega) \subseteq \cup\{\text{supp}(\lambda) | \lambda \in \Lambda\}.$$

The *superposition closure* of Λ is defined to be the set Λ^{sp} of all superpositions of states in Λ. If $\Lambda = \Lambda^{sp}$, then Λ is called *superposition closed.* A state ω is *pure* if the set $\{\omega\}$ is superposition closed. If ω is a pure state, Λ is a set of pure states, and $\omega \in \Lambda^{sp}$, then ω is a *coherent superposition* of the states in Λ. In what follows, we denote by $\mathcal{L}$ the set of all superposition-closed subsets of Σ. Note that $\mathcal{L}$ is closed under set-theoretic intersection, and hence, it forms a complete lattice under set-theoretic inclusion.

It has long been a tenet of natural philosophy that affiliated with a physical system $\mathcal{S}$ is a class $\mathcal{A}$ of *attributes* or *properties.* At any given moment, some of these attributes may be *actual,* while the others are only *potential.* The attributes of $\mathcal{S}$ that are always actual are its *intrinsic* attributes; those that can be either actual or potential are its *accidental* attributes. The charge of an electron is one of its intrinsic attributes, whereas the attribute "spin up in the z direction" is accidental.

To each attribute $A \in \mathcal{A}$ there corresponds a set $\Lambda_A \subseteq \Sigma$ consisting precisely of those states ω such that A is actual whenever $\mathscr{S}$ is in the state ω. A heuristic argument, which we omit here, indicates that Λ_A should be superposition closed, so that $\Lambda_A \in \mathscr{L}$. Similar arguments suggest that every element of $\mathscr{L}$ corresponds in this way to an attribute, and thus lead us to our third postulate:

> *(Attribute postulate) Each attribute* A *determines a corresponding superposition-closed subset* Λ_A *of the state space* Σ *such that* A *is actual if and only if the system* $\mathscr{S}$ *is in a state* $\omega \in \Lambda_A$*; furthermore, every* $\Lambda \in \mathscr{L}$ *has the form* Λ_A *for some* $A \in \mathscr{A}$.

Just as we identified states with probability states, we propose to identify elements Λ of the complete lattice $\mathscr{L}$ with attributes of the system $\mathscr{S}$. (Note that, as a perhaps undesirable consequence, all of the intrinsic attributes of $\mathscr{S}$ become identified with the superposition-closed subset Σ itself.) Thus, we shall refer to the complete lattice $\mathscr{L}$ as the *attribute lattice* for the system $\mathscr{S}$.

If $\Lambda, \Gamma \in \mathscr{L}$ are attributes of $\mathscr{S}$, then $\Lambda \subseteq \Gamma$ if and only if Γ is actual whenever Λ is actual. Furthermore, the attribute $\Lambda \cap \Gamma \in \mathscr{L}$ corresponds to a bona fide *conjunction* of the attributes Λ and Γ in the sense that $\Lambda \cap \Gamma$ is actual if and only if both Λ and Γ are actual. However, the least upper bound of Λ and Γ in $\mathscr{L}$ is $(\Lambda \cup \Gamma)^{sp}$, and it can be actual in states in which neither Λ nor Γ is actual. Following Aerts (1982), we say that the attributes Λ and Γ are *separated by a superselection rule* if $\Lambda \cup \Gamma$ is superposition closed, so that the least upper bound of Λ and Γ in $\mathscr{L}$ corresponds to a bona fide *disjunction* of the attributes Λ and Γ.

3.6 The Canonical Mapping

We continue our discussion of the physical system $\mathscr{S}$ subject to the logic, stochastic, and attribute postulates of Sec. 3.5.

Von Neumann (1955, p. 249) writes,

> Apart from the physical quantities . . . , there exists another category of concepts that are important objects of physics—namely the properties of the states of the system $\mathscr{S}$.

Furthermore, he goes on to identify these properties (or attributes) with the projections in the standard quantum logic L affiliated with the quantum-mechanical system $\mathscr{S}$.

In the more general situation under discussion, it is also possible to relate propositions $p \in L$ and properties (i.e., attributes) $\Lambda \in \mathscr{L}$. For $p \in L$, define

$$[p] = \{\omega \in \Omega \mid \omega(p) = 1\}.$$

We claim that $[p]$ is superposition closed. Indeed, suppose that $\alpha \in [p]^{sp}$, but that $\alpha \notin [p]$. Then $\alpha(p) \neq 1$, and so $\alpha(p') > 0$, $p' \in \operatorname{supp}(\alpha)$, and so $p' \in \operatorname{supp}(\omega)$ for some $\omega \in [p]$. But, then, $\omega(p') > 0$, and so $\omega(p) < 1$, contradicting $\omega \in [p]$. Thus $p \to [p]$ provides a mapping from experimental propositions $p \in L$ to attributes $[p] \in \mathscr{L}$. We refer to $p \to [p]$ as the *canonical mapping* (Foulis *et al.*, 1983).

An attribute of the form $[p]$ is called a *principal attribute;* the principal attributes are those that can be identified with experimental propositions as von Neumann did. It is not difficult to show that every attribute is an intersection (i.e., a conjunction) of (possibly infinitely many) principal attributes. The state space Σ is unital if and only if $[p] = 0$ implies that $p = 0$.

Evidently, $p,q \in L$ with $p \leq q$ implies that $[p] \subseteq [q]$. If the converse holds, so that $[p] \subseteq [q]$ implies that $p \leq q$, then $\mathscr{S}$ is said to have a *full* set of states. If $\mathscr{S}$ has a full set of states and every attribute is principal, then the logic L is isomorphic to the attribute lattice $\mathscr{L}$—this is precisely what happens for a standard quantum logic and it accounts for von Neumann's identification of projections and properties.

3.7 Critique of Quantum Logic

Quantum logic is a relatively young subject, it is still under vigorous development, and many consequences of the epistemological and mathematical insights that it has already provided have yet to be exploited. Quantum-logical techniques involving the tensor product have already cast some light on the well-known Einstein–Podolsky–Rosen paradox (Kläy, 1988), and it is hoped that they will also clarify some of the other classical paradoxes (Wigner's friend, Schrödinger's cat, etc.). The problem of hidden variables can be formulated, understood, and studied rigorously in terms of quantum logics (Greechie and Gudder, 1973). Quantum-logical techniques have enhanced our understanding of group-theoretic imprimitivity methods and the role of superselection rules (Piron, 1976), and ideas related to quantum logic have been used to help unravel the measurement problem (Busch *et al.*, 1991)

There is a strong possibility that unrestricted orthoalgebras are too general to serve as viable models for quantum logic. Some orthoalgebras are extremely "pathological" and thus may be suitable only for the construction of counterexamples. It seems likely that only an appropriately specialized class of orthoalgebras, e.g., unital orthoalgebras, might prove to be adequate as models for a general logic of experimental propositions.

The main drawback of quantum logic is already evident in the standard quantum logic L of a Hilbert space $\mathcal{H}$: In the passage from the wave functions ψ in $\mathcal{H}$ to the projections $P \in L$, all phase information is lost. The lost information becomes critical when sequential measurements—e.g., iterated Stern–Gehrlach spin resolutions (Wright, 1978)—are to be performed. There are at least two ways to restore the lost information, both of which are currently being studied. One can introduce complex-valued *amplitude functions* on the logic L (Gudder, 1988), or one can introduce a general mathematical infrastructure called a *manual* or *test space* (Randall and Foulis, 1973; Foulis, 1989) that can carry phase information and that gives rise to orthoalgebras as derived structures in much the same way that Hilbert spaces give rise to the standard quantum logics.

4. THE LOGICIAN'S APPROACH

We now present an approach to quantum logic more closely aligned with that of standard logical techniques. In the preceding section, we gave an axiomatic approach to orthoalgebras, the most general mathematical structures currently used as models for quantum logic. This section deals with quantum logics by using the methods of logical tradition. In so doing, we will speak of *abstract quantum logics*. As we have seen, *standard quantum logic* is identified with the complete orthomodular lattice of the projections on a separable Hilbert space of dimension at least three over the complex number field. Thus standard quantum logic is a particular kind of semantic model for a form of abstract quantum logic. Generally, a logic **L** can be determined as a triple $\langle FL, \vdash, \models \rangle$, consisting of a formal language *FL*, a *proof-theoretic consequence* relation, and a *semantic-* (or *model-theoretic*) *consequence* relation. For the sake of simplicity, we will consider only sentential languages, generated by an alphabet containing

1. a denumerably infinite sequence of *atomic sentences* (i.e., sentences whose proper parts are not sentences),
2. a finite sequence of primitive logical connectives.

The set of the *sentences* of the language *FL* is the smallest set that contains the atomic sentences and is closed under the logical connectives.

The proof-theoretic concept of consequence $\vdash$ for **L** is defined by referring to a *calculus* (a set of *axioms* and of *rules*) that, in turn, determines a notion of *proof from a set of premises to a conclusion.* A sentence β is called a *proof-theoretic consequence* of a sentence α ($\alpha \vdash \beta$) if and only if (hereafter abbreviated as iff) there is a proof where ω is the premise and β the conclusion. The semantic-consequence relation $\models$ refers to a class of possible interpretations (*models*) of the language, which render any sentence "more or less" *true* or *false.* A sentence β is called a *semantic consequence* of α ($\alpha \models \beta$) iff in any possible model of the language, β is at least as true as α.

The two consequence relations $\vdash$ and $\models$ are *reciprocally adequate* iff they are equivalent. In other words: for any sentences α, β:

$$\alpha \vdash \beta \quad \text{iff}\ \alpha \models \beta.$$

The "if arrow" represents the *soundness* property of the logic, whereas the "only if arrow" is the semantic *completeness* property.

Naturally, a logic can be characterized by different consequence relations that turn out to be equivalent. A logic **L** is called *axiomatizable* iff it admits a proof-theoretic relation, where the notion of proof is decidable. Further, **L** is called *decidable* iff the proof-theoretic–consequence relation $\vdash$ is decidable.

5. ALGEBRAIC AND POSSIBLE-WORLD SEMANTICS

In the logical tradition, logics can be generally characterized by means of two privileged kinds of semantics: an algebraic semantics, or a possible-world semantics (called also Kripkean semantics).

These semantics give different answers to the question: What does it mean to interpret a formal language? In the algebraic semantics, the basic idea is that interpreting a language essentially means associating to any sentence an abstract *truth value* or, more generally, an *abstract meaning:* an element of an algebraic structure. Hence, generally, an algebraic model for a logic **L** will have the form

$$\mathfrak{M} = \langle \mathcal{A}, v \rangle,$$

where $\mathcal{A}$ is an algebraic structure belonging to a class $\mathfrak{K}$ of structures satisfying a given set of conditions and v transforms sentences into elements of $\mathcal{A}$, preserving the logical form (in other words, logical constants are interpreted as operations of the structure). We will consider only structures where a binary relation $\leq$ (possibly a partial order) is defined. On this basis, the semantic-consequence relation is defined as follows:

DEFINITION 5.1—β is a *semantic consequence* of α ($\alpha \models \beta$) iff for any model $\mathfrak{M} = \langle \mathcal{A}, v \rangle$, $v(\alpha) \leq v(\beta)$ (in other words, the abstract meaning of α precedes the abstract meaning of β).

In the possible-world semantics, instead, one assumes that interpreting a language essentially means associating to any sentence α the set of the *possible worlds* (or *situations*) where α holds: This set, that represents the *extensional meaning* of α, is called the *proposition associated to* α (simply, the *proposition of* α). Hence, generally, a Kripkean model for a logic **L** will have the form:

$$\mathfrak{M} = \langle I, \mathbf{R}_i, \mathbf{o}_j, \Pi, v \rangle,$$

where the meanings of the symbols are as follows.

1. I is a nonempty set of possible worlds possibly correlated by relations in the sequence $\mathbf{R}_i$ and operations in the sequence $\mathbf{o}_j$. In most cases, we have only one relation R, called the *accessibility* relation.
2. Π is a set of sets of possible worlds, representing possible propositions of sentences. Any proposition and the total set of propositions Π must satisfy convenient closure conditions that depend on the particular logic.
3. v transforms sentences into propositions preserving the logical form.

A world i is said to *verify* a sentence α ($i \models \alpha$) iff $i \in v(\alpha)$.

On this basis, the Kripkean semantic-consequence relation is defined as follows:

DEFINITION 5.2—β is a *semantic consequence* of α ($\alpha \models \beta$) iff for any model $\mathfrak{M} = \langle I, \mathbf{R}_i, \mathbf{o}_j, \Pi, v \rangle$ and for any world $i \in I$,

$$\text{if } i \models \alpha \quad \text{then } i \models \beta$$

(in other words: whenever α is verified, also β is verified).

In both semantics, a sentence α is called a *logical truth* ($\models \alpha$) iff α is the consequence of any sentence β.

An interesting variant of Kripkean semantics is represented by the *many-valued possible-world semantics,* founded on a generalization of the notion of proposition. As we have seen, in the standard possible-world semantics, the proposition of a sentence α is a set of worlds: the worlds where α holds. This automatically determines the set of the worlds where α does not hold (the "meaning" of the negation of α). Intermediate truth values are not considered. In the many-valued possible-world semantics, instead, one fixes, at the very beginning, a set of truth values $V \subseteq [0,1]$ and any proposition is represented as a function X that associates to any truth value $r \in [0,1]$ a convenient set of possible worlds (the worlds where our proposition holds with truth value r). As a consequence, the total set of propositions Π turns out to behave like a family of *fuzzy* subsets of I (see THEORY AND APPLICATIONS OF FUZZY LOGIC).

Classical logic (CL) can be characterized both in the algebraic and in the Kripkean semantics. Algebraically, it is determined by the class of all algebraic structures $\langle \mathcal{A}, v\rangle$, where $\mathcal{A}$ is a Boolean algebra and v interprets the classical connectives (negation, conjunction, disjunction) as the corresponding Boolean operations (complement, meet, join). In the framework of Kripkean semantics, instead, CL is characterized by the class of all models $\langle I,R,\Pi,v\rangle$, where

1. the accessibility relation R is the identity relation (in other words, any world is accessible only to itself);
2. the set of the possible propositions Π is the set of all subsets of I;
3. v interprets the classical connectives as the corresponding set-theoretic operations.

6. ORTHODOX QUANTUM LOGIC

In the abstract quantum-logical universe, a privileged element is represented by *orthodox quantum logic* (QL), first described "as a logic" by Birkhoff and von Neumann (Birkhoff and von Neumann, 1936). QL is a singular point in the class of all logics that are weaker than classical logic. Many logical and metalogical problems concerning QL have been solved. However, some questions seem to be stubbornly resistant to being resolved.

6.1 Semantic Characterizations of QL

Similarly to classical logic, QL can be characterized both in the algebraic and in the Kripkean semantics. The language of QL contains the two primitive connectives $\neg$ (not), $\owedge$ (and). Disjunction is supposed to be metalinguistically defined via De Morgan's law:

$$\alpha \ovee \beta := \neg(\neg\alpha \owedge \neg\beta).$$

A conditional connective can be defined as the "Sasaki hook":

$$\alpha \rightarrow \beta := \neg\alpha \ovee (\alpha \owedge \beta).$$

Definition 6.1.1—An *algebraic model* of QL is a pair $\mathfrak{M} = \langle \mathcal{A}, v\rangle$, where

1. $\mathcal{A} = \langle A,\leq,{}',\mathbf{1},\mathbf{0}\rangle$ is an orthomodular lattice;
2. v (the interpretation function) interprets the connective $\neg$ as the operation $'$, the connective $\owedge$ as the lattice-meet $\wedge$:
   - **a.** $v(\alpha) \in A$ for any atomic sentence α.
   - **b.** $v(\neg\beta) = v(\beta)'$.
   - **c.** $v(\beta \owedge \gamma) = v(\beta) \wedge v(\gamma)$.

Definition 6.1.2—A sentence α is called *true* in a model $\langle \mathcal{A}, v\rangle$ iff $v(\alpha) = \mathbf{1}$. Accordingly, we will have that β is a *consequence of* α *in the algebraic semantics* of QL ($\alpha \models^{A}_{QL} \beta$) iff $v(\alpha) \leq v(\beta)$ in any model $\langle \mathcal{A}, v\rangle$ based on an orthomodular lattice $\mathcal{A}$. Further, α is a *quantum-logical truth in the algebraic semantics* ($\models^{A}_{QL} \alpha$) iff α is true in any algebraic model of QL.

As a consequence of the orthomodular property, a semantic version of a "deduction lemma" can be proved:

Lemma 6.1.1—$\alpha \models^{A}_{QL} \beta$ iff $\models^{A}_{QL} \alpha \rightarrow \beta$. In other words, $\rightarrow$ represents a "good" conditional connective: $\alpha \rightarrow \beta$ is logically true iff β is a consequence of α.

Definition 6.1.3—A *Kripkean model* of QL has the form $\mathfrak{M} = \langle I,R,\Pi,v\rangle$, where the following conditions held:

1. The accessibility relation R is reflexive and symmetric [we will also write $i \not\perp j$ for Rij; and $i \perp j$ for not Rij. Moreover, if $X \subseteq I$, we will write $i \perp X$ for $\forall j \in X\ (i \perp j)$].

   A *possible proposition* of $\mathfrak{M}$ is a *maximal* set X of worlds, which contains all and only those worlds whose accessible worlds are accessible to at least one element of X. In other words, $i \in X$ iff $\forall j \not\perp i, \exists k \not\perp j$ with $k \in X$.

   For any $X \subseteq I$, let $X^{\obot} := \{i \in I | i \perp X\}$. One can prove that $X^{\obot}$ is a possible proposition for any $X \subseteq I$; X is a possible proposition iff $X = X^{\obot\obot}$; $\emptyset$ and I are possible propositions; if X, Y are possible propositions, then $X \cap Y$ is a possible proposition.
2. Π is a set of possible propositions closed under, I, ${}^{\obot}$, $\cap$.
3. Π is orthomodular: $X \cap (X \cap (X \cap Y)^{\obot})^{\obot} \subseteq Y$, for any $X, Y \in \Pi$.

4. **a.** $v(\alpha) \in \Pi$, for any atomic sentence α;
   b. $v(\neg\beta) = v(\beta)^{\circledperp}$;
   c. $v(\beta \owedge \gamma) = v(\beta) \cap v(\gamma)$.

DEFINITION 6.1.4—A sentence α is called *true* in a model $\mathfrak{M} = \langle I,R,\Pi,v\rangle$ iff α is verified by any world $i \in I$.

Accordingly, we will have that β is a *consequence of α in the Kripkean semantics* of QL ($\alpha \models^{K}_{\mathrm{QL}} \beta$) iff for any Kripkean model $\mathfrak{M} = \langle I,R,\Pi,v\rangle$ of QL and for any world i, if $i \models \alpha$ then $i \models \beta$. Further, α is a *quantum-logical truth in the Kripkean semantics* for QL ($\models^{K}_{\mathrm{QL}} \alpha$) iff α is true in any Kripkean model of QL.

The algebraic and the Kripkean semantics for QL turn out to characterize the same logic:

THEOREM 6.1.1—$\alpha \models^{A}_{\mathrm{QL}} \beta$ *iff* $\alpha \models^{K}_{\mathrm{QL}} \beta$. This permits us to write simply $\alpha \models_{\mathrm{QL}} \beta$ instead of $\alpha \models^{A}_{\mathrm{QL}} \beta$ and $\alpha \models^{K}_{\mathrm{QL}} \beta$.

Both the algebraic and the Kripkean models of QL admit of Hilbert-space exemplifications, which are the basis for the physical interpretations. Let $\mathcal{H}$ be the separable complex Hilbert space associated to a physical system $\mathcal{S}$. An algebraic model $\langle \mathcal{A},v\rangle$ can be constructed by taking as $\mathcal{A}$ the standard quantum logic based on $\mathcal{H}$—in other words, the orthomodular lattice of the projections on $\mathcal{H}$; whereas v will follow the intended physical meaning of the atomic sentences. At the same time, a Kripkean model $\mathfrak{M} = \langle I,R,\Pi,v\rangle$ can be constructed by putting I = the set of the pure states (represented by normalized vectors ψ of $\mathcal{H}$), R = the nonorthogonality relation between pure states, and Π = the set of the possible propositions, which are uniquely determined by the closed subspaces of $\mathcal{H}$. v will follow the physical meaning of the atomic sentences. It turns out that the propositions of the model correspond to superposition-closed subsets of the pure-state space. We will call this kind of models *Hilbertian models* of QL.

A question arises: Is QL characterized by the class of all algebraic Hilbertian models? The answer is negative as proved by Greechie (1981). For instance, there is a complicated sentence of QL (corresponding to the so-called *orthoarguesian law*) that is true in all Hilbertian models, and not true in some QL models. Let us call *Hilbertian quantum logic* (HQL) the logic that is semantically characterized by the class of all Hilbertian models. Apparently, HQL is stronger than QL. Hence, abstract quantum logic turns out to be definitely more general with respect to its physical and historical origin. The axiomatizability of HQL is still an open problem.

DEFINITION 6.1.5—A sentence α is called *semantically consistent* iff for any β, $\alpha \not\models_{\mathrm{QL}} \beta \owedge \neg\beta$ (in other words, no contradiction is a semantic consequence of α).

One can show that α is semantically consistent iff there is at least one algebraic model $\langle \mathcal{A},v\rangle$ such that $v(\alpha) \neq \mathbf{0}$ iff there exists at least one Kripkean model $\mathfrak{M} = \langle I,R,\Pi,v\rangle$ and at least one world i such that $i \models \alpha$.

6.2 An Axiomatization of QL

QL is an axiomatizable logic. Many axiomatizations are known: in the Hilbert–Bernays style (Hardegree, 1979), in the natural deduction, and in the sequent style (Gibbins, 1985; Nishimura, 1980). We will present here a calculus (Goldblatt, 1974; Dalla Chiara, 1986) that represents a kind of "logical copy" of orthomodular lattices. Our calculus (that has no axioms) is determined as a set of rules. Any rule has the form

$$\frac{\alpha_1 \vdash \beta_1, \ldots, \alpha_n \vdash \beta_n}{\alpha \vdash \beta.}$$

(If β_1 is inferred from $\alpha_1, \ldots, \beta_n$ is inferred from α_n, then β can be inferred from α.) The configurations $\alpha_1 \vdash \beta_1, \ldots, \alpha_n \vdash \beta_n$ represent the *premises* of the rule, while $\alpha \vdash \beta$ is the *conclusion*. An *improper rule* is a rule whose set of premises is empty. Instead of

$$\frac{\emptyset}{\alpha \vdash \beta},$$

we will write $\alpha \vdash \beta$.

The rules of QL are as follows:

R1 $\alpha \vdash \alpha$ (identity).

R2 $\dfrac{\alpha \vdash \beta \quad \beta \vdash \gamma}{\alpha \vdash \gamma}$ (transitivity).

R3 $\alpha \owedge \beta \vdash \alpha$.

R4 $\alpha \owedge \beta \vdash \beta$.

R5 $\dfrac{\gamma \vdash \alpha \quad \gamma \vdash \beta}{\gamma \vdash \alpha \owedge \beta}$.

R6 $\alpha \vdash \neg\neg\alpha$ (weak double negation).

R7 $\neg\neg\alpha \vdash \alpha$ (strong double negation).

R8 $\dfrac{\alpha \vdash \beta}{\neg\beta \vdash \neg\alpha}$ (contraposition).

R9 $\alpha \owedge \neg(\alpha \owedge \neg(\alpha \owedge \beta)) \vdash \beta$ (orthomodularity).

Definition 6.2.1—A *proof* is a finite sequence of configurations $\alpha \vdash \beta$ where any element of the sequence is either an improper rule or the conclusion of a proper rule whose premises are previous elements of the sequence.

Definition 6.2.2—β is a *proof-theoretic consequence* of α (or *provable* from α) ($\alpha \vdash_{\text{QL}} \beta$) iff there is a proof whose last configuration is $\alpha \vdash \beta$.

Definition 6.2.3—β is a *proof-theoretic consequence* of a set of sentences T (or *provable* from T) ($T \vdash_{\text{QL}} \beta$) iff T includes a finite subset $\{\alpha_1, \ldots, \alpha_n\}$ such that $\alpha_1 \owedge \cdots \owedge \alpha_n \vdash_{\text{QL}} \beta$.

Definition 6.2.4—A set of sentences T is called *contradictory* if $T \vdash_{\text{QL}} \beta \owedge \neg\beta$ for some sentence β; *noncontradictory*, otherwise. A sentence α is contradictory if $\{\alpha\}$ is contradictory; noncontradictory, otherwise.

The proof-theoretic and the semantic-consequence relations turn out to be equivalent. Namely, a soundness and a completeness theorem can be proved:

Theorem 6.2.1—*Soundness*

If $\alpha \vdash_{\text{QL}} \beta$ *then* $\alpha \vDash_{\text{QL}} \beta$.

Theorem 6.2.2—*Completeness*

If $\alpha \vDash_{\text{QL}} \beta$ *then* $\alpha \vdash_{\text{QL}} \beta$.

As a consequence, one obtains the result that a sentence is noncontradictory iff it is semantically consistent.

A characteristic "anomaly" of QL is the violation of a metalogical condition, which is satisfied not only by CL but also by a large class of nonclassical logics. This condition is represented by the *Lindenbaum property*, according to which any noncontradictory set of sentences T can be extended to a noncontradictory and *complete* set T^* such that for any sentence α, either $\alpha \in T^*$ or $\neg\alpha \in T^*$. The set $T := \{\neg(\alpha \rightarrow (\beta \rightarrow \alpha))\}$ (which contains the negation of the *a fortiori* principle) represents an example of a noncontradictory set that cannot be extended to a noncontradictory and complete set. The set T is noncontradictory, because in some models $\langle \mathcal{A}, v\rangle$: $v(\neg(\alpha \rightarrow (\beta \rightarrow \alpha))) \neq \mathbf{0}$. For instance, take $\langle \mathcal{A}, v\rangle$ based on the orthomodular lattice of the closed subspaces of $\mathbb{R}^2$, where $v(\alpha)$ and $v(\beta)$ are two nonorthogonal unidimensional subspaces. However, one can easily check that $v(\neg(\alpha \rightarrow (\beta \rightarrow \alpha))) = \mathbf{1}$ is impossible. Hence, $\neg(\alpha \rightarrow (\beta \rightarrow \alpha))$ cannot belong to a noncontradictory and complete set T^*, which would trivially admit a model $\langle \mathcal{A}, v\rangle$ such that $v(\beta) = \mathbf{1}$, for any $\beta \in T^*$. From an intuitive point of view, the failure of the Lindenbaum property represents a very strong incompleteness result. The *tertium non datur* principle breaks down at the very deep level: There are theories that are intrinsically incomplete, even *in mente Dei*.

Among the questions that are still unsolved, let us mention at least the following:

1. Is QL decidable?
2. Does QL admit the *finite-model property?* In other words, if a sentence is not a quantum-logical truth, is there any finite model where our sentence is not verified? A positive answer to the finite-model property would automatically provide a positive answer to the decidability question, but not vice versa.
3. Is the set of all possible propositions in the Kripkean *canonical* model of QL orthomodular? (The worlds of the canonical model are all the noncontradictory and deductively closed sets of sentences T, whereas two worlds T and T' are accessible iff whenever T contains a sentence α, T' does not contain its negation $\neg\alpha$.) This problem is correlated to the critical question whether any orthomodular lattice is embeddable into a complete orthomodular lattice. Only partial answers are known.

7. ORTHOLOGIC AND UNSHARP QUANTUM LOGICS

By dropping the orthomodular condition both in the algebraic and in the Kripkean semantics, one can characterize a weaker form of quantum logic, which is usually called *orthologic* or *minimal quantum logic* (MQL). This logic turns out to be more "tractable" from a metalogical point of view: It satisfies the finite-model property; consequently, it is decidable (Goldblatt, 1974). A calculus that represents an adequate axiomatization for MQL can be, naturally, obtained by replacing the orthomodular rule **R9** of our QL calculus with the weaker Duns Scotus rule $\alpha \owedge \neg\alpha \vdash \beta$ (*ex absurdo sequitur quodlibet:* Any sentence is a consequence of a contradiction).

A less investigated form of quantum logic is represented by *paraconsistent quantum logic* (PQL) (Dalla Chiara and Giuntini, 1989), which is a weak example of an unsharp quantum logic, possibly violating the noncontradiction and the excluded-middle principles. As we will see, unsharp quantum logics represent natural abstractions from the *unsharp approaches* to quantum theory. Algebraically, PQL is characterized by the class of all models based on an involutive lattice $\langle A,\leq,',\mathbf{1},\mathbf{0}\rangle$, with smallest element $\mathbf{0}$ and largest element $\mathbf{1}$. Equivalently, in the Kripkean semantics, PQL is characterized by the class of all models $\langle I,R,\Pi,v\rangle$, where R is a symmetric, not necessarily reflexive, relation, and Π behaves like in the MQL case. Differently from QL and MQL, a world i of a PQL model may verify a contradiction. Since R is generally not reflexive, it may happen that $i \in v(\beta)$ and $i \perp v(\beta)$. Hence: $i \models \beta \owedge \neg\beta$. An adequate axiomatization for PQL can be obtained by dropping the orthomodular rule **R9** in our QL calculus. Like MQL, also PQL satisfies the finite-model property and consequently is decidable.

Interesting unsharp extensions of PQL are the *Brouwer–Zadeh logics* first investigated by Cattaneo and Nisticò (1989). A characteristic of these logics is a splitting of the connective "not" into two forms of negation: a fuzzylike negation, which gives rise to a paraconsistent behavior, and an intuitionisticlike negation. The fuzzy "not" represents a weak negation, which inverts the truth values truth and falsity, satisfies the double-negation principle, but generally violates the noncontradiction and the excluded-middle principles. The second "not" is a stronger negation, a kind of necessitation of the fuzzy "not." As a consequence, the language of the Brouwer–Zadeh logics is an extension of the QL language, with two primitive negations: $\neg$ represents the fuzzy "not," whereas $\sim$ is the intuitionistic "not." On this basis, a necessity operator can be defined in terms of the two negations:

$$L\alpha := \sim \neg\alpha.$$

In other words: "necessarily α" means the intuitionistic negation of the fuzzy negation of α. A possibility operator is then defined in terms of L and $\neg$:

$$M\alpha := \neg L \neg\alpha.$$

We will consider two forms of Brouwer–Zadeh logics: BZL (weak Brouwer–Zadeh logic) and BZL^3, which represents a form of three-valued quantum logic. Both logics admit of Hilbert-space exemplifications. Algebraically, BZL is characterized by the class of all models $\mathcal{M} = \langle \mathcal{A},v\rangle$, where $\mathcal{A} = \langle A,\leq,',^{\sim},\mathbf{1},\mathbf{0}\rangle$ is a Brouwer–Zadeh lattice (simply a BZ lattice). In other words:

1. **a.** $\langle A,\leq,',\mathbf{1},\mathbf{0}\rangle$ is an involutive lattice with smallest element $\mathbf{0}$ and largest element $\mathbf{1}$.
   b. $^{\sim}$ behaves like an intuitionistic complement:

   $$a \wedge a^{\sim} = \mathbf{0}.$$

   $$a \leq a^{\sim\sim}.$$

   $$\text{If } a \leq b, \quad \text{then } b^{\sim} \leq a^{\sim}.$$

   c. The following relation holds between the fuzzy and the intuitionistic complement:

   $$a^{\sim\prime} = a^{\sim\sim}.$$

   d. The *regularity condition* holds:

   $$a \wedge a' \leq b \vee b'.$$

2. v interprets the fuzzy negation $\neg$ as the fuzzy complement $'$, and the intuitionistic negation $\sim$ as the intuitionistic complement $^{\sim}$.

The logic BZL, which can be equivalently characterized also by a Kripkean semantics, is axiomatizable and decidable (Giuntini, 1991). The modal operators of BZL behave similarly to the corresponding operators of the famous modal system S_5. For instance, $LL\alpha$ is equivalent to $L\alpha$; and $LM\alpha$ is equivalent to $M\alpha$.

The three-valued BZL^3 can be naturally characterized by a kind of many-valued possible-world semantics. The intuitive idea can be sketched as follows: One supposes that interpreting a language means associating to any sentence two *domains of certainty:* the domain of possible worlds where the sentence holds, and the domain of possible worlds where the sentence does not hold. All the other worlds are supposed to associate an intermediate truth value (*indetermined*) to our sentence. The models of this semantics will be called *models with positive and negative domains* (shortly, *ortho-pair models*).

Briefly, an ortho-pair model has the form $\mathcal{M} = \langle I,R,\Pi,v\rangle$, where

1. I is a nonempty set of worlds and R (the accessibility relation) is reflexive and symmetric (like in the Kripkean characterization of QL).

The possible propositions (in the sense of our definition of the Kripkean model for QL) will be here called *simple propositions.* The set Σ of all simple propositions gives rise to an ortholattice; let us indicate by $\#$, $\sqcap$, $\sqcup$ the lattice operations defined on Σ.

2. A *possible proposition* of $\mathcal{M}$ is any pair $\langle X_1,X_0\rangle$, where X_1, X_0 are simple propositions such that $X_1 \subseteq X_0^{\#}$ (in other words: X_1, X_0 are orthogonal). The following operations and relations are defined on the set of all possible propositions:
   - **a.** the fuzzy complement

     $$\langle X_1,X_0\rangle' = \langle X_0,X_1\rangle;$$

   - **b.** the intuitionistic complement

     $$\langle X_1,X_0\rangle^{\sim} = \langle X_0,X_0^{\#}\rangle;$$

   - **c.** the propositional conjunction

     $$\langle X_1,X_0\rangle \wedge \langle Y_1,Y_0\rangle = \langle X_1 \sqcap Y_1, X_0 \sqcup Y_0\rangle;$$

   - **d.** the order relation

     $$\langle X_1,X_0\rangle \le \langle Y_1,Y_0\rangle \text{ iff } X_1 \subseteq Y_1 \text{ and } Y_0 \subseteq X_0.$$

3. Π is a set of possible propositions closed under $\wedge$, $'$, $^{\sim}$, and $\mathbf{0} := \langle\emptyset,I\rangle$.
4. v (the interpretation function) maps sentences into propositions in Π and interprets the connectives $\owedge$, $\sim$, $\neg$ as the corresponding operations.

The other basic semantic definitions are like in the algebraic semantics. One can show that in any ortho-pair model the set of propositions has the structure of a BZ lattice. As a consequence, the logic BZL^3 is at least as strong as BZL. In fact, one can prove that BZL^3 is properly stronger than BZL. As a counterexample, let us consider an instance of the fuzzy excluded middle and an instance of the intuitionistic excluded middle applied to the same sentence α. One can easily check:

$$\alpha \ovee \neg\alpha \models_{\mathrm{BZL}^3} \alpha \ovee \sim \alpha \quad \text{and}$$
$$\alpha \ovee \sim \alpha \models_{\mathrm{BZL}^3} \alpha \ovee \neg\alpha.$$

However, generally

$$\alpha \ovee \neg\alpha \not\models_{\mathrm{BZL}} \alpha \ovee \sim \alpha.$$

Also BZL^3 is axiomatizable (Cattaneo *et al.*, 1993) and can be characterized by means of an algebraic semantics.

8. HILBERT-SPACE MODELS OF THE BROUWER–ZADEH LOGICS

Hilbert-space models of both BZL and BZL^3 can be obtained in the framework of the *unsharp* (or *operational*) *approach* to quantum theory that was first proposed by Ludwig (1954) and developed (among others) by Kraus (1983), Davies (1976), Busch *et al.* (1991), and Cattaneo and Laudisa (1994). One of the basic ideas of this approach is a "liberalization" of the mathematical counterpart for the intuitive notion of "experimentally testable proposition." As we have seen, in orthodox Hilbert-space quantum mechanics, experimental propositions are mathematically represented as projections P on the Hilbert space $\mathcal{H}$ corresponding to the physical system $\mathcal{S}$ under investigation. If P is a projection representing a proposition and W is a density operator representing a state of $\mathcal{S}$, the number $\mathrm{tr}(WP)$ represents the probability value that the system $\mathcal{S}$ in the state W

verifies P (*Born probability*). However, projections are not the only operators for which a Born probability can be defined. Let us consider the class $\mathcal{E}(\mathcal{H})$ of all linear bounded operators D such that for any density operator W,

$$\mathrm{tr}(WD) \in [0,1].$$

It turns out that $\mathcal{E}(\mathcal{H})$ properly includes the set $L(\mathcal{H})$ of all projections on $\mathcal{H}$. In a sense, the elements of $\mathcal{E}(\mathcal{H})$ represent a "maximal" possible notion of experimental proposition, in agreement with the probabilistic rules of quantum theory. In the framework of the unsharp approach, the elements of $\mathcal{E}(\mathcal{H})$ have been called *effects*. An important difference between projections and proper effects is the following: Projections can be associated to *sharp* propositions having the form "the value for the observable A lies in the exact Borel set F," whereas effects may represent also *fuzzy* propositions like "the value of the observable A lies in the fuzzy Borel set F." As a consequence, there are effects D that are different from the null projection $\mathbb{O}$ and that are verified with certainty by no state [for any W, $\mathrm{tr}(WD) \neq 1$]. A limit case is represented by the *semitransparent effect* $\frac{1}{2}\mathbb{1}$ (where $\mathbb{1}$ is the identity operator), to which any state W assigns probability value $\frac{1}{2}$.

The class of all effects of $\mathcal{H}$ gives rise to a structure $\langle\mathcal{E}(\mathcal{H}),\leq,{}',{}^{\sim},\mathbf{1},\mathbf{0}\rangle$ which is a BZ poset (not a BZ lattice!). In other words, $\leq$ is a partial order with largest element $\mathbf{1}$ and smallest element $\mathbf{0}$, while the fuzzy and the intuitionistic complement ($'$ and $^{\sim}$) behave like in the BZ lattices. The relation and the operations of the effect-structure are defined as follows:

1. $D_1 \leq D_2$ iff for any density operator W, $\mathrm{tr}(WD_1) \leq \mathrm{tr}(WD_2)$.
2. $\mathbf{1} = \mathbb{1}$.
3. $D' = \mathbb{1} - D$.
4. $D^{\sim}$ is the projection $P_{\mathrm{Ker}(D)}$ into the subspace $\mathrm{Ker}(D)$, consisting of all vectors that are transformed by the operator D into the null vector.
5. $\mathbf{0} = \mathbf{1}'$.

In the particular case where D is a projection, it turns out that $D' = D^{\sim}$. In other words, the fuzzy and the intuitionistic complement coincide for sharp propositions. One can show that any BZ poset can be embedded into a complete BZ lattice [for the *MacNeille completion* (Birkhoff, 1967) of a BZ poset is a complete BZ lattice (Giuntini, 1991)]. As a consequence, the MacNeille completions of the effect-BZ posets represent natural Hilbert-space models for the logic BZL.

As to BZL^3, Hilbert-space models $\langle I,R,\Pi,v\rangle$ in the ortho-pair semantics can be constructed as follows:

1. I and R are defined like in the Kripkean Hilbertian models of QL. The simple propositions turn out to be in one-to-one correspondence to the set of the projections of $\mathcal{H}$.
2. Π is the set of all possible propositions. Any effect D can be transformed into a proposition $f(D) = \langle X_1^D, X_0^D\rangle$, where

   $$X_1^D := \{\psi \in I \mid \mathrm{tr}(P_\psi D) = 1\} \quad \text{and} \quad X_0^D := \{\psi \in I \mid \mathrm{tr}(P_\psi D) = 0\}$$

   (P_ψ is the projection onto the unidimensional subspace spanned by the vector ψ). In other words, X_1^D and X_0^D represent respectively the positive and the negative domain of D (in a sense, the extensional meaning of D in the model). The map f turns out to preserve the order relation and the two complements.
3. The interpretation function v follows the intuitive physical meaning of the atomic sentences.

9. PARTIAL QUANTUM LOGICS

So far we have considered only examples of abstract quantum logics, where conjunctions and disjunctions are supposed to be always defined. However, as we have seen, the experimental and the probabilistic meaning of conjunctions of incompatible propositions in quantum theory has been often put in question. How do we construct logics where we admit that conjunctions and disjunctions are possibly meaningless? For instance, how do we give a natural semantic characterization for a logic corresponding to the class of all orthoalgebras or to the class of all orthomodular posets? Let us call these logics respectively *weak partial quantum logic* (WPaQL) and *strong partial quantum logic*

(SPaQL). Are WPaQL and SPaQL axiomatizable?

9.1 Algebraic Semantics for WPaQL

The language of WPaQL contains two primitive connectives: the negation $\neg$, and the exclusive disjunction $\boxplus$ (*aut*). A conjunction is metalinguistically defined, via De Morgan's law:

$$\alpha \square \beta := \neg(\neg\alpha \boxplus \neg\beta).$$

The intuitive idea underlying our semantics for WPaQL is the following: Disjunctions and conjunctions are considered "legitimate" from a mere linguistic point of view. However, semantically, a disjunction $\alpha \boxplus \beta$ will have the *intended meaning* only in the "well-behaved cases" (where the values of α and β are orthogonal in the corresponding orthoalgebra). Otherwise, $\alpha \boxplus \beta$ will have any meaning whatsoever (generally not connected with the meanings of α and β). A similar semantic "trick" is used in some standard treatments of the description operator ι ("the unique individual that satisfies a given property") in classical model theory.

Definition 9.1.1—An *algebraic model* of WPaQL is a pair $\mathcal{M} = \langle \mathcal{A}, v \rangle$, where

1. $\mathcal{A} = \langle A, \oplus, \mathbf{1}, \mathbf{0} \rangle$ is an orthoalgebra.
2. v (the interpretation function) satisfies the following conditions:
   $v(\alpha) \in A$, for any atomic sentence α;
   $v(\neg\beta) = v(\beta)'$, where $'$ is the orthocomplement operation that is defined in $\mathcal{A}$;
   $$v(\beta \boxplus \gamma) = \begin{cases} v(\beta) \oplus v(\gamma), & \text{if } v(\beta) \oplus v(\gamma) \text{ is defined in } \mathcal{A}, \\ \text{any element} & \text{otherwise} \end{cases}.$$

Accordingly, we will have that

$$\alpha \models_{\mathrm{WPaQL}} \beta \quad \text{iff in any WPaQL model } \mathcal{M} = \langle \mathcal{A}, v \rangle,\ v(\alpha) \leq v(\beta),$$

where $\leq$ is the partial order relation defined in $\mathcal{A}$.

9.2 An Axiomatization of Partial Quantum Logics

The logic WPaQL is axiomatizable. We present here a calculus that is obtained as a natural transformation of our QL calculus.

The rules of WPaQL are as follows:

R1 $\alpha \vdash \alpha$ (identity).

R2 $\dfrac{\alpha \vdash \beta \quad \beta \vdash \gamma}{\alpha \vdash \gamma}$ (transitivity).

R3 $\alpha \vdash \neg\neg\alpha$ (weak double negation).

R4 $\neg\neg\alpha \vdash \alpha$ (strong double negation).

R5 $\dfrac{\alpha \vdash \beta}{\neg\beta \vdash \neg\alpha}$ (contraposition).

R6 $\beta \vdash \alpha \boxplus \neg\alpha$ (excluded middle).

R7 $\dfrac{\alpha \vdash \neg\beta \quad \alpha \boxplus \neg\alpha \vdash \alpha \boxplus \beta}{\neg\alpha \vdash \beta}$ (unicity of negation).

R8 $\dfrac{\alpha \vdash \neg\beta \quad \alpha \vdash \alpha_1 \quad \alpha_1 \vdash \alpha \quad \beta \vdash \beta_1 \quad \beta_1 \vdash \beta}{\alpha \boxplus \beta \vdash \alpha_1 \boxplus \beta_1}$ (weak substitutivity).

R9 $\dfrac{\alpha \vdash \neg\beta}{\alpha \boxplus \beta \vdash \beta \boxplus \alpha}$ (weak commutativity).

R10 $\dfrac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \boxplus \gamma)}{\alpha \vdash \neg\beta}$.

R11 $\dfrac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \boxplus \gamma)}{\alpha \boxplus \beta \vdash \neg\gamma}$.

R12 $\dfrac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \boxplus \gamma)}{\alpha \boxplus (\beta \boxplus \gamma) \vdash (\alpha \boxplus \beta) \boxplus \gamma}$.

R13 $\dfrac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \boxplus \gamma)}{(\alpha \boxplus \beta) \boxplus \gamma) \vdash \alpha \boxplus (\beta \boxplus \gamma)}$.

(**R10–R13** require a weak associativity.)

The other basic proof-theoretic definitions are given like in the QL case. Some derivable rules of the calculus are the following:

D1 $\dfrac{\alpha \vdash \beta}{\beta \vdash \alpha \boxplus \neg(\alpha \boxplus \neg\beta)}$.

D2 $\dfrac{\alpha \vdash \beta}{\alpha \boxplus \neg(\alpha \boxplus \neg\beta) \vdash \beta}$.

D3
$$\frac{\alpha \vdash \neg\gamma \quad \beta \vdash \neg\gamma \, \alpha \boxplus \gamma \vdash \beta \boxplus \gamma \, \beta \boxplus \gamma \vdash \alpha \boxplus \gamma}{\alpha \vdash \beta}.$$

D4 $\dfrac{\alpha \vdash \neg\beta \quad \alpha \vdash \gamma \quad \beta \vdash \gamma \quad \gamma \vdash \alpha \boxplus \beta}{\alpha \boxplus \beta \vdash \gamma}$.

The proof-theoretic and the semantic-consequence relations for the logic WPaQL are reciprocally adequate. Namely, a soundness and a completeness theorem can be proved.

Theorem 9.2.1—*Soundness*

If $\alpha \vdash_{\mathrm{WPaQL}} \beta$ *then* $\alpha \models_{\mathrm{WPaQL}} \beta$.

Theorem 9.2.2—*Completeness*

If $\alpha \models_{\mathrm{WPaQL}} \beta$ *then* $\alpha \vdash_{\mathrm{WPaQL}} \beta$.

As to strong partial quantum logic (SPaQL), an axiomatization can be obtained by adding to our WPaQL calculus the following rule:

R14 $$\frac{\alpha \vdash \neg\beta \quad \alpha \vdash \gamma \quad \beta \vdash \gamma}{\alpha \boxplus \beta \vdash \gamma}.$$

Semantically, the models of SPaQL will be based on orthoalgebras $\mathcal{A} = \langle A,\oplus,\mathbf{1},\mathbf{0}\rangle$, satisfying the following condition: If defined, $a \oplus b$ is the sup of a and b. As we have seen in Sec. 3.1, this condition is necessary and sufficient in order to make the orthoposet induced by the orthoalgebra $\mathcal{A}$ an orthomodular poset. The soundness and the completeness theorems for SPaQL (with respect to this semantics) can be proved similarly to the case of WPaQL.

10. CRITIQUE OF ABSTRACT QUANTUM LOGICS

Do abstract quantum logics represent "real" logics or should they rather be regarded as mere extrapolations from particular algebraic structures that arise in the mathematical formalism of quantum mechanics? Different answers to this question have been given in the history of the logicoalgebraic approach to quantum theory. According to our analysis, the logical *status* of abstract quantum logics can be hardly put in question. These logics turn out to satisfy all the canonical conditions that the present community of logicians require in order to call a given abstract object a *logic:* syntactical and semantical descriptions, proofs of soundness and completeness theorems, and so on.

Has the quantum-logical research definitely shown that "logic is empirical"? At the very beginning of the history of quantum logic, the thesis according to which the choice of the "right" logic to be used in a given theoretic situation may depend also on experimental data appeared a kind of extremistic view, in contrast with the traditional description of logic as "an *a priori* and analytical science." These days, an empirical position in logic is no more regarded as a "daring heresy." At the same time, we are facing a new difficulty: As we have seen, quantum logic is not unique. Besides orthodox quantum logic, different forms of partial and unsharp quantum logics have been developed. In this situation, one can wonder whether it is still reasonable to look for the most adequate abstract logic that should faithfully represent the structures arising in the quantum world.

A question that has been often discussed concerns the compatibility between quantum logic and the mathematical formalism of quantum theory, based on classical logic. Is the quantum physicist bound to a kind of "logical schizophrenia"? At first sight, the compresence of different logics in one and the same theory may give a sense of uneasiness. However, the splitting of the basic logical operations (negation, conjunction, disjunction, . . .) into different connectives with different meanings and uses is now a well-accepted logical phenomenon that admits consistent descriptions. As we have seen, classical and quantum logic turn out to apply to different sublanguages of quantum theory that must be sharply distinguished.

GLOSSARY

Abstract Quantum Logic: A logic $\langle FL,\vdash,\models\rangle$, where the proof-theoretic and the semantic-consequence relations violate some characteristic classical principles like the distributivity of conjunction and disjunction.

Adjoint: If A is a bounded operator on a Hilbert space, then the adjoint of A is the unique bounded operator A^* that satisfies $\langle A\psi|\phi\rangle = \langle\psi|A^*\phi\rangle$ for all vectors ψ, ϕ in the space.

Algebraic Model of a Language: A pair $\langle\mathcal{A},v\rangle$ consisting of an algebraic structure $\mathcal{A}$ and of an interpretation function v that transforms the sentences of the language into elements of $\mathcal{A}$, preserving the logical form.

Algebraic Semantics: The basic idea is that interpreting a formal language means associating to any sentence an element of an algebraic structure.

Attribute: One of a class of properties affiliated with a physical system. At any given moment some of the attributes of the system may be actual, while others are only potential.

Axiomatizable Logic: A logic is axiomatizable when its concept of proof is decidable.

Boolean Algebra: An orthocomplemented lattice L that satisfies the distributive law $p \wedge (q \vee r) = (p \wedge q) \vee (p \wedge r)$ for all $p, q, r \in L$.

Borel Set: A (real) Borel set is a set that belongs to the smallest collection of subsets of the real numbers $\mathbb{R}$ that contains all open intervals and is closed under the formation of complements and countable unions.

Brouwer–Zadeh Lattice (or Poset): A lattice (or poset) L with smallest element $\mathbf{1}$ and largest element $\mathbf{0}$, equipped with a regular involution $'$ (a fuzzylike complement), and an intuitionisticlike complement $^{\sim}$, subject to the following conditions for all $p,q \in L$: (i) $p \leq q \Rightarrow q^{\sim} \leq p^{\sim}$, (ii) $p \wedge p^{\sim} = \mathbf{0}$, (iii) $p \leq p^{\sim\sim}$, (iv) $p^{\sim\prime} = p^{\sim\sim}$.

Brouwer–Zadeh Logic: A logic that is characterized by the class of all models based on Brouwer–Zadeh lattices.

Compatible: A set C of elements in an orthoalgebra L is a compatible set if there is a Boolean subalgebra B of L such that $C \subseteq$ B.

Complete Lattice: A lattice in which every subset has a least upper bound, or join, and a greatest lower bound, or meet.

Completeness: A logic $\langle FL, \vdash, \models \rangle$ is (semantically) complete when all the semantic consequences are proof-theoretic consequences (if $\alpha \models \beta$ then $\alpha \vdash \beta$).

Conjunction (in an Orthoalgebra): If L is an orthoalgebra and $p, q \in L$, then p and q have a conjunction $p \,\&\, q \in L$ if there is a Boolean subalgebra B of L with $p, q \in B$, and the meet $p \wedge_B q$ of p and q in B is independent of the choice of B, in which case $p \,\&\, q = p \wedge_B q$.

Decidable Logic: A logic is decidable when its proof-theoretic consequence relation is decidable.

Density Operator: A self-adjoint, nonnegative, trace-class operator W on a Hilbert space, such that $\mathrm{tr}(W) = 1$.

Direct Sum (or Cartesian Product) of Hilbert Spaces: The direct sum of the Hilbert spaces $\mathcal{H}$ and $\mathcal{K}$ is the Hilbert space $\mathcal{H} \oplus \mathcal{K}$ consisting of all ordered pairs (x,y) with $x \in \mathcal{H}$, $y \in \mathcal{K}$, and with coordinatewise vector operations. The inner product is defined by $\langle (x_1,y_1)|(x_2,y_2)\rangle = \langle x_1|x_2\rangle + \langle y_1|y_2\rangle$.

Disjunction (in an Orthoalgebra): If L is an orthoalgebra and $p, q \in L$, then p and q have a disjunction $p + q$ if there is a Boolean subalgebra B of L with $p, q \in B$ and the join $p \vee_B q$ of p and q in B is independent of the choice of B, in which case $p + q = p \vee_B q$.

Dynamics: The evolution in time of the state of a physical system.

Effect: A linear bounded operator A of a Hilbert space such that for any density operator W, $\mathrm{tr}(WA) \in [0,1]$. In the unsharp approach to quantum mechanics, effects represent possible experimental propositions.

Experimental Proposition: A proposition whose truth value can be determined by conducting an experiment.

Greatest vs Maximal: If L is a partially ordered set (poset) and $X \subseteq L$, then an element $b \in X$ is a greatest element of X if $x \leq b$ for all $x \in X$. An element $b \in X$ is a maximal element of X if there exists no element $x \in X$ with $b < x$.

Involution: A mapping $p \to p'$ on a poset L satisfying the following conditions for all $p, q \in L$: (i) $p \leq q \Rightarrow q' \leq p'$, (ii) $p'' = p$.

Involutive Lattice (or Poset): A lattice (or poset) with smallest element $\mathbf{0}$ and largest element $\mathbf{1}$, equipped with an involution.

Join: If L is a partially ordered set (poset) and $p, q \in L$, then the join (or least upper bound) of p and q in L, denoted by $p \vee q$ if it exists, is the unique element of L satisfying the following conditions: (i) $p, q \leq p \vee q$ and (ii) $r \in L$ with $p, q \leq r \Rightarrow p \vee q \leq r$.

Kripkean Model of a Language: A system $\langle I, R_1, \ldots, R_m, o_1, \ldots, o_n, \Pi, v\rangle$ consisting of a set I of possible worlds, a (possibly empty) sequence of world relations $R_1, \ldots, R_m$ and of world operations $o_1, \ldots, o_n$, a family Π of subsets of I (called the propositions), and an interpretation function v that transforms the sentences of the language into propositions, preserving the logical form.

Kripkean Semantics: The basic idea is that interpreting a formal language means associating to any sentence the set of the possible worlds where the sentence holds. This set is called also the proposition associated to the sentence.

Lattice: A partially ordered set (poset) in which every pair of elements p, q has a least upper bound, or join, $p \vee q$ and a greatest lower bound, or meet, $p \wedge q$.

Least vs Minimal: If L is a partially ordered set (poset) and $X \subseteq L$, then an element $a \in X$ is a least element of X if $a \leq x$ for all

$x \in X$. An element $a \in X$ is a minimal element of X if there exists no element $x \in X$ with $x < a$.

Lindenbaum Property: A logic satisfies the Lindenbaum property when any noncontradictory set of sentences T can be extended to a noncontradictory and *complete* set T^* (such that T^* contains, for any sentence of the language, either the sentence or its negation). Abstract quantum logics generally violate the Lindenbaum property.

Logic: According to the tradition of logical methods, a logic can be described as a system $\langle FL, \vdash, \models \rangle$ consisting of a *formal language*, a *proof-theoretic–consequence* relation $\vdash$ (based on a notion of *proof*), and a *semantic-consequence* relation $\models$ (based on a notion of *model* and of *truth*).

MacNeille Completion of a Brouwer–Zadeh Lattice: Let L be a Brouwer–Zadeh lattice (or poset). For $X \subseteq L$, let $X' = \{p \in L | \forall q \in X, p \leq q'\}$, $X^{\sim} = \{p \in L | \forall q \in X, p \leq q^{\sim}\}$, and $P(L) = \{X \subseteq L | X = X''\}$. The structure $\mathcal{P}(L) = \langle P(L), \subseteq, {}', {}^{\sim}, \{\ \}'', L \rangle$ is called the MacNeille completion of L. $\mathcal{P}(L)$ is a complete Brouwer–Zadeh lattice and L is embeddable into $\mathcal{P}(L)$ via the mapping $p \rightarrow \langle p]$, where $\langle p] = \{q \in L | q \leq p\}$.

Meet: If L is a partially ordered set (poset) and p, $q \in L$, then the meet (or greatest lower bound) of p and q, denoted by $p \wedge q$ if it exists, is the unique element of L satisfying the following conditions: (i) $p \wedge q \leq p, q$ and (ii) $r \in L$ with $r \leq p, q \Rightarrow r \leq p \wedge q$.

Minimal Quantum Logic: A logic that is semantically characterized by the class of all models based on orthocomplemented lattices.

Modular Lattice: A lattice L satisfying the modular law: $p \leq r \Rightarrow p \vee (q \wedge r) = (p \vee q) \wedge r$ for all $p,q,r \in L$.

Nonnegative Operator: A self-adjoint operator A on a Hilbert space $\mathcal{H}$ such that $\langle A\psi | \psi \rangle \geq 0$ for all vectors $\psi \in \mathcal{H}$.

Observable or Dynamical Variable: A numerical variable associated with a physical system the value of which can be determined by conducting a test, a measurement, or an experiment on the system.

Orthoalgebra: A mathematical system consisting of a set L with two special elements $\mathbf{0}$, $\mathbf{1}$ and equipped with a relation $\perp$ such that, for each pair $p,q \in L$ with $p \perp q$, an orthogonal sum $p \oplus q \in L$ is defined subject to the following conditions for all $p,q,r \in L$: (i) $p \perp q \Rightarrow q \perp p$ and $p \oplus q = q \oplus p$, (ii) $p \perp q$ and $(p \oplus q) \perp r \Rightarrow q \perp r$, $p \perp (q \oplus r)$ and $p \oplus (q \oplus r) = (p \oplus q) \oplus r$, (iii) $p \in L \Rightarrow$ there is a unique $p' \in L$ such that $p \perp p'$ and $p \oplus p' = \mathbf{1}$, and (iv) $p \perp p \Rightarrow p = \mathbf{0}$.

Orthocomplementation: A mapping $p \rightarrow p'$ on a poset L with smallest element $\mathbf{0}$ and largest element $\mathbf{1}$ satisfying the following conditions for all p, $q \in L$: (i) $p \vee p' = \mathbf{1}$, (ii) $p \wedge p' = \mathbf{0}$, (iii) $p \leq q \Rightarrow q' \leq p'$, and (iv) $p'' = p$.

Orthocomplemented Lattice (or Poset): A lattice (or poset) equipped with an orthocomplementation $p \rightarrow p'$.

Orthodox Quantum Logic: A logic that is semantically characterized by the class of all algebraic models based on orthomodular lattices. Standard quantum logic is a particular model of orthodox quantum logic.

Orthogonal: If L is an orthocomplemented poset and p, $q \in L$, then p is orthogonal to q, in symbols $p \perp q$, if $p \leq q'$.

Orthomodular Lattice: An orthocomplemented lattice L satisfying the orthomodular law: For all $p,q \in L$, $p \leq q \Rightarrow q = p \vee (q \wedge p')$.

Orthomodular Poset: An orthoalgebra L such that, for all $p,q \in L$, $p \perp q \Rightarrow p \oplus q = p \vee q$.

Paraconsistent Quantum Logic: A logic that is semantically characterized by the class of all models based on involutive lattices with smallest element $\mathbf{0}$ and largest element $\mathbf{1}$.

Partially Ordered Set (or Poset): A set L equipped with a relation $\leq$ satisfying the following conditions for all $p,q,r \in L$: (i) $p \leq p$, (ii) $p \leq q$ and $q \leq p \Rightarrow p = q$, (iii) $p \leq q$ and $q \leq r \Rightarrow p \leq r$.

Probability Measure: A function $\omega : L \rightarrow [0,1] \subseteq \mathbb{R}$ on an orthoalgebra L such that $\omega(\mathbf{0}) = 0$, $\omega(\mathbf{1}) = 1$, and, for all $p,q \in L$ with $p \perp q$, $\omega(p \oplus q) = \omega(p) + \omega(q)$.

Projection: An operator P on a Hilbert space that is self-adjoint ($P = P^*$) and idempotent ($P = P^2$).

Pure State: A state ψ is pure if the set $\{\psi\}$ consisting only of that state is superposition closed. In Hilbert-space quantum mechanics, the pure states are precisely the vector states.

Quantum Logic: The study of the formal structure of experimental propositions affiliated with a quantum physical system, or any mathematical model (e.g., an orthoalgebra) representing such a structure.

Regular Involution: An involution $'$ on a poset L that satisfies the regularity condition: For all $p,q \in L$: $p \leq p'$ and $q \leq q' \Rightarrow p \leq q'$. If L is a lattice, then an involution is regular iff it satisfies the Kleene condition: For all $p,q \in L$: $p \wedge p' \leq q \vee q'$.

Soundness: A logic $\langle FL, \vdash, \models \rangle$ is sound when all the proof-theoretic consequences are semantic consequences (if $\alpha \vdash \beta$ then $\alpha \models \beta$).

Spectral Measure: A mapping from real Borel sets into projection operators on a Hilbert space that maps the empty set into $\mathbb{0}$, maps $\mathbb{R}$ into $\mathbb{1}$, and maps the union of a disjoint sequence of real Borel sets into the least upper bound (join) of the corresponding projection operators.

Spectral Theorem: The theorem establishing a one-to-one correspondence between (not necessarily bounded) self-adjoint operators A on a Hilbert space $\mathcal{H}$ and spectral measures $E \rightarrow P_E$ on $\mathcal{H}$ such that, if $P_\lambda = P_{(-\infty,\lambda]}$ for all $\lambda \in \mathbb{R}$, then $A = \int_{-\infty}^{\infty} \lambda dP_\lambda$.

Spectrum: If A is a (not necessarily bounded) self-adjoint operator on a Hilbert space and $E \rightarrow P_E$ is the corresponding spectral measure, then a real number λ belongs to the spectrum of A if $P_{(\lambda-\epsilon,\lambda+\epsilon)} \neq \mathbb{0}$ for all $\epsilon > 0$.

Standard Quantum Logic: The complete orthomodular lattice L of all projection operators on a Hilbert space. For $P, Q \in L$, $P \leq Q$ is defined to mean that $P = PQ$ and the orthocomplement of P is defined by $P' = \mathbb{1} - P$.

State: The state of a physical system encodes all information concerning the results of conducting tests or measuring observables on the system. It is usually assumed that, corresponding to each state ψ of the system, there is a probability measure ω_ψ on the logic L of the system such that $\omega_\psi(p)$ is the probability that the experimental proposition $p \in L$ is true when the system is in the state ψ.

State Space: The set of all possible states of the physical system.

Strong Partial Quantum Logic: A logic that is semantically characterized by the class of all models based on orthomodular posets.

Superselection Rule: A rule that determines the possible states of a physical system. The usual quantum-mechanical superselection rules state that only vector states that commute with a certain set of pairwise orthogonal projections (i.e., projections onto superposition sectors) represent possible states of the systems.

Support: If W is a density operator on a Hilbert space $\mathcal{H}$, then the support of W is defined to be the set $\text{supp}(W)$ of all projection operators P on $\mathcal{H}$ such that $\text{tr}(WP) \neq 0$. More generally, if ω is a probability measure on an orthoalgebra L, then $\text{supp}(\omega) = \{p \in L | \omega(p) \neq 0\}$.

Superposition Closed: A set of states is superposition closed if it contains all of its own superpositions.

Superposition in Hilbert Space: For a Hilbert space $\mathcal{H}$, if (W_α) is a family of vector states determined by the corresponding family (ψ_α) of normalized vectors in $\mathcal{H}$, and if ψ is a normalized linear combination of the vectors in this family, then the vector state W determined by ψ is a (coherent) superposition of the family (W_α). If (W_α) is an arbitrary family of density operators on $\mathcal{H}$ and (t_α) is a corresponding family of nonnegative real numbers such that $\Sigma_\alpha t_\alpha = 1$, then $W = \Sigma_\alpha t_\alpha W_\alpha$ is an (incoherent) superposition (or mixtures) of the family (W_α).

Superposition in an Orthoalgebra: A probability measure ω on an orthoalgebra L is a superposition of a family (ω_α) of probability measures on L if $\text{supp}(\omega) \subseteq \cup_\alpha \text{supp}(\omega_\alpha)$.

Tensor Product of Hilbert Spaces: If $\mathcal{H}$ and $\mathcal{K}$ are Hilbert spaces, then the tensor product $\mathcal{H} \otimes \mathcal{K}$ is a Hilbert space together with a mapping $(x,y) \rightarrow x \otimes y \in \mathcal{H} \otimes \mathcal{K}$ for $x \in \mathcal{H}$, $y \in \mathcal{K}$ that is separately linear in each argument and has the property that if (ψ_i) is an orthonormal basis for $\mathcal{H}$ and (ϕ_j) is an orthonormal basis for $\mathcal{K}$, then $(\psi_i \otimes \phi_j)$ is an orthonormal basis for $\mathcal{H} \otimes \mathcal{K}$.

Trace: The trace of an operator A on a Hilbert space $\mathcal{H}$ is defined by $\text{tr}(A) = \Sigma_{\psi \in B} \langle A\psi | \psi \rangle$, where B is an orthonormal basis for $\mathcal{H}$, provided that the series converges.

Trace Class: An operator A on a Hilbert space $\mathcal{H}$ belongs to the trace class if $\text{tr}(A) = \Sigma_{\psi \in B} \langle A\psi | \psi \rangle$ converges absolutely, where B is an orthonormal basis for $\mathcal{H}$.

Unsharp Quantum Logics: Examples of paraconsistent logics where the noncontradiction principle is generally violated.

Vector State: A probability measure on the standard quantum logic L of a Hilbert space $\mathcal{H}$ determined by a normalized vector

$\psi \in \mathcal{H}$ and assigning to each projection operator $P \in L$ the probability $\langle P\psi|\psi\rangle$.

Weak Partial Quantum Logic: A logic that is semantically characterized by the class of all models based on orthoalgebras.

INTRODUCTION

The following discussion is divided into two parts. In part 1, we consider some general features of quantum mechanics and show how a so-called *measurement problem* is inherent in the quantum description of events. In part 2, we deal more specifically with quantum limitations on measurement introduced by quantum interference effects, and the possibilities this allows for the appearance of new nonclassical phenomena in the behavior of measurement devices.

1. THE INTERPRETATION OF QUANTUM MECHANICS AND THE MEASUREMENT PROBLEM

1.1 The Interpretation of the Quantum State

In classical mechanics, the state of a system fixes the values of all dynamical variables of the system and is in this sense "dispersion free." We can form probability distributions over these dispersion-free states to represent a situation where we have less than perfect knowledge of a system (as in classical statistical mechanics). In quantum mechanics, states specify probabilities for ranges of values of the dynamical variables or "observables" of a system and do not fix their values. Quantum states can be either "pure" or "mixed." A mixed state can be represented (in general, nonuniquely) as a probability distribution or mixture over pure quantum states, but a pure quantum state cannot be decomposed into a mixture of other pure quantum states.

The question arises as to whether the pure quantum states can, in principle, be replaced by more complete states defined in terms of additional "hidden variables" not considered in the current theory—perhaps states that would specify definite values for the observables, instead of probabilities. If this were possible, the pure-state probabilities could be interpreted as representing a

measure of our ignorance as to the precise dynamical state of the system, as in classical statistical mechanics (where we can think of the hidden variables as the positions and momenta that define the dispersion-free classical states of the particles that make up the system).

The question of hidden variables underlying the quantum statistics is sometimes posed as the question of whether a statistical interpretation of the pure quantum state is appropriate—in which the pure state is taken as providing a description of the statistical properties of an ensemble of similarly prepared systems—or whether we are required to interpret the pure state as a complete description of an individual system, so that the pure state represents, in some sense, a "rock-bottom" description of the system. The statistical interpretation has been defended by Ballentine (1970) and is often attributed to Einstein, while the opposing position is associated with Bohr and the "orthodox" or Copenhagen interpretation of the theory.

There is a confusion we should dispel here between two senses of the notion of a "statistical interpretation" of the quantum state. If the quantum theory is understood "instrumentally"—as merely a tool for making predictions of measurement outcomes on systems prepared in accordance with certain operationally defined procedures—then the quantum state indeed has a purely statistical significance: Different states simply represent different ensembles of systems prepared by different operationally defined procedures that yield different distributions of outcomes for subsequent measurements. This instrumental sense of statistical interpretation is neutral with respect to the question of hidden variables underlying the quantum statistics. It is only if we interpret the theory "realistically"—as a proposed structural description of dynamical processes at the microlevel—that the question of hidden variables underlying the quantum statistics arises in any interesting sense. In this realist sense of statistical interpretation, the proposed statistical ensemble to which the quantum state refers is defined by a distribution over definite values of hypothetical hidden variables that are presumed to characterize the precise dynamical state of the system—not a distribution over measurement outcomes.

There is a long history of investigations of the hidden-variable problem. A variety of "no go" theorems have been proposed, beginning with a theorem by von Neumann (1955), and also several hidden-variable theories, notably by Bohm and collaborators (Bohm, 1952; Bohm and Bub, 1966; Bohm and Hiley, 1993). The no go theorems prove the impossibility of hidden variables satisfying various constraints. One such physically motivated constraint is locality. Following a result by Bell (1964), extended in various ways by several authors (e.g., Clauser and Horne, 1974; Garuccio and Selleri, 1980; Garg and Mermin, 1964; Greenberger *et al.*, 1989, 1990) and eventually tested experimentally (Aspect *et al.*, 1982) (see Sec. 2.3.1), it is now widely accepted that any hidden-variable theory capable of reproducing the correlations predicted by quantum mechanics for measurements on certain separated systems cannot be a local theory. Roughly, there must be a mechanism in the hidden-variable theory that allows measurement outcomes of observables of a system S_1 to depend on measurement outcomes of observables of a system S_2, where the events in question can lie outside each other's light cones. (Bohm's 1952 theory incorporates such a mechanism.)

The argument for interpreting the pure quantum state as referring to an individual system and not an ensemble rests on the rejection of the statistical interpretation in the realist sense, i.e., the rejection of hidden variables underlying the quantum statistics. If there are no hidden variables, then the probabilistic description defined by the pure state provides as complete a description as possible of the dynamical state of an individual system. But now a fundamental conceptual problem of measurement arises for this orthodox interpretation of the quantum state.

1.2 The Measurement Problem

Any measurement involves an interaction between the system measured, S, and a second system, M, that functions as a measuring instrument. In an ideal measurement, the interaction must be such as to set up a correlation between the values of the measured observable of S and the values of an indicator or "pointer" observable R of M, so that the final value of R after the interaction has ceased indicates the value of the S observable measured in the interaction. Suppose, for simplicity, that a spin-$\frac{1}{2}$ particle interacts with a measuring instrument that ideally measures the z component of spin, and suppose that S is initially in some eigenstate, $|+\rangle$ or $|-\rangle$, of z-spin. Suppose that the interaction induces a transition from an initial or ready state $|r_0\rangle$ of the instrument M (an eigenstate of the indicator observable R) to a final state $|r_+\rangle$ or $|r_-\rangle$, depending on the initial eigenstate of z-spin. Formally, the state of the composite system $S + M$ undergoes the following (unitary) transformation:

$$|+\rangle|r_0\rangle \rightarrow |+\rangle|r_+\rangle$$

or

$$|-\rangle|r_0\rangle \rightarrow |-\rangle|r_-\rangle.$$

If, now, the initial state of S is a pure state represented by a linear superposition of spin eigenstates, say

$$c_+|+\rangle + c_-|-\rangle,$$

it follows from the linearity of the transformation that the corresponding transformation of the composite state is

$$(c_+|+\rangle + c_-|-\rangle)|r_0\rangle \rightarrow c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle.$$

On the orthodox interpretation of the quantum state, the pure state $c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle$ is a complete description of the dynamical state of the composite system, $S + M$, after the measurement interaction. But after the measurement, we expect that the instrument registers either r_+ or r_-, depending on whether the spin state of the system S is found to be $+$ or $-$, i.e., we expect the final quantum state of the composite system $S + M$ to be *either* $|+\rangle|r_+\rangle$ with probability $|c_+|^2$, *or* $|-\rangle|r_-\rangle$ with probability $|c_-|^2$. In other words, the measurement interaction should result in the stochastic transition from the pure state $(c_+|+\rangle + c_-|-\rangle)|r_0\rangle$ to the mixed state representing a probability distribution over the pure states $|+\rangle|r_+\rangle$ and $|-\rangle|r_-\rangle$ with weights $|c_+|^2$ and $|c_-|^2$, respectively, rather than the deterministic transition from the pure state $(c_+|+\rangle + c_-|-\rangle)|r_0\rangle$ to the pure state $c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle$.

Of course, the pure state $c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle$ describes an ensemble in the instrumental sense: an ensemble over the possible outcomes ($+$ and $-$) of a *further measurement* by a second instrument M' on the composite system $S + M$. But this is not an ensemble over actual values of the relevant observables, z-spin of S and the pointer observable R of the instrument M. These values are indeterminate in the pure state $c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle$, just as z-spin is indeterminate, neither $+$ nor $-$, in the state $c_+|+\rangle + c_-|-\rangle$. And, of course, if the further measurement of $S + M$ by M' is treated as an interaction between M' and $S + M$, the same problem arises.

1.3 Von Neumann's Solution

Von Neumann's solution to this measurement problem—that the theory yields a pure state instead of the expected mixture for the state of the composite system $S + M$ after measurement—was to propose two modes of evolution for quantum systems (von Neumann, 1955, pp. 351, 417 ff). Systems that are not being measured undergo unitary time evolutions described by Schrödinger's time-dependent equation of motion. Measurements involve nonunitary, stochastic evolutions described by a new "projection postulate" introduced by von Neumann. [The term "projection postulate" is due to Margenau (1936), who rejected the postulate.] The projection postulate validates the transition from $c_+|+\rangle + c_-|-\rangle$ to one of the pure states $|+\rangle$ or $|-\rangle$ in a measurement of z-spin, depending on the outcome, r_+ or r_-, of the measurement, or the transition from the pure state $c_+|+\rangle + c_-|-\rangle$ to the mixed state representing a probability distribution over the pure states $|+\rangle$ and $|-\rangle$ with weights $|c_+|^2$ and $|c_-|^2$, respectively. The pure state is said to "collapse" onto one of the eigenstates of z-spin, $|+\rangle$ or $|-\rangle$, in the measurement, with probability $|c_+|^2$ or $|c_-|^2$, respectively. Similarly, a position measurement involves a collapse or "reduction" of the wave packet.

Von Neumann's justification for this duality was that a measurement divides the world into two parts: the observed system and the observer, with the boundary between the two somewhat arbitrary. On his view, we can follow all physical processes in the observed system with arbitrary precision, in principle, but not in the observer. The unitary transitions of quantum mechanics describe events in the observed part of the world, so long as they do not interact with the observing part. When such an interaction occurs, the projection postulate applies.

Von Neumann proved a consistency theorem for the two modes of evolution. Consider the measurement of S by an instrument M, and a further measurement of $S + M$ by M'. We can think of S as the system actually observed, M as the measuring instrument, and M' as the observer, or M as the instrument and M' as a recording device. The boundary between the observed system and the observer can be drawn between S and $M + M'$ or between $S + M$ and M'. In the first case, the projection postulate is applied to the interaction between S and $M + M'$. Prior to the interaction, S evolves unitarily. In the second case, the projection postulate is applied to the interaction between $S + M$ and M'. Prior to the interaction, $S + M$ evolves unitarily. Von Neumann showed that both procedures yield the same probabilities for S observables (S being the only system that belongs to the observed part of the world, however the boundary between the observer and the observed is drawn). We have consistency in the sense that the application of the projection postulate directly to the system S is consistent with its application to the system $S + M$, after a suitable unitary interaction between S and M governed by the equation of motion of the theory.

Now, showing that the postulation of a special mode of evolution for systems undergoing measurement avoids a certain kind of inconsistency with the unitary evolutions of quantum-mechanical interactions does not explain why a fundamental theory of mechanics should incorporate a special postulate applicable only to state transitions on measurement, nor why these transitions should yield mixtures from pure states. Von Neumann's explanation that unitary evolutions can be expected to apply only to the observed part of the world, and that a special process should apply to the "interaction" between the observed part and the observer, is hardly reassuring, if only because classical mechanics requires no such process.

1.4 Schrödinger's Cat

The problem is often dramatized as the problem of Schrödinger's cat (Schrödinger, 1935), where macroscopic properties of a cat become indeterminate in a measurement interaction. Suppose we take the interaction between S and M as some interaction that correlates the states $|+\rangle$ and $|-\rangle$ of a microsystem S with the states $|r_+\rangle = |\text{alive}\rangle$ and $|r_-\rangle = |\text{dead}\rangle$ of a cat (M). We might suppose that the state space of the cat is divided into two parts, representing the quantum state of the live cat and the quantum state of the dead cat. Then $|\text{alive}\rangle$ and $|\text{dead}\rangle$ represent two of these states that become correlated with microsystem states $|+\rangle$ and $|-\rangle$ in the interaction. After the interaction, the cat is alive if the final state of the composite system is $|+\rangle|\text{alive}\rangle$, the cat is dead if the final state of the composite system is $|-\rangle|\text{dead}\rangle$, but the cat is neither alive nor dead if the final state is the linear superposition $(c_+|+\rangle|\text{alive}\rangle + c_-|-\rangle|\text{dead}\rangle)$, which is the final state required by the linear dynamics. Schrödinger regarded this consequence of the theory as unacceptable.

What we expect, on the basis of the orthodox interpretation of the quantum state, is that the final state of the composite system is a mixed state representing a mixture of the pure states $|+\rangle|\text{alive}\rangle$ and $|-\rangle|\text{dead}\rangle$, with weights $|c_+|^2$ and $|c_-|^2$ respectively. But the dynamics of the theory yields a final pure state of the form $(c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle)$. The evolution to the mixed state is nonunitary, stochastic, and entropy increasing, while the evolution to the pure state is, of course, unitary and deterministic (via Schrödinger's time-dependent equation of motion), and does not increase the entropy of the composite system.

1.5 Other Solutions

Proposed solutions to the measurement problem either

1. take the dynamics of the theory seriously and modify the orthodox interpretation of the quantum state, or
2. accept the orthodox interpretation of the quantum state and modify the dynamics, or
3. accept both the dynamics and the ortho-

dox interpretation of the state and attempt to show that, for all practical purposes, the interference terms can be ignored in real measurement interactions.

Type **1** or "no collapse" solutions include Bohm's 1952 hidden variable theory, the "many-worlds" interpretation proposed by Everett (1957), and the variety of modal interpretations related to van Fraassen's "modal" interpretations. The central idea here is that a pure state can be interpreted, without inconsistency, as specifying actual values for certain observables, even when the state is not an eigenstate of these observables. Different versions of this proposal (van Fraassen, 1981; Kochen, 1985; Healey, 1989; Dieks, 1989; Bub, 1992) involve different ways of selecting these observables for a given pure state. The aim is to show that even when the state of the composite system $S + M$ is a pure state of the form $(c_+|+\rangle|r_+\rangle + c_-|-\rangle|r_-\rangle)$, both z-spin and the indicator observable R have definite values.

Type **2** or "collapse" solutions include the theory of Ghirardi *et al.* (1986) and the Bohm–Bub hidden variable theory (Bohm and Bub, 1966). Essentially, the Ghirardi–Rimini–Weber theory involves a modified dynamics for the quantum state that results in the occasional spontaneous localization of individual microsystems—so infrequently that the time evolution of a single particle remains unitary over long time intervals with high probability. For macrosystems, the modified dynamics results in the almost instantaneous transition of superpositions over states separated by macroscopic distances to the corresponding mixtures over these states. So linear superpositions over different position indicator states of a macroscopic measuring instrument are very short-lived and collapse immediately to a single pointer position state, with the appropriate probability. The theory resolves the measurement problem by modifying quantum dynamics in such a way that the behavior of microsystems is essentially unchanged, while the behavior of macroscopic systems, induced by the dynamics of their constituent microsystems, conforms to classical mechanics. The Bohm–Bub theory also introduces a modified equation of motion, with an additional nonunitary term that has a negligible effect on the quantum state, except during certain processes that include measurement processes. The nonunitary term involves hidden variables that determine the outcome of the collapse. Averaging over the hidden variables yields the quantum statistics.

Finally, type **3** or "for all practical purposes" solutions include such approaches as the Daneri–Loinger–Prosperi (1962) quantum ergodic theory of macrosystems, "decoherence" theories (Joos and Zeh, 1985; Zurek, 1993; Paz and Zurek, 1993), and various other attempts to exploit the large number of degrees of freedom of the amplifying recording device or the environment of the system as the source of a dissipative process that effectively yields a mixed state after a measurement.

While none of the proposals for resolving the measurement problem has achieved general acceptance, the detailed investigation of measurement processes in quantum mechanics from a wide variety of perspectives has considerably sharpened the debate on the conceptual foundations of quantum mechanics, and the peculiar nonclassical features of quantum interference effects have been brought out in new and unexpected ways.

We turn now to a discussion of some of these effects in quantum measurements.

2. THE NONINTUITIVE NATURE OF QUANTUM THEORY AND SOME MEASUREMENT CONSEQUENCES

The nonintuitive aspects of the theory can be ascribed primarily to three sources. First is the superposition principle, whereby quantum amplitudes add, rather than probabilities (which are determined by the square of the magnitude of the amplitude). The second is the measurement postulate, which states that a measurement yields only eigenvalues of the operator representing the observable being measured and "forces" the system into an eigenstate of this operator. In other words, the measurement acts as a filter, and forces the system to choose an eigenstate among the various possible outcomes of the experiment. This reduction or collapse of the state is also sometimes known as the "projection postulate," which we have discussed.

The main consequence of superposition is that before a measurement is made, a system may have a component of the amplitude corresponding to each possible outcome of a future measurement, and that all these possibilities may produce interference, which can be seen by varying some system parameter. Different aspects of interference are evident in one-particle and multiparticle systems. Once a measurement is made, the system will be forced into one of those states of the variable being measured, and other states cannot contribute, provided that they are experimentally distinguishable from this state.

The third nonintuitive effect is due to nonlocality, of which there are two main types. In the first, two systems that should intuitively be independent of each other can produce interference that cannot be explained by any local, realistic model, such as in the Einstein–Podolsky–Rosen "paradox." In the second, one particle confined to one of two paths nonetheless seems to be aware of what happens between the two paths, even though it has no amplitude for being there. This type of nonlocality is exemplified by the Aharonov–Bohm effect and the Berry phase, both of which seem to be topological in nature.

There are many aspects of these effects, and we shall be content with a few examples that illustrate the issues involved.

2.1 The Superposition Principle

2.1.1 Wave–Particle Duality The most obvious effect of the superposition principle is what has been called the wave–particle duality. Bohr always emphasized the principle of "complementarity," according to which one can measure either the particle or wave aspects of a quantum system, but not both together. This is a special case of the rule that if two possible paths for a system are distinguishable in principle by the experimental arrangement employed, one cannot see interference between them. This is the "particle" aspect of the system since classically, particles do not interfere. If the paths are indistinguishable, they can interfere. This interference manifests their "wave" aspect.

In the early days of the theory it was thought that this was necessarily an "all or nothing" split; however, it has been shown that in the classic two-slit interference experiment, one can characterize the system as partly wave, partly particle (Wootters and Zurek, 1979). The more particlelike the system is, the less wavelike it will be.

We illustrate some of the properties of particles and waves with a very simple model of a neutron interferometer. (The model is so simple that the particles passing through it can just as well be thought of as photons.) The neutron has shown wavelike behavior over an astonishingly large range of energies, from 10^{-7} up to 10^{9} eV. In the neutron interferometer, its energy is thermal, about 10^{-2} eV, with a de Broglie wavelength of about 10^{-8} cm, so that it undergoes coherent Bragg scattering off perfect crystals. A typical interferometer is a few centimeters long, and the neutron is inside it for about 10^{-5} s, and only about one coherent neutron per second passes through it, so that there are rarely two inside simultaneously. So each particle is clearly interfering only with itself. A simple but more detailed description of the device can be found in Greenberger (1983).

The device (Fig. 1) is called a Mach–Zehnder interferometer. It contains a beam splitter, A, such that there is a 50% chance that a particle will be either transmitted or reflected. (For probability conservation, imagine the reflected beam being retarded by 90°.) After being split, the two diverging beams are refocused by mirrors. There is also a phase shifter F, which delays the phase in one beam by a phase α. The beams converge on a second beam splitter. After the second beam splitter, there are two detectors, and a given particle will land in one of the detectors. The relative number of counts in each of the detectors depends on α, and in

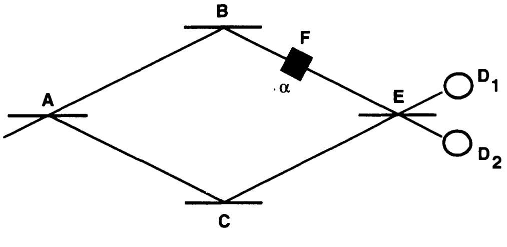

FIG. 1. Model of a neutron interferometer. This simple model shows the most important aspects of particle interferometers. Beam splitters are located at A and E to split and recombine the beams, which are also bent by mirrors at B and C. F is a phase shifter, which retards one beam by phase α. This changes the relative counting rates at the detectors D_1 and D_2.

Fig. 1, the counting rate in counter D_1 will be $\cos^2(\alpha/2)$ and in counter D_2 will be $\sin^2(\alpha/2)$. Thus the interference can be detected by varying α.

2.1.2 The Wheeler "Delayed-Choice" Experiment In the apparatus we have described, if one thinks of the incident neutron as a particle, one would expect it to take one of the two paths through the interferometer. If one thinks of the neutron as a wave, like a light wave, one might think it splits and takes both paths. An especially dramatic "proof" that both these points of view are incorrect is given by Wheeler's "delayed-choice" experiment (Wheeler, 1978), which shows nothing so much as that the results of an experiment depend critically on exactly what experiment is actually performed. For instance, imagine a neutron passing through a system such as that in Fig. 1. There is an amplitude for the neutron to take either path to the second beam splitter, where there will be interference. However, imagine that the second beam splitter at E is removed just before the neutron reaches it. Then there will be no combining of the amplitudes, and no interference. The particle in either beam will head straight toward its detector. So the particle in this case will land in one detector or the other, and the probability for landing in each detector will be 50%, independent of α, proving that it was in one beam or the other, just as one might expect for a classical particle. However, if the beam splitter at E is not removed, one will get interference, depending on α.

From a quantum-mechanical point of view this is a simple experiment, and shows that the result depends on whether the beam splitter at E is present or not. But from a classical point of view, whether the particle is to act as a particle and be completely in one beam, or act as a wave and be somehow partly in both beams, must be determined back at the beam splitter at A. And yet the decision to have the beam splitter at E present or absent need not be made until the neutron has already long since passed through the beam splitter at A, and is in fact just about to reach E. So we see that it is a mistake to think of the neutron as somehow having a "trajectory," as a classical particle would. Actual experiments equivalent to this have been performed with photons (Alley *et al.*, 1984; Hellmuth *et al.*, 1986), where they yield the expected quantum result.

2.1.3 Schrödinger's Cat Revisited The dilemma presented by the delayed-choice experiment is exactly the same as that in the famous example of Schrödinger's cat (Schrödinger, 1935), which we have already discussed as a measurement problem. There, a cat is in a closed cage with a bottle of poison gas. Whether the bottle is to be opened or not depends on the outcome of some atomic decay event. If we have not opened the cage, there is an amplitude for the decay to have happened, which translates to the same amplitude for the cat to be dead. So we have an amplitude for the cat to be either alive or dead, until we look.

There is a perfect analogy between the cat experiment and the delayed-choice experiment we have discussed. In the interferometer, after the particle has passed the first beam splitter, if the second beam splitter is absent the particle has an amplitude to be in one beam or the other, which corresponds to the cat being dead or alive. But as in that case we cannot know which beam it is in until it is detected. This is even more convincing than the cat experiment, because here we can check that a superposition really exists, by inserting the second beam splitter. But in the cat experiment, there is no way to show that a superposition of the two states really exists before we look.

So, the Schrödinger cat experiment actually works for neutrons or photons, but it is probably unlikely to do so for cats! And yet the only difference is their size, or rather their coherence properties. For a cat would transfer momentum to its cage whenever it breathed or twitched, which could be detected from the outside. The same is true for the breaking of the bottle, or even the thermodynamically irreversible escape of the gas from the bottle. So for a truly macroscopic object like a cat in its environment there is no realistic way to perform such an experiment without the information becoming available outside, to a careful observer, or frittered away inside through friction, etc. The real question is at what point does it become impossible to retain coherence in a many-body system. Here, the barriers have been pushed back, and coherence seen on a larger and larger scale (Webb and Washburn, 1988), and the question is still open. Leggett (1984) has made a careful theoretical investigation of the subject.

2.1.4 The Renninger–Dicke Effect A further complication to the notion that the reduction of a wave packet must come from the macroscopic nature of the observation apparatus comes from the possibility of reducing the wave packet by failing to measure it (Renninger, 1960; Dicke, 1981, 1986). If in our interferometer in Fig. 1 we replaced the phase shifter at F by a completely absorbing crystal, we could arrange it that if the neutron passed through beam ABE it would be absorbed by the crystal with 100% certainty. Furthermore, on absorption, the crystal would emit a γ ray, which could be detected with high efficiency. Thus if one failed to detect the γ ray, one would know that the neutron had taken the path ACE. So here the wave function has been reduced by *not* detecting the particle!

But there is a difference between detecting the particle and not detecting it. Once the counter has fired, all coherence has been lost, and so all phase knowledge has been destroyed. However if the counter has not fired, the reduction in the wave packet acts like a pure filter. The possibility that the particle has taken the path ABE has been removed, but the wave function has not been totally reduced. For example, if the neutron were in some definite spin state processing about a magnetic field, then the knowledge of the precession phase would be retained and could be made use of further down the line, in the path ACE. However, in the path ABE, any such knowledge would be destroyed by the detection of the particle.

2.1.5 The "Quantum Eraser" Another complication is revealed by Scully's "quantum-eraser" experiment (Scully *et al.*, 1978, 1991). Here, even after one has seemingly "erased" information in a system by some suitable experimental arrangement, one still has the choice of whether to confirm the information that remains available by making a measurement on the system. If one does not bother to make the measurement, the information one has "lost" is still coherent with that part of the wave function one has retained. Therefore, by further changing the experimental setup, it should be possible to regain the "erased information," whereas had one made the original measurement this would not be possible.

As an example, return to the system in Fig. 1 with a neutron beam passing through it. This time, imagine that the beam is polarized upward, out of the plane of the figure, in the z direction. As the two beams emerge from the first beam splitter at A, there is a polarization device that rotates the angle of polarization of one of the beams, say the one along the path ACE, by 90° so that this beam is now polarized in the plane of the paper, say along the x direction. The two beams are now polarized perpendicularly to each other. Assume that the detector at D_1 is sensitive to polarization. Then if it counts only z-polarized neutrons, there can be no interference, because all the neutrons it counts will have taken the path ABE, since they are polarized along the z axis. Similarly, if the detector at D_1 only counts x-polarized neutrons then there again will be no interference because all the neutrons it counts will have taken the beam ACE.

However, if the detector D_1 is now rotated so that it is in the x-z plane, at 45° from each axis, then it can count particles from both beams, and one is no longer aware of which path any neutron took, and one will have interference between the two beams, which can be seen by varying the angle α. Thus by changing the experimental setup, what appeared to be two incoherent beams are seen to be coherent. One would have had to make a measurement on the intermediate system (i.e., the separate beams) to confirm that they were incoherent. By not doing so, one can yet manipulate the system to make it coherent again. (See Kwiat *et al.*, 1992. They did a two-particle version of this experiment. The effect is much more subtle in that case, since the coherence shows up only in coincident counts between the particles. The individual particles appear to be totally incoherent.) This illustrates Wheeler's dictum "No elementary phenomenon is a phenomenon until it is a registered (observed) phenomenon" (Wheeler and Zurek, 1983, p. 192).

Scully *et al.* (1991) have suggested an even subtler version of this experiment. In one version it involves passing an atomic beam successively through two microwave cavities. In either cavity, the beam can be made to interact with the cavity such that the atom can absorb or emit a photon. If it is initially in an excited state, and after it passes the second cavity it is in its ground state, it must have given up its photon and decayed in one of the two cavities. Since it could have decayed in either cavity, the amplitudes for these two possibilities might be expected to interfere with each other.

But in fact, one can trap the photon in the cavity. Thus, by looking to see which cavity has the photon, one can tell which of the two cases occurred. Because one can distinguish these two cases experimentally, the two amplitudes cannot interfere. But if one were to couple the cavities weakly so as to mix the photon coherently between them, then one can no longer tell in which one it was created. This would then make it possible for the amplitudes to interfere again, even though by now the atom is a long way from the cavities.

Here, indistinguishability is used to recreate coherence in the system long after the two subsystems have ceased to interact. (To see interference, one would have to count coincidences between the particle beam and the cavity photons.)

2.1.6 The Quantum Zeno Paradox

The wave function of a system evolves continuously according to the Schrödinger equation. However, when a measurement is made, there is a discontinuous reduction of the wave packet. The concepts of a continuous evolution and a measurement must be rigorously distinguished. In fact, if one could make a continuous set of measurements on a system, the system would never evolve. That is the essence of the quantum Zeno Paradox (Misra and Sudershan, 1977; Peres, 1980).

We can illustrate the point simply. Consider a two-state system, $|1\rangle,|2\rangle$, that starts in state $|1\rangle$ at $t = 0$. The energy expectation values in the two states are E_1 and E_2 and there is a cross term ϵ in the Hamiltonian connecting the two states. Then the amplitude for the system to be in state $|2\rangle$ at short times t is $(i\epsilon t/\hbar)|2\rangle$, and the probability of finding the system there is $(\epsilon t/\hbar)^2$. This is quadratic in t, and so in the limit of very short times the transition rate (probability/time) for making a transition from $|1\rangle \rightarrow |2\rangle$ goes to zero.

A pretty example consists of a photon moving in the z direction passing through an optically active medium that rotates the polarization in the x-y plane. The medium is of length L, which rotates the polarization by $\pi/2$. A photon whose polarization is initially pointing along the x direction will emerge from the medium polarized along the y direction. The polarization will vary as the photon passes through the medium as $\mathbf{p} = \mathbf{i} \times \cos(\pi z/2L) + \mathbf{j} \sin(\pi z/2L)$. A polarization analyzer pointed along the x direction and placed at the far end of the medium will have probability $P = 0$ of detecting the photon.

Now imagine that the medium is split in half at $z = L/2$, and an analyzer pointed along the x axis is placed at $z = L/2$, while the one at L is retained. Then the photon will be pointed at $\pi/4$ to the x axis as it hits the first analyzer, so it has a probability $P_1 = \frac{1}{2}$ of passing through the analyzer and it will also have probability $P_2 = \frac{1}{2}$ of passing through the second analyzer. The probability that it passes through both analyzers is then $P = P_1P_2 = \frac{1}{4}$.

If there were three equally spaced analyzers, the probability for passing the first analyzer would be $P_1 = \cos^2(\pi/6) = \frac{3}{4}$, and the probability of passing all three analyzers would be $P = P_1P_2P_3 = [\cos^2(\pi/6)]^3 = 27/64 = 0.42$. For n equally spaced analyzers,

$$P = \left(\cos^2 \frac{\pi}{2n}\right)^n \underset{n \to \infty}{\longrightarrow} \left(1 - \frac{\pi^2}{4n}\right) \rightarrow 1.$$

Here, each analyzer makes a measurement of the polarization, "reducing" the wave function to the state of x polarization. In the limit of many closely spaced measurements, the transition is completely suppressed. While illustrative, of course this experiment can be interpreted classically, in terms of electric fields, rather than photons.

However a beautiful conceptually similar experiment was performed by Itano *et al.* (1990) using an atom in one of two states, 1 and 2. A resonant pulse was used to cause transitions between the states, playing the role of the medium rotating the polarization in our example. The measurement was made by using a third atomic level, which could make transitions to level 1 but not level 2. A pulse of radiation of frequency ω_{13} would cause transitions between these two levels

(1–3) and could be monitored. This could tell how many atoms were in level 1 at the time of the pulse (so that it "reduced the atomic state" to level 1, which could make a transition). The other atoms were reduced to level 2 (the Dicke–Renninger effect). By making the pulses close together, transitions between levels 1 and 2 were inhibited. While the experiment beautifully illustrates the laws of quantum theory, there is some controversy as to whether one is seeing a pure "Zeno paradox" effect. The problem is whether one has indeed destroyed all coherence by the measurement. (Our example above is subject to the same objection.)

Rather than using oscillating states, one can also see an inhibition effect with decaying states. Even exponentially decaying states go through a short period with a quadratic component, although experimentally this is almost impossible to see.

2.2 Nonlocality in One-Particle Systems

2.2.1 The Aharonov–Bohm Effect and the Berry Phase The Aharonov–Bohm effect (Aharonov and Bohm, 1959) (A–B) is a striking demonstration of the nonlocality of quantum theory, and it produces a result that is classically very puzzling, but very necessary in quantum theory. According to this effect, a beam of particles that is split and later recombined will experience a phase shift if a magnetic field is present anywhere in the area between the split beams, even though neither beam itself is exposed to a magnetic field. We discuss the effect only to the extent needed to show why it is crucial to quantum theory.

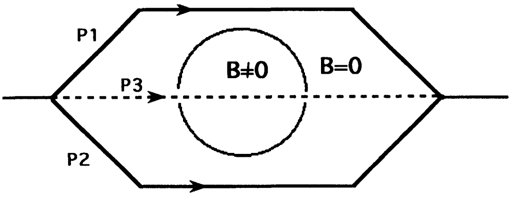

FIG. 2. The Aharonov–Bohm effect. This is a nonlocal effect that can be demonstrated by passing a beam of electrons around both sides of a solenoid (whose axis is perpendicular to the plane of the paper), enclosing a magnetic field. Even though neither beam P_1 nor P_2 ever passes through the field, there will be a phase shift between them when they recombine, proportional to the enclosed flux. One may develop an intuitive feeling for why this phase shift is necessary by considering a third beam, P_3, that does penetrate the field.

In the A–B effect, in its simplest form, an electron beam is split and the two halves go, via paths P_1 and P_2, around opposite sides of an infinite solenoid whose axis is perpendicular to the plane of the beam (Fig. 2). In both classical and quantum theory, an external magnetic field is added to the Hamiltonian by changing p to $p - eA/c$, where p is the canonical momentum and A is the vector potential. This can be accommodated in the quantum case by changing the state function ψ to $\psi\exp[(ie/\hbar c)\int_P \mathbf{A}\cdot d\mathbf{l}]$, where the line integral is along P, the classical path of the particle. When the two parts of the electron wave function recombine, the total accumulated phase difference between them is

$$\frac{ie}{\hbar c}\int_{P_1}\mathbf{A}\cdot d\mathbf{l} - \frac{ie}{\hbar c}\int_{P_2}\mathbf{A}\cdot d\mathbf{l} = \frac{ie}{\hbar c}\oint \mathbf{A}\cdot d\mathbf{l}$$
$$= \frac{ie}{\hbar c}\int \mathbf{B}\cdot d\mathbf{S} = \frac{ie}{\hbar c}\Phi,$$

where Φ is the flux enclosed by the solenoid between the two paths. So there will be a phase shift between the two beams, proportional to this flux, which is a gauge-invariant physical effect. What is so surprising about the effect is that it occurs even though neither electron beam has ever been in the magnetic field, or ever feels any force.

One can get a good insight into why such an effect must occur within quantum theory. The path integral is necessary there because it is what produces the phase changes necessary to bend the beam in a real magnetic field. But it is necessary even when the beam avoids the real fields. Consider a third beam, the dotted beam in Fig. 2, which passes along path P_3, right through the solenoid, through two tiny holes, which produce a negligible flux leak. Now consider the same experiment as above, only with one beam traveling along path P_1, and the other along path P_3. In this case, the phase difference will be only half as great, $(ie/2\hbar c)\Phi$, with path P_3 leading path P_1, but it is easy to understand. The beam inside the solenoid feels a force, bending it sideways (to the right for a + charge), away from the beam P_1, and this real deflection causes the phase shift.

Now consider yet another version of the same experiment, this time with the beam split into the paths P_3 and P_2. In this case also, the phase shift will be only half as great, with beam P_2 leading P_3, and again it is easy to understand. For the beam P_3 is again subject to a force, and again it is to the right, toward the beam P_2, and beam P_2 leads P_3, the force effects being asymmetrical in the two cases. But now we see that the phase of P_2 leads that of P_1 by the required amount (since P_2 leads P_3, and P_3 leads P_1), even though neither beam ever feels any force.

The reason for this phase shift is that the Hamiltonian contains the effects of every possible experiment that can be performed on the system. One can choose to create a wave packet that goes to the left or right of the field, but the results had better be consistent with those for a wave packet that passes through the field. Thus the integrated effects of all phase changes are contained in the solutions to the Hamiltonian, because the entire problem is nonlocal, quantum mechanically. The locality is an illusion created by choosing to perform an experiment with a local wave packet. In contradistinction to this, classically a particle is affected only by actual fields locally present along its trajectory.

So quantum mechanically the electromagnetic fields themselves do not contain enough information to determine all the physics inherent in the system, and the vector potential contains too much (since one can make gauge transformations). Actually, it is the phase factor $\exp[(ie/\hbar c)\int_P \mathbf{A}\cdot d\mathbf{l}]$ that contains exactly the information needed (Wu and Yang, 1975). This information is nonlocal, being path dependent. In practice, one always observes the difference between two paths, which is gauge invariant. The nonlocality is especially apparent in that the path enclosing the flux cannot be shrunk down to a point.

Experimentally, the A–B effect has been repeatedly confirmed, but most spectacularly with tiny, superconducting circuits (Tonomura, 1987), and the effect occurs in many forms throughout quantum physics (Olariu and Popescu, 1985; Peshkin and Tonomura, 1989; Anandan, 1990).

For example, there is also an electrostatic version (Allman *et al.*, 1993) of this experiment, where the vector potential is replaced by the scalar one, $(ie/\hbar)\int_P V\,dt$. This experiment has been done on neutrons, using the scalar potential $\boldsymbol{\mu}\cdot\mathbf{B}$, rather than the electrostatic one. (The interpretation is somewhat controversial, because although there is no force on the neutrons, there is a torque.) Finally, a symmetrical analog of the A–B effect exists, called the Aharonov–Casher effect, where the solenoid is replaced by a line electric charge, and the phase shift is produced on a split beam of particles with a magnetic moment. Again, this effect has been confirmed with neutrons (Cimmino *et al.*, 1989).

A closely related nonlocal effect is the Berry phase (Berry, 1984; see TOPOLOGICAL PHASE EFFECTS). If one imagines a particle moving in an external field—for example, a neutron in a magnetic field—then if one very slowly changes the field, the particle will slowly accommodate to the change. Classically, one can find some adiabatic invariant of the motion, which will not change as the field changes. Quantum mechanically, the particle will stay in an eigenstate corresponding to the slowly changing field (in the neutron example above, if the neutron were in the $m_z = +\frac{1}{2}$ state of the original field, it will stay in that state of the adiabatically varied field).

Finally, if the field ultimately returns to its original value, the particle will be back in its original state, and so the wave function cannot differ from the original one by more than a phase factor. Part of this phase factor has a deep topological significance in the space defined by the parameters of the external field (B_x, B_y, B_z in the case of the neutron). If one plots the changing direction of $\mathbf{B}$ in this space, $\mathbf{B}$ will return to its initial value, and thus form a cone, with the vertex at the origin. The solid angle swept out by this cone is proportional to the phase factor multiplying the neutron wave function, and is called the Berry phase. The Aharonov–Bohm effect can be considered as a special case of the Berry phase. Many experiments have been carried out to confirm the effect in many contexts, and its significance has been carried over to nonadiabatic changes (Shapere and Wilczek, 1989).

2.3 Multiparticle Superpositions

2.3.1 The Einstein–Rosen–Podolsky "Paradox" The extension of the superposition theorem to multiparticle systems brings both new phenomena into play and new insights. There is a type of nonlocality present in multiparticle systems that is different from the above for one-particle systems, and which is very troubling, from a classical point of view. This is the kind of nonlocality first discussed by Einstein, Rosen, and Podolsky (EPR) (Einstein *et al.*, 1935), and it occurs when the wave function of the two particles cannot be factored into the product of two one-particle wave functions. If the particles are independent of each other, they can be represented as such a product, $\psi(1,2) = \varphi_1(1)\varphi_2(2)$, and if the wave functions do not overlap, the particles will act independently of each other, in the sense that any forces, etc., applied to one of them will have no effect on the other.

However, when the total wave function cannot be factored (which will then be true in any representation), the particles can have long-range effects on each other. Schrödinger (1935) called such nonfactorable states "entangled states." The classic example, introduced into this discussion by Bohm (1951), is the singlet state of two spin-$\frac{1}{2}$ systems, $\psi(1,2) = 2^{-1/2}(|+\rangle_1|-\rangle_2 - |-\rangle_1|+\rangle_2)$, where $+,-$ refer to the spin states of the particles, and 1,2 refer to the particles.

EPR introduced the idea of an "element of reality," which refers to a property that objectively belongs to a particle independently of how an experimenter manipulates the system. For one-particle systems it is essentially impossible to introduce such a notion quantum mechanically, but EPR noticed that for an entangled state, such as the Bohm state above, one can do this. For example, if the particles are far apart, but one measures the spin of particle 1 to be "up" $(+)$, then one immediately knows that the spin of particle 2 must be "down" $(-)$, and vice versa. Thus one has determined the spin of particle 2, without in any way interfering with the particle, and so to EPR this seemed like an objective determination of a property already there, as the experiment could not have affected this property. The states of these two particles are said to be "perfectly correlated," because one can make a prediction of the state of the second particle with 100% accuracy by measuring the first one. Such perfect correlations are necessary for elements of reality to exist. They also introduced the idea of "locality," which they defined as an experimental situation wherein nothing done to one of the particles could have any effect on the other—for example, if they are far away from each other. Thus according to EPR, one has proven that in the Bohm state, each of the particles must have a definite spin even if we are unable to know what it is before making a measurement.

Of course quantum theory totally denies this explanation and says that the spin of particle 2 could not have been determined until one measured particle 1. The two points of view, that of EPR and that of quantum theory, are totally at odds, but it was long taken for granted that there was no experimentally detectable difference between the two viewpoints. But amazingly, Bell (1964) was able to show that by using the EPR concepts of reality, locality, and completeness (they called a theory complete if all elements of reality were accounted for by the theory), in the Bohm situation of a particle of spin 0 decaying into two particles, each of spin $\frac{1}{2}$, in an entangled state, one could actually show that the EPR point of view had detectable consequences, which violated the results of quantum theory. He proved that in an experiment that measures the correlation between the spin states of the spin-$\frac{1}{2}$ particles, it follows from the EPR assumptions that there is an upper limit to the possible correlations one can obtain between the spins. It is easy to show that a quantum-mechanical calculation of this correlation violates this limit, which has been taken to mean that by making such a measurement one could experimentally rule out the possibility of obtaining a classically realistic and local interpretation of quantum theory.

Bell's theorem set off a major experimental effort to see whether this upper limit of correlations was violated in nature. First, one had to make some plausible assumptions in order to accommodate the fact that experimental detectors are not 100% efficient (Clauser *et al.*, 1969), and then one could apply the results to actual experiments. Many such experiments have been made, and they overwhelmingly endorse the quantum-mechanical picture of the problem. The first such experiment was by Clauser and Freedman (1972), and the most famous by Aspect *et al.* (1982). (For a critical discussion of the early experiments, see Clauser and Shimony, 1978, and for a later, skeptical interpretation, see Selleri, 1990.)

Recently, a new technique, parametric down-conversion (the original experiments were Shih and Alley, 1986, and Ghosh and Mandel, 1987), has been developed, wherein one can create a definite quantum-mechanical two-photon state, which is distinct from a laser-created coherent state that may have two particles present on average. One can show that in such states one can see two-particle correlations, but one can no longer detect one-particle correlations. This means that one can measure coincidences between the two photons and see correlations in the joint counting rate, but for either photon separately one cannot detect any interference between two different paths taken by the photon (as in a Young's two-slit diffraction experiment). This is a general feature of two-particle entangled states.

With this technique one can perform clean tests of Bell's theorem (Rarity and Tapster, 1990) by measuring coincidences between the two photons, and these experiments have also come down clearly on the side of the quantum description. An interesting development here is that one may create a "Franson state" (Franson, 1989), which is an entangled state of two particles created at different times, so that one has two particles entangled in time, as well as in space (Kwiat *et al.*, 1993).

One may also produce states where one photon has been emitted by one of two different atoms, but one does not know which atom produced it (Grangier *et al.*, 1985), and these states can interfere. One can also create two-photon states that are produced by two different lasers, where one does not know in which laser each photon is produced, and the amplitudes for both cases can interfere (Pfleegor and Mandel, 1967; see also Yurke and Stoler, 1992).

All these cases discussed verify the basic consequence of superposition, which is that interference can be seen only in situations where the interfering states are not experimentally distinguishable. Here, "distinguishable" means that the experimental arrangement cannot in principle distinguish between the two states, and *not* that the experimenter does not bother to distinguish between them, even though his apparatus is capable of doing so.

For example, in our neutron interferometer (Fig. 1), one cannot experimentally determine which path the neutron takes through the interferometer, and so the two possibilities can interfere. However, if one placed some device close to one of the beams, then one could determine whether a neutron was in that beam by detecting, say, its magnetic field as it passed. But then the interaction between the neutron and the device would necessarily destroy any phase knowledge carried by the neutron wave function, and there could be no interference between the two paths through the interferometer when the paths met again. Even if one did not bother to read the output of the disturbing device, there would be no interference. The mere possibility of determining the path in that experimental arrangement is enough to destroy the interference pattern.

Dirac, in his textbook (1958), said that a photon could only interfere with itself. That was true when it was written since different photons were generally produced incoherently. But today, with correlated multiphoton systems available, the statement is ambiguous or not relevant in many experiments.

2.3.2 The Extension to Three-Particle States The Bell theorem depends on a statistical sample of spin correlations between particles, measured at arbitrary angles. It says nothing about those special cases in which a perfect correlation exists between the spins, which is the condition for EPR elements of reality to exist (in the Bohm case, when the spin component of particle 1 is measured at 0° or 180° to particle 2). In systems of three or more particles there exists a much more stringent restriction on EPR states than that given by Bell's theorem. There one can show (the GHZ theorem) (Greenberger *et al.*, 1989, 1990, 1993; Mermin, 1990, 1993) that even when perfect correlations are present, one cannot construct a realistic, local model to explain these perfect correlations. Thus in this case the EPR assumption that there exist elements of reality is directly inconsistent with their other assumptions. It leads to predictions that are the exact opposite of those of quantum theory for every individual set of test particles, rather than the statistical predictions of Bell's theorem. (Unfortunately, no such three-particle perfectly correlated state has been constructed experimentally yet.)

3. CONCLUSIONS

Thus we see that quantum theory yields many predictions that are quite disturbing to the classically trained mind. However, most of these predictions have been tested and shown to be true experimentally. Thus the problem is not whether quantum theory works or not. It is abundantly clear that it works, and to great precision. Rather, the problem has always been in interpreting the theory. No one has come up with an interpretation of the theory that is in all ways satisfying, and that explains the process of a quantum measurement in a fully acceptable way, in spite of the experimental successes of the theory.

GLOSSARY

Aharonov–Bohm Effect: An interference effect found in regions where the electromagnetic potentials are nonzero, but the fields themselves are zero. An intrinsically nonlocal quantum effect.

Bell's Theorem: Bell showed that for a two-particle system in an entangled state, the realistic, local assumptions of Einstein, Podolsky, and Rosen lead to an upper limit on the maximum correlation possible between the particles. Quantum theory predictions exceed this upper limit, and the quantum predictions have been confirmed by experiment, ruling out a large class of such alternative theories.

Berry Phase: A system carried through a series of adiabatic changes, by varying a set of parameters, will return to its initial state when the parameters have their initial values. But the state will be multiplied by a phase factor that depends on the entire history of variation of the parameters, and is thus nonlocal.

Collapse (Reduction) of Wave Packet: The process described by the projection postulate.

Complementarity: Bohr's word for the fact that in a given experimental arrangement, one can measure either the particle aspects or the wave aspects of an electron, or other "particle," but not both simultaneously.

Delayed-Choice Experiment: An experiment in which a beam is split by a beam splitter, and a system parameter is varied down-field of the split. The beams are later recombined and interfere. Such experiments are extremely troublesome for local, realistic theories that place a particle in one beam or the other.

Density Operator: A Hilbert-space operator representing a quantum state (technically: a positive, Hermitian operator with unit trace).

Eigenstate: A state of a quantum system for which the observables in some commuting (hence, simultaneously measurable) set have definite values, in the orthodox interpretation of the theory.

Einstein–Podolsky–Rosen (EPR) Paradox: If two particles are in an entangled state, then a measurement of one can affect the state of the other instantaneously, even if they are separated. It is not a true paradox, merely highly nonintuitive behavior, if one accepts the realistic and local assumptions of EPR. But the quantum predictions are fully verified by experiment.

Entangled State: A state of a two-particle or multiparticle system that cannot be factored into a product of one-particle states. Such states can have intrinsically nonlocal correlations.

GHZ Theorem: An extension of Bell's theorem to three or more particles (by Greenberger, Horne, and Zeilinger). It shows that the Einstein–Rosen–Podolsky assumptions lead to predictions that are exactly the opposite of those of quantum theory.

Hidden Variables: Hypothetical variables, in addition to the quantum state, that specify definite values for the observables of a quantum system.

Hilbert Space: The state space of quantum mechanics, a linear vector space over the complex numbers.

Instrumental Interpretation: An interpretation of a theory as purely predictive and not necessarily descriptive of the structure of reality at any level.

Many-Worlds Interpretation: An interpretation of quantum mechanics according to which the different components of a pure quantum state, expressed as a linear superposition of eigenstates of some observable, all—in some sense—represent actualities.

Mixture: A quantum state that can be decomposed (in general, nonuniquely) into a probability distribution over pure quantum states.

Modal Interpretation: An interpretation of quantum mechanics incorporating some principle for attributing actual values to observables of a quantum system, as opposed to possible values with probabilities, when the state is not an eigenstate of these observables.

Projection Operator: An operator that projects (maps) vectors in Hilbert space onto a subspace.

Projection Postulate: The postulate describing the transition of a pure quantum state to an appropriate mixture associated with the different possible outcomes of a measurement.

Pure State: A quantum state that cannot be further decomposed into other quantum states (but is still not dispersion free for all observables).

Quantum Eraser: Normally, interactions of the system with its environment produce random phases and incoherence. However, if one does not make a measurement on the system the phases may only appear random, but still maintain coherence. If one is sufficiently clever, one may recombine the parts of the system and undo the interactions, making the coherence manifest again.

Quantum Zeno Paradox: Zeno said motion was impossible because before reaching a goal, one had to get halfway there. Before that, one had to get halfway to the midpoint, etc. The quantum version is that a continuously observed system cannot make transitions. (Normal systems are not continuously observed.)

Spin-$\frac{1}{2}$ Particle: A quantum system whose spin observables have two possible values.

Superposition Principle: The principle that quantum amplitudes add, which includes both their magnitudes and phases, and which can cause interference effects. Interfering amplitudes are responsible for most of the nonintuitive aspects of quantum theory. Probabilities depend only on the square of the magnitudes.

Unitary Evolution: The dynamical evolution of a quantum state in Hilbert space, described by Schrödinger's time-dependent equation of motion (as opposed to the evolution described by the projection postulate).

Watched-Pot Effect: Another name for the quantum Zeno paradox, after the proverb, "A watched pot never boils."

1.1
Introduction

Quantum mechanics (QM), also called *wave mechanics*, is the modern theory of matter, of atoms, molecules, solids, and of the interaction of electromagnetic fields with matter. It supersedes the classical mechanics embodied in Newton's laws and contains them as a limiting case (the so-called classical limit of QM). Its development was stimulated in the early part of the twentieth century by the failure of classical mechanics and classical electrodynamics to explain important discoveries, such as the photoelectric effect, the spectral density of blackbody radiation, and the electromagnetic absorption and emission spectra of atoms. QM has proven to be an extremely successful theory, tested and confirmed to an outstanding degree of accuracy for physical systems ranging in size from subatomic particles to macroscopic samples of matter, such as superconductors and superfluids. Despite its undisputed success in the description of physical phenomena, QM has continued to raise many conceptual and philosophical questions, in part due to its counterintuitive character, defying common-sense interpretation.

One distinguishes between nonrelativistic quantum mechanics and relativistic quantum mechanics depending on the characteristic speed v of the constituents of the system under study. The domain of nonrelativistic QM is characterized by speeds that are small compared with the speed of light:

$$v \ll c \tag{1}$$

where $c = 3 \times 10^8\,\mathrm{m\,s^{-1}}$ is the speed of light. For v approaching c, relativistic extensions are necessary. They are referred to as *relativistic wave equations*. Because of the possibility of production and destruction of particles by conversion of relativistic energy E into mass M (or vice versa) according to the relation (*see* chapter 2)

$$E = Mc^2 \tag{2}$$

a satisfactory formulation of relativistic quantum mechanics can only be developed within the framework of quantum field theory. This chapter focuses primarily on nonrelativistic quantum mechanics, its formalism and techniques as well as applications to atomic, molecular, optical, and condensed-matter physics. A brief discussion of extensions to relativistic wave equations is given at the end of the chapter.

The new "quantum world" will be contrasted with the old world of classical mechanics. The bridge between the latter and the former is provided by the

semiclassical mechanics, whose rigorous formulation and application have only recently been developed.

1.2
Particle-Wave Duality and the Uncertainty Principle

The starting point of modern quantum mechanics is the hypothesis of the particle-wave duality put forward by de Broglie (1924): the motion of each particle of mass M is associated with a wave (''matter wave'') of wavelength

$$\lambda = \frac{h}{p} \tag{3a}$$

where $h = 6.63 \times 10^{-34}$ J s is Planck's constant, discovered by M. Planck in 1900 in his investigation of blackbody radiation, and $p = Mv$ is the classical momentum of the particle. Similarly, the frequency ν of the wave is associated with the mechanical energy of the particle through the expression

$$\nu = \frac{E}{h} \tag{3b}$$

These relations, ascribing wave properties to particles, are the logical complements to postulates put forward 20 years earlier by Einstein (1905), assigning the characteristics of particles (''photons,'' particles of zero rest mass) to electromagnetic radiation. In fact, Einstein employed, in his explanation of the ''photoelectric effect,'' the expression $E = h\nu$ (Eq. 3b) to find the energy E of each photon associated with electromagnetic radiation of frequency ν. Photons can eject electrons from the atoms of a material provided that the energy exceeds the binding energy of the electron. This particle-wave duality of QM unifies the description of distinct entities of classical physics: mechanics and electromagnetism. Particles, the fundamental constituents of matter, possess, in addition to mechanical properties such as momentum and angular momentum, wave character. Conversely, electromagnetic radiation, successfully described by Maxwell's theory of electromagnetic waves, takes on, under appropriate conditions, the property of quasiparticles, the photons, carrying mechanical energy and momentum. The particle and wave character are complementary to each other. An object behaves either like a particle or like a wave.

The hypothesis of particle-wave duality has been experimentally verified in remarkable detail. Interference of matter waves due to the indistinguishability of paths was demonstrated first for electrons (Davisson and Germer, 1927), later for neutrons, and, most recently, for neutral atoms. The particle-wave duality of electromagnetic radiation and its complementarity have been explored through modern versions of Young's double-slit experiment using state-of-the-art laser technology and fast switches. Hellmuth and colleagues (1987) succeeded, for example, in switching from particle to wave character and vice versa even after the photon has passed through the slit (in the experiment, a beam splitter) by activating a switch (a Pockels cell) in one of the two optical paths of the interferometer. By use of the switch, the interference patterns are made to appear or disappear, as expected for a wavelike or particlelike behavior of the photon, respectively. This ''delayed choice'' experiment not only demonstrates the particle-wave duality for photons but also elucidates important conceptual aspects of the nonlocality of quantum mechanics. The decision as to whether the photon will behave like a particle or a wave need not be made at the double slit itself but can be spatially separated and temporarily postponed.

The consequences of the wave-particle duality for the description of physical phenomena are far reaching and multifaceted. One immediate consequence that represents the most radical departure from classical physics is the *uncertainty principle* (Heisenberg, 1927). One deeply rooted notion of classical physics is that all dynamical observables can be measured, at least in principle, with arbitrary accuracy. Uncertainties in the measurement are a matter of experimental imperfection that, in principle, can be overcome. The wave nature of particles in QM imposes, however, fundamental limitations on the simultaneous accuracy of measurements of dynamical variables that cannot be overcome, no matter how much the measurement process can be improved. This uncertainty principle is an immediate consequence of the wave behavior of matter. Consider a wave of the form

$$\psi(x) = Ae^{i(kx-\omega t)} \tag{4}$$

traveling along the x coordinate (Figure 1.1). Equation (4) is called a *plane wave* because the wave fronts form planes perpendicular to the direction of propagation. The physical interpretation of the amplitude A was provided by Born (1926) in terms of a probability density

$$P(x) = |\psi(x)|^2 = |A|^2 \tag{5}$$

for finding the particle at the coordinate x. The matter wave (Eq. 4) is further characterized by the wave number $k = 2\pi/\lambda = p/\hbar$ and the angular frequency $\omega = 2\pi\nu = E/\hbar$. The "rationalized" Planck's constant $\hbar = h/2\pi = 1.05 \times 10^{-34}$ J s is frequently used in QM.

The uncertainty principle is inherent to all wave phenomena. Piano tuners have exploited it for centuries. They sound a vibrating tuning fork of standard frequency in unison with a piano note of the same nominal frequency and listen to a beat tone between the struck tune and the tuning fork. For a fork frequency of $\nu = 440$ Hz and a string frequency of $\nu' = 441$ Hz, one beat tone will be heard per second ($\delta\nu = \nu' - \nu = 1$ Hz). The goal of the tuner is to reduce the number of beats as much as possible. To achieve an accuracy of $\delta\nu = 0.01$ Hz, the tuner has to wait for at least about $\delta t = 100$ s (in fact, only a fraction of this time since the frequency mismatch can be detected prior to completion of one beat period) to be sure no beat had

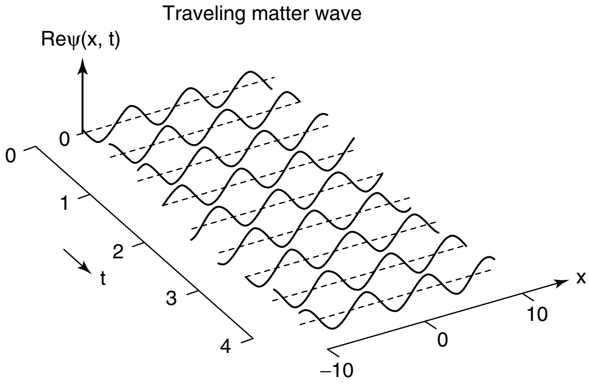

Fig. 1.1 Matter wave traveling along the x direction; the figure shows the real part of $\psi(x)$, Eq. (4) (after Brandt and Dahmen, 1989).

occurred. Piano tuning therefore relies on the frequency–time uncertainty

$$\Delta\nu\,\Delta t \gtrsim 1 \tag{6}$$

Measurement of the frequency with infinite accuracy ($\Delta\nu \to 0$) requires an infinite time period of measurement ($\Delta t \to \infty$), or equivalently, it is impossible within any finite period of time to determine the frequency of the string exactly since time and frequency are *complementary variables*. Similarly, the variables characterizing the matter wave (Eq. 4) are complementary:

$$\begin{aligned}\Delta k\,\Delta x &\geq 1\\ \Delta\omega\,\Delta t &\geq 1\end{aligned} \tag{7}$$

These relations, well known from classical theory of waves and vibrations, have unexpected and profound consequences when combined with the de Broglie hypothesis (Eq. 3) for quantum objects:

$$\begin{aligned}\Delta p\,\Delta x &\geq \hbar\\ \Delta E\,\Delta t &\geq \hbar\end{aligned} \tag{8}$$

The momentum and the position of a particle, its energy and the time, and more generally, any other pair of complementary variables, such as angular momentum and angle, are no longer simultaneously measurable with infinite precision. The challenge to the classical laws of physics becomes obvious when one contemplates the fact that Newton's equation of motion uses the simultaneous knowledge of the position and of the change of momentum.

Since $\hbar$ is extremely small, the uncertainty principle went unnoticed during the era of classical physics for hundreds of years and is of little consequence for everyday life. Its far-reaching implications become obvious only in the microscopic world of atoms, molecules, electrons, nuclei, and elementary particles. More generally, whenever the size of an object or mean distance between constituents becomes comparable to the de Broglie wavelength λ, the wave nature of matter comes into play. The size of λ also provides the key for quantum effects in macroscopic systems such as superfluids, superconductors, and solids.

1.3
Schrödinger Equation

The Schrödinger equation for matter waves ψ describes the dynamics of quantum particles. In the realm of quantum physics, it plays a role of similar importance to that which Newton's equation of motion does for classical particles. As with Newton's laws, the Schrödinger equation cannot be rigorously derived from some underlying, more fundamental principles. Its form can be made plausible, however, by combining the Hamiltonian function of classical mechanics,

$$H = T + V = E \tag{9}$$

which equals the mechanical energy, with the de Broglie hypothesis of matter waves (Eq. 4). The potential energy is denoted by V and the kinetic energy by $T = p^2/2M$. Formally multiplying the wave function $\psi(x,t)$ by Eq. (9) yields

$$H\psi(x,t) = \frac{p^2}{2M}\psi(x,t) + V\psi(x,t) \tag{10}$$

In order to connect the de Broglie relations for energy and momentum appearing in the arguments of the plane wave (Eq. 4) with the energy and momentum in the

Hamiltonian function, H and p in Eq. (10) must be taken as differential operators,

$$\begin{aligned} H &\longleftrightarrow i\hbar\frac{\partial}{\partial t} \\ p &\longleftrightarrow \frac{\hbar}{i}\frac{\partial}{\partial x} \end{aligned} \tag{11}$$

This substitution into Eq. (10) leads to the time-dependent Schrödinger equation

$$\begin{aligned} i\hbar\frac{\partial}{\partial t}\psi(x,t) &= H\psi(x,t) \\ &= \left(-\frac{\hbar^2}{2M}\frac{\partial^2}{\partial x^2} + V(x)\right) \\ &\quad\times \psi(x,t) \end{aligned} \tag{12}$$

which describes the time evolution of the matter wave. For physical systems that are not explicitly time dependent, i.e., that have time-independent potentials $V(x)$, the energy is conserved and $i\hbar\ \partial/\partial t$ can be replaced by E, giving the time-independent Schrödinger equation

$$E\psi(x) = \left(-\frac{\hbar^2}{2M}\frac{\partial^2}{\partial x^2} + V(x)\right)\psi(x) \tag{13}$$

If no interaction potential is present $(V(x) = 0)$, Eq. (12) is referred to as the *free-particle Schrödinger equation*. The plane waves of Eq. (4) are solutions of the free-particle Schrödinger equation with eigenenergies $E = (\hbar k)^2/2M$.

The *correspondence principle*, first formulated by Bohr, provides a guide to quantizing a mechanical system. It states that in the limit of large quantum numbers or small de Broglie wavelength, the quantum-mechanical result should be the same, or nearly the same, as the classical result. One consequence of this postulate is that the quantum-mechanical Hamiltonian operator in the Schrödinger equation (Eq. 12) should be derived from its corresponding classical analog, the classical Hamiltonian function (Eq. 9), through the replacement of the classical observable by the operator equivalents (Eq. 11).

The replacement of dynamical variables by differential operators leads to the *noncommutativity* of pairs of conjugate variables in QM, for example,

$$[x, p_x] \equiv x\frac{\hbar}{i}\frac{\partial}{\partial x} - \frac{\hbar}{i}\frac{\partial}{\partial x}x = i\hbar \tag{14}$$

with similar relations for other complementary pairs, such as Cartesian coordinates of position and momentum $(y,\ p_y)$, (z, p_z), or energy and time. It is the noncommutativity that provides the basis for a formal proof of the uncertainty principle, Eq. (8). The Schrödinger equation (Eqs. 12 and 13) is a linear, homogeneous, and (in general) partial differential equation. One consequence of this fact is that matter waves ψ satisfy the *superposition principle*. If ψ_1 and ψ_2 are two acceptable solutions of the Schrödinger equation, called *states*, a linear combination

$$\psi = c_1\psi_1 + c_2\psi_2 \tag{15}$$

is an acceptable solution, as well. The physical implication of Eq. (15) is that the quantum particle can be in a ''coherent superposition of states'' or ''coherent state,'' a fact that leads to many strange features of QM, such as destructive and constructive interference, the collapse of the wave function, and the revival of wave packets.

A solution of a linear, homogeneous differential equation is determined only up to an overall amplitude factor, which is arbitrary. The probability interpretation of the matter wave (Eq. 5), however, removes this arbitrariness. The probability for finding the particle somewhere is unity,

$$\int dx P(x) = \int dx |\psi(x)|^2 = 1 \tag{16}$$

Equation (16) and its generalization to three dimensions are referred to as the *normalization condition* on the wave function and eliminate the arbitrariness of the modulus of the wave function. A wave function that can be normalized according to Eq. (16) is called *square integrable*. The only arbitrariness remaining is the overall "phase factor" of the wave function, $e^{i\phi}$, i.e., a complex number of modulus 1.

1.4
Boundary Conditions and Quantization

In order to constitute a physically acceptable solution of the Schrödinger equation, i.e., to represent a state, ψ must satisfy appropriate boundary conditions. While their detailed forms depend on the coordinates and symmetry of the problem at hand, their choice is always dictated by the requirement that the wave function be normalizable and unique and that physical observables take on only real values (more precisely, real expectation values) despite the fact that the wave function itself can be complex. Take, as an example, the Schrödinger equation for a rotator with a moment of inertia I, constrained to rotate about the z axis. The classical Hamiltonian function $H = L_z^2/2I$, with L_z the z component of the angular momentum,

$$L_z = xp_y - yp_x = \frac{\hbar}{i}\frac{\partial}{\partial\phi} \tag{17}$$

gives rise, according to the correspondence principle, to the following time-independent Schrödinger equation:

$$-\frac{\hbar^2}{2I}\frac{\partial}{\partial\phi^2}\psi(\phi) = E\psi(\phi) \tag{18}$$

where ϕ is the angle of rotation about the z axis. Among all solutions of the form

$$\psi(\phi) = Ae^{i(m\phi+\phi_0)} \tag{19}$$

only those satisfying the periodic boundary conditions

$$\psi(\phi + 2\pi) = \psi(\phi) \tag{20}$$

are admissible in order to yield a uniquely defined single-valued function $\psi(\phi)$. (The implicit assumption is that the rotator is spinless, as discussed below.) The magnetic quantum number m therefore takes only integer values $m = -\infty, \dots, -1, 0, 1, \dots \infty$. Accordingly, the z component of the angular momentum

$$L_z\psi(\phi) = m\hbar\psi(\phi) \tag{21}$$

takes on only discrete values of multiples of the rationalized Planck's constant $\hbar$. The real number on the right-hand side that results from the operation of a differential operator on the wave function is called the *eigenvalue* of the operator. The wave functions satisfying equations that are of the form of Eqs (18) or (21) are called *eigenfunctions*. The eigenvalues and eigenfunctions contain all relevant information about the physical system; in particular, the eigenvalues represent the measurable quantities of the systems.

The amplitude of the eigenfunction follows from the normalization condition

$$\int_0^{2\pi} d\phi |\psi(\phi)|^2 = 1 \tag{22}$$

as $A = (2\pi)^{-1/2}$. The eigenvalues of E in Eq. (18) are $E_m = \hbar^2 m^2/2I$. Just like for a vibrating string, it is the imposition of boundary conditions (in this case, periodic boundary conditions) that leads to "quantization," that is, the selection of an infinite but discrete set of modes of matter waves, the eigenstates of matter, each of which is characterized by certain quantum numbers.

Different eigenstates may have the same energy eigenvalues. One speaks then of *degeneracy*. In the present case, eigenstates with positive and negative quantum numbers $\pm m$ of L_z are degenerate since the Hamiltonian depends only on the square of L_z. Degeneracies reflect the underlying symmetries of the Hamiltonian physical system. Reflection of coordinates at the x–z plane, ($y \rightarrow -y$, $p_y \rightarrow -p_y$ and therefore $L_z \rightarrow -L_z$) is a symmetry operation, i.e., it leaves the Hamiltonian invariant. In more general cases, the underlying symmetry may be dynamical rather than geometric in origin.

1.5
Angular Momentum in Quantum Mechanics

The quantization of the projection of the angular momentum, L_z, is called *directional quantization*. The Hamiltonian function for the interaction of an atom having a magnetic moment $\boldsymbol{\mu} = \gamma \mathbf{L}$ with an external magnetic field $\mathbf{B}$ reads

$$H = -\boldsymbol{\mu} \cdot \mathbf{B} = -\gamma \mathbf{L} \cdot \mathbf{B} \tag{23}$$

The proportionality constant γ between the magnetic moment and the angular momentum is called the *gyromagnetic ratio*. According to the correspondence principle, the Schrödinger equation for the magnetic moment in a field with field lines oriented along the z axis becomes

$$-\gamma B L_z \psi(\phi) = E_m \psi(\phi) \tag{24}$$

The eigenenergies

$$E_m = -\gamma B \hbar m \tag{25}$$

are quantized and depend linearly on the magnetic quantum number. Depending on the sign of γ, states with positive m for $\gamma > 0$, or negative m for $\gamma < 0$, correspond to states of lower energy and are preferentially occupied when the atomic magnetic moment is in thermal equilibrium. This leads to an alignment of the magnetic moments of the atoms along one particular direction and to paramagnetism of matter when its constituents carry a net magnetic moment.

The force an atom experiences as it passes through an inhomogeneous magnetic field depends on the gradient of the magnetic field, ∇B. Because of the directional quantization of the angular momentum, a beam of particles passing through an inhomogeneous magnetic field will be deflected into a set of discrete directions determined by the quantum number m. A deflection pattern consisting of a few spots rather than a continuous distribution of a beam of silver atoms was observed by Stern and Gerlach (1921, 1922) and provided the first direct evidence of directional quantization.

In addition to the projection of the angular momentum along one particular axis, for example, the z axis, the total angular momentum $\mathbf{L}$ plays an important role in QM. Here, one encounters a conceptual difficulty, the noncommutativity of different angular momentum components.

Application of Eq. (14) leads to

$$\begin{aligned}&\left[L_x, L_y\right] = i\hbar L_z, \quad \left[L_y, L_z\right] = i\hbar L_x\\&\left[L_z, L_x\right] = i\hbar L_y\end{aligned}\tag{26}$$

As noncommutativity is the formal expression of the uncertainty principle, the implication of Eq. (26) is that different components of the angular momentum cannot be simultaneously determined with arbitrary accuracy. The maximum number of independent quantities formed by components of the angular momentum that have simultaneously ''sharply'' defined eigenvalues is two. Specifically,

$$[L^2, L_z] = 0\tag{27}$$

with $L^2 = L_x^2 + L_y^2 + L_z^2$ being the square of the total angular momentum. Therefore, one projection of the angular momentum vector (conventionally, one chooses the z projection) and the L^2 operator can have simultaneously well-defined eigenvalues, unaffected by the uncertainty principle. The differential operator of L^2 in spherical coordinates gives rise to the following eigenvalue equation:

$$\begin{aligned}L^2 Y(\theta, \phi) &= -\hbar^2 \left[\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\phi^2}\right] Y(\theta, \phi)\\&= \hbar^2 l(l+1) Y(\theta, \phi)\end{aligned}\tag{28}$$

The solutions of Eq. (28), $Y_l^m(\theta, \psi)$, are called *spherical harmonics*. The superscript denotes the magnetic quantum number of the z component, as above, while the quantum number $l = 0, 1, \dots \infty$ is called the *angular momentum quantum number*. Since $|L_z| \leq |L|$, we have the restriction $|m| \leq l$, that is, for given angular momentum quantum number l, the z component varies between $-l$ and l: $m = -l, \dots, -1, 0, 1, \dots l$. The total number of quantized projections of L_z is $2l+1$. The eigenvalue of the L^2 operator is, however, $\hbar^2 l(l+1)$ and not $\hbar^2 l^2$. The latter can be understood in terms of the uncertainty principle and can be illustrated with the help of a vector model (Figure 1.2). Because of the uncertainty principle, the projections L_y and L_x do not take a well-defined value and cannot be made to be exactly zero, when L_z possesses a well-defined quantum number. Therefore, the z projection $m\hbar$ will always be smaller than the magnitude of $L = \hbar\sqrt{l(l+1)}$ in order to accommodate the nonzero fluctuations in the remaining components.

The spherical harmonics are given in terms of associated Legendre functions $P_l^m(\cos\theta)$ by

$$\begin{aligned}Y_l^m(\theta, \phi) = (-1)^m \left[\frac{(2l+1)}{4\pi}\;\frac{(l-m)!}{(l+m)!}\right]^{1/2}\\ \times P_l^m(\cos\theta) e^{im\phi}\end{aligned}\tag{29}$$

The eigenfunctions of L_z (Eq. 19) can be recognized as one factor in the expression for Y_l^m. The probability densities $|Y_l^m|^2$ of the first few eigenfunctions are represented by the polar plots in Figure 1.3.

In addition to the orbital angular momentum operator **L**, which is the quantum-mechanical counterpart to the classical angular momentum, another type of angular momentum, the spin angular momentum, plays an important role for which, however, no classical analog exists. The spin is referred to as an *internal degree of freedom*. The Stern–Gerlach experiment discussed above provided the major clue for the existence of the electron spin (Goudsmit and Uhlenbeck, 1925). The orbital angular momentum quantization allows only for an odd number of discrete values of L_z ($2l+1 = 1,\ 3,\ 5, \dots$) and therefore an odd number of spots in

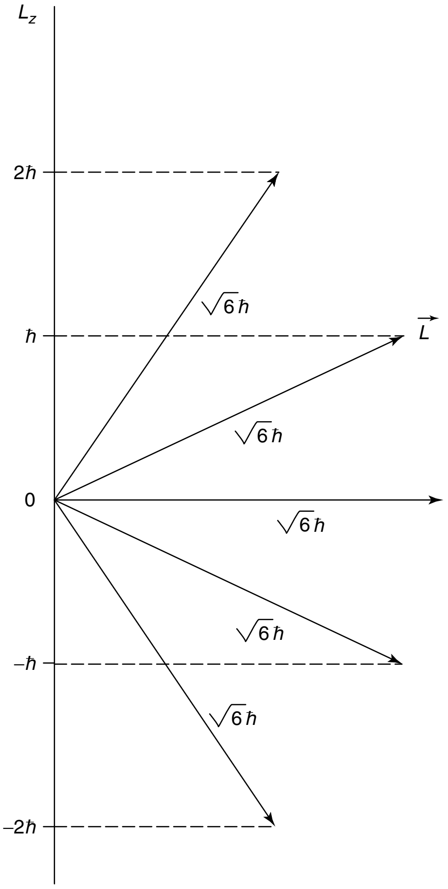

Fig. 1.2 Vector model of angular momentum **L** for quantum number $l = 2$ and $|\mathbf{L}| = \sqrt{6}\,\hbar$.

the deflection pattern. Stern and Gerlach observed, however, two discrete directions of deflection (see schematic illustration in Figure 1.14). The spin hypothesis solved this mystery. The outermost electron of a silver atom has a total orbital angular momentum of zero but has a spin angular momentum of $s = \frac{1}{2}$. The number of different projections of the spin is therefore $2s + 1 = 2$ in accordance with the number of components into which the beam was magnetically split. Within nonrelativistic quantum mechanics, the spin must be introduced as an additional degree of freedom on empirical grounds. A conceptually satisfactory description is provided by relativistic quantum mechanics (see Section 1.11). The identification of the spin as an angular momentum rests on the validity of the commutation rules (Eq. 26),

$$\left[S_x, S_y\right] = i\hbar S_z, \quad \left[S_y, S_z\right] = i\hbar S_x, \\ \left[S_z, S_x\right] = i\hbar S_y \qquad (30)$$

identical to those of the orbital angular momentum. Any set of the components of a vector operator satisfying Eq. (26) has a spectrum of eigenvalues (quantum numbers) of an angular momentum with quantum numbers $j = 0, \frac{1}{2}, 1, \ldots$ and $m = -j, -j + 1 \ldots, +j$. The quantum number j is an integer in systems with an even

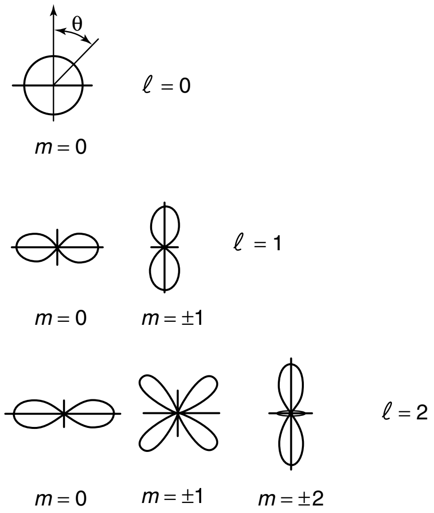

Fig. 1.3 Polar plots of the probability distributions $|Y_l^m(\theta, \phi)|^2$ of angular momentum eigenfunctions.

number of spin $\frac{1}{2}$ particles (including zero) and half-integer in systems with an odd number of spin $\frac{1}{2}$ particles. The Hamiltonian for the interaction of an electron spin with an external magnetic field is given in direct analogy to Eq. (23) by

$$H = -\gamma g \mathbf{S} \cdot \mathbf{B} \tag{31}$$

The only difference is the "anomalous" gyromagnetic ratio represented by the factor g. An approximate value of g can be deduced from the relativistic wave equation (Dirac's equation) for the electron (see Section 1.11).

1.6
Formalism of Quantum Mechanics

The quantum-mechanical description outlined in the previous section with the help of specific examples can be expanded to a general formalism of quantum mechanics. The starting point is the identification of wave functions with vectors in an infinite-dimensional vector space, the Hilbert space,

$$\psi \longrightarrow |\psi\rangle \tag{32}$$

with the vectors represented by a "ket." The ket notation was first introduced by Dirac (1930). The coherent superposition illustrated by Eq. (15) can be recognized as vector addition in Hilbert space. Physical observables such as the Hamiltonian or the angular momentum can be represented by linear and Hermitian operators. Linearity of an operator B means

$$B(c_1|\psi_1\rangle + c_2|\psi_2\rangle) = c_1 B|\psi_1\rangle + c_2 B|\psi_2\rangle \tag{33}$$

for all complex numbers c_1, c_2 and all vectors $|\psi_1\rangle, |\psi_2\rangle$. Hermitian operators are defined as those for which

$$B^\dagger = B \tag{34}$$

that is, the operator is equal to its Hermitian adjoint. The Hermiticity assures that the eigenvalue equation

$$B|\psi\rangle = \lambda|\psi\rangle \tag{35}$$

possesses real eigenvalues λ, which can be identified with measurable quantities. The time-independent Schrödinger equation, Eq. (13), is of the form in Eq. (35) with B being the Hamiltonian operator H and λ being the eigenenergy E. The result of a measurement of a physical observable yields an eigenvalue λ of the corresponding operator, B.

The noncommutativity of operators (Eq. 14) corresponds to the well-known noncommutativity of matrices in linear algebra. The overlap of wave functions can be identified with the scalar product in Hilbert space:

$$\langle\phi|\psi\rangle \equiv \int d^3r\ \phi^*(\mathbf{r})\psi(\mathbf{r}) \tag{36}$$

The adjoint of a vector in Hilbert space $\langle\psi|$ is called a *bra* and the scalar product a *bracket* (Dirac, 1930). The normalization requirement imposed on the wave function can be expressed in terms of the scalar product as $\langle\psi \mid \psi\rangle = 1$. The requirement of normalizability (Eq. 22) implies that the Hilbert space is spanned by square-integrable functions. Since eigenstates of Hermitian operators belonging to different eigenvalues are orthogonal to each other, each physical dynamical variable possesses a complete orthonormal set of eigenstates:

$$\langle\psi_i|\psi_j\rangle = \delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases} \tag{37}$$

The operator B is a diagonal matrix in a basis consisting of its eigenstates, the "eigenbasis" $|\psi_i\rangle$ with $i = 1, \ldots, \infty$. In its eigenbasis, the operator B possesses the following "spectral representation":

$$B = \sum_i \lambda_i|\psi_i\rangle\langle\psi_i| \tag{38}$$

containing only its eigenstates $\{\psi_i\}$ and its eigenvalues λ_i. Two operators possess the same eigenbasis when they commute with each other. Physical observables whose operators commute with each other are called *compatible observables*. A state of a physical system is therefore specified to the maximum extent possible, consistent with the uncertainty principle, by one common eigenstate of a maximum set of compatible observables. For example, the set $\{L^2, L_z\}$ is the maximum set of compatible observables for the angular momentum with the common eigenstate $|lm\rangle$.

The probability amplitude for finding the system in a particular state $|\psi_1\rangle$ is given by the projection of the state vector onto this state, i.e., by the scalar product $\langle\psi_1 \mid \psi\rangle$. The corresponding probability is

$$P(\psi_1) = |\langle\psi_1|\psi\rangle|^2 \tag{39}$$

Formally, Eq. (39) can be viewed as the expectation value of the projection operator $\overline{P} = |\psi_1\rangle\langle\psi_1|$ in the state $|\psi\rangle$. The process of a measurement is therefore associated with a projection in Hilbert space. This projection is sometimes referred to as the *collapse of the wave function*. The process of measurement thus influences the quantum system to be measured.

The state of a physical system is often not completely specified by a "pure" state described by a single Dirac ket $|\psi\rangle$ or a coherent superposition of kets $\sim c_1 \mid \psi_1\rangle + c_2 \mid \psi_2\rangle$. The limited information available may only allow us to specify a statistical mixture of states. Such a mixture is described by the statistical operator or density operator

$$\rho = \sum_i P_i|\psi_i\rangle\langle\psi_i| \tag{40}$$

with P_i denoting the probability for the system to be found in a particular state $|\psi_i\rangle$. The result of the measurement of an observable B is then given by the statistical expectation value

$$\langle B\rangle = \mathrm{Tr}(\rho B) = \sum_i \langle\psi_i|B|\psi_i\rangle P_i \tag{41}$$

i.e., by the diagonal elements of the operator B, each weighted with the probability to find the system in the corresponding state. The preferred set of states, $|\psi_i\rangle$, for which the density matrix is "diagonal," that is, of the form in Eq. (40), is sometimes referred to as the *set of pointer states.*

In light of the expression for the probability as a projection, Eq. (39), we can rewrite Eq. (5) as

$$P(\mathbf{r}) = |\psi(\mathbf{r})|^2 = |\langle\mathbf{r}|\psi\rangle|^2 \tag{42}$$

where $|\mathbf{r}\rangle$ is formally treated as a vector ("ket") in Hilbert space. This definition leads to the difficulty that $|\mathbf{r}\rangle$ cannot be defined as a square-integrable function. Nevertheless, it can be consistently incorporated into the formalism by employing the concept of generalized functions ("distributions"; see Lighthill, 1958; Schwartz, 1965). One defines a scalar product through

$$\begin{aligned}\langle\mathbf{r}|\mathbf{r}'\rangle &= \delta(\mathbf{r}-\mathbf{r}')\\ &= \delta(x-x')\delta(y-y')\delta(z-z')\end{aligned} \tag{43}$$

where the right-hand side is called *Dirac's δ function*. The δ function is zero almost everywhere:

$$\delta(x) = \begin{cases} 0, & x \neq 0 \\ \infty, & x = 0 \end{cases} \tag{44}$$

with the strength of the singularity such that the area underneath the peak is

$$\int dx\,\delta(x) = 1 \tag{45}$$

While the δ function is not an ordinary (Riemann integrable) function, it can be approximated as a limit of Riemann integrable functions, for example,

$$\lim_{\varepsilon\longrightarrow 0}\frac{1}{\pi}\frac{\varepsilon}{x^2+\varepsilon^2} = \delta(x) \tag{46}$$

Equation (46) satisfies Eq. (45) provided one evaluates the integral first and takes the limit $\varepsilon \to 0$ afterward. As the order of the operations of integration and taking the limit is not interchangeable, Eq. (46) is said to converge "weakly" toward a δ function in the limit $\varepsilon \to 0$. δ functions play an important role in the quantum theory of scattering.

The time evolution of the Hilbert-space vectors is given by Schrödinger's equation written in Dirac's ket notation:

$$i\hbar\frac{\partial}{\partial t}|\psi\rangle = H|\psi\rangle \tag{47}$$

For systems with a classical analog, the Hamiltonian operator is given, according to the correspondence principle, by the classical Hamiltonian function $H(\mathbf{r}, \mathbf{p})$ upon treating the canonical variables $(\mathbf{r}, \mathbf{p})$ as noncommuting operators (see Eq. 14). There are, however, additional dynamical variables in quantum mechanics, such as spin, for which no classical counterparts exist.

A vector in Hilbert space can be expanded in terms of any basis (a "representation"),

$$|\psi\rangle = \sum_i c_i|\phi_i\rangle = \sum_i \langle\phi_i|\psi\rangle|\phi_i\rangle \tag{48}$$

where $c_i = \langle\phi_i \mid \psi\rangle$ are the expansion coefficients of the ket $|\psi\rangle$ in the basis

$\{|\phi_i\rangle\}$. Switching from one representation to another $|\psi\rangle \to |\psi'\rangle = U|\psi\rangle$ amounts to a unitary transformation, U, since the norm of a state vector must be conserved,

$$\begin{aligned}\langle\psi'|\psi'\rangle &= \langle\psi|U^\dagger U|\psi\rangle \\ &= \langle\psi|\psi\rangle\end{aligned} \tag{49}$$

or $U^\dagger U = 1$. Transformations among representations play an important role in QM. While the maximum number of compatible observables is determined by commutation rules, the choice of observables that are taken to be diagonal or to have "good" quantum numbers depends on the specific problem under consideration. Unitary transformations provide the tool to switch from a basis within which one set of observables is diagonal to another. The transformation law for state vectors $|\psi'\rangle = U|\psi\rangle$ implies the transformation law for operators

$$A' = UAU^\dagger \tag{50}$$

The latter follows from the invariance of the expectation value $\langle\psi'|A'|\psi'\rangle = \langle\psi|U^\dagger A' U|\psi\rangle$ under unitary transformations.

Classical Hamiltonian functions as well as quantum-mechanical Hamiltonian operators possess discrete symmetries. For example, the Hamiltonian function of the harmonic oscillator,

$$H(x,p) = \frac{p^2}{2M} + \tfrac{1}{2}M\omega^2x^2 \tag{51}$$

is invariant under reflection of all spatial coordinates ($x \to -x$, $p \to -p$) since H depends only on the square of each canonical variable. In classical mechanics, this symmetry is of little consequence since the solution of Newton's equation of motion depends on the initial conditions $x(t = t_0)$, $p(t = t_0)$, which are not subject to any symmetry constraint. They may "break" the symmetry and usually do so. In quantum mechanics, however, the parity of a state vector becomes a dynamical observable.

We can define a parity operator $\hat{p}$ through

$$\hat{p}H(x,p)\hat{p}^\dagger = H(-x,-p) \tag{52}$$

Since $\hat{p}^2$ is the unit operator (two successive reflections restore the original function), we have $\hat{p} = \hat{p}^\dagger = \hat{p}^{-1}$. Eigenfunctions of $\hat{p}$, $\psi(x) = \langle x|\psi\rangle$, can now be characterized by their parity:

$$\langle x|\hat{p}|\psi\rangle = \langle -x|\psi\rangle = \pm\langle x|\psi\rangle \tag{53}$$

The ± sign in Eq. (53) is referred to as *indicating positive* or *negative parity*. A wave function cannot always be assigned a well-defined parity quantum number ±1. However, when $\hat{p}$ commutes with H,

$$\hat{p}H(x,p)\hat{p} = H(x,p) \tag{54}$$

there exists a common eigenbasis in which both the Hamiltonian operator and the parity operator are diagonal and, consequently, ψ is an eigenstate of $\hat{p}$ with a well-defined parity. A similar argument can be developed for symmetry with respect to the time-reversal operator T: $t \to -t$, $\mathbf{p} \to -\mathbf{p}$, $\mathbf{r} \to \mathbf{r}$.

An additional discrete symmetry, which is of fundamental importance for the quantum mechanics of identical particles, is the permutation symmetry. Consider a wave function describing the state of two identical particles $\psi(\mathbf{r}_1, \mathbf{r}_2)$. The permutation operator $\hat{p}_{12}$ exchanges the two particles in the wave function:

$$\hat{p}_{12}\psi(\mathbf{r}_1,\mathbf{r}_2) = \psi(\mathbf{r}_2,\mathbf{r}_1) \tag{55}$$

The spin-statistics postulate of quantum mechanics makes a general statement concerning the permutation symmetry. A many-body system consisting of identical particles of integer spin ("bosons") possesses wave functions that are even under all interchanges of two particles, whereas the wave function is odd for half-integer spin particles ("fermions"). The eigenvalue of $\hat{p}_{ij}$, the operator of permutation for any two particles of an N-body system, is $+1$ for bosons and -1 for fermions. Wave functions are totally symmetric under particle exchange for bosons and totally antisymmetric for fermions. An immediate consequence is that two fermions cannot be in identically the same state for which all quantum numbers agree (the so-called Pauli exclusion principle) since the antisymmetric wave function would vanish identically.

1.7
Solution of the Schrödinger Equation

1.7.1
Methods for Solving the Time-Dependent Schrödinger Equation

1.7.1.1 Time-Independent Hamiltonian
If the Hamilton operator is not explicitly time dependent, i.e., the total energy is conserved, the time-dependent Schrödinger equation can be reduced to the time-independent Schrödinger equation. Equation (47) can be formally solved by

$$|\psi(t)\rangle = U(t,t_0)|\psi(t_0)\rangle \tag{56}$$

where $U(t, t_0)$ is called the *time-evolution operator*, a unitary transformation describing the translation of the system in time. Substitution of Eq. (56) into Eq. (47) shows that

$$U(t,t_0) = \exp\left[\frac{-iH(t-t_0)}{\hbar}\right] \tag{57}$$

where the exponential function of the operator H is defined through its power-series expansion

$$\begin{aligned} U(t,t_0) = 1 - i\frac{t-t_0}{\hbar}H \\ -\frac{1}{2}\left(\frac{t-t_0}{\hbar}\right)^2 H\cdot H + \cdots \end{aligned} \tag{58}$$

If one is able to solve the time-independent Schrödinger equation

$$H|\psi_n\rangle = E_n|\psi_n\rangle \tag{59}$$

where n labels the eigenstate, one can calculate the time evolution of the eigenstate:

$$\begin{aligned} U(t,t_0)|\psi_n\rangle &= e^{-iH(t-t_0)/\hbar}|\psi_n\rangle \\ &= e^{-iE_n(t-t_0)/\hbar}|\psi_n\rangle \end{aligned} \tag{60}$$

using the definition in Eq. (58). The phase factor in Eq. (60) is called the *dynamical phase*. The explicit solution for an arbitrary state can then be found by expanding $|\psi(t_0)\rangle$ in terms of eigenstates of the Hamilton operator:

$$\begin{aligned} |\psi(t_0)\rangle &= \sum_n |\psi_n\rangle\langle\psi_n|\psi(t_0)\rangle \\ |\psi(t)\rangle &= U(t,t_0)|\psi(t_0)\rangle \\ &= \sum_n e^{-iE_n(t-t_0)/\hbar}|\psi_n\rangle \\ &\quad\times\langle\psi_n|\psi(t_0)\rangle \end{aligned} \tag{61}$$

Hence, for time-independent systems, the solution of the energy eigenvalue problem (Eq. 59) is sufficient to determine the time evolution for any initial state.

1.7.1.2 Time-Dependent Hamiltonian

For a time-dependent Hamiltonian $H(t)$, the solution of the time-evolution operator U in terms of the exponential function Eq. (57) must be redefined in order to take into account that the Hamiltonian operator at different instances of time may not commute, $[H(t), H(t')] \neq 0$. We have

$$\begin{aligned} U(t, t_0) &= 1 - \frac{i}{\hbar}\int_{t_0}^{t} dt' H(t') \\ &\quad -\frac{1}{\hbar^2}\int_{t_0}^{t} dt' H(t') \\ &\quad \times \int_{t_0}^{t'} dt'' H(t'') \cdots \\ &= T \exp\left(-\frac{i}{\hbar}\int_{t_0}^{t} H(t')dt'\right) \end{aligned} \tag{62}$$

Equation (62) is called the *time-ordered exponential function* and T is called the *time-ordering operator*. In two limiting cases, the evolution operator for time-dependent Hamiltonian systems can be easily calculated by reducing the problem to the time-independent Hamiltonian. One is the adiabatic limit. If the temporal changes in $H(t)$ are very slow compared with the changes in the dynamical phases of Eq. (60) for all t, the U matrix is diagonal in the slowly changing eigenbasis of $H(t)$ at each instant t,

$$|\psi_n(t)\rangle = e^{i\gamma_n(t)} \exp\left[-\frac{i}{\hbar}\int_{t_0}^{t} dt' E_n(t')\right] |\phi_{n,t}\rangle \tag{63}$$

The dynamical phase factor is determined by $E_n(t')$, the energy eigenvalue of the stationary Schrödinger equation for the Hamiltonian operator $H(t')$ at time t'. In Eq. (63), the state $|\psi_n(t)\rangle$ denotes the evolved state and the state $|\phi_{n,t}\rangle$ represents the stationary eigenstate for the Hamiltonian $H = H(t)$ at the time t, where the time plays the role of a parameter.

The additional phase $\gamma_n(t)$ is called *Berry's phase* (Berry, 1984) or the *geometric phase*, since it records the information on the excursion of the Hamiltonian $H(t')$ in parameter space in the case of adiabatic evolution. The role of $\gamma_n(t)$ is to relate the phases of the adiabatic wave function $|\psi_n(t)\rangle$ at different points in time. Insertion of Eq. (63) into Schrödinger's equation yields the equation that defines the real phase function $\gamma_n(t)$,

$$\dot{\gamma}_n(t) - i\left\langle \phi_{n,t} \middle| \frac{d}{dt}\phi_{n,t} \right\rangle = 0 \tag{64}$$

The analogy to the parallel transport of vectors on a sphere (Figure 1.4) can give a glimpse of the concept underlying Berry's phase. Consider a quantum-mechanical state to be represented by a vector at point A. By infinitely slowly (adiabatically) varying an external parameter, for example, the direction of the magnetic field, one can ''transport'' state vectors successively from point A to B, then to C, and finally back to A. After completion of the closed loop, the vector does not coincide with its original orientation but is rotated by an angle γ that is proportional to the solid angle subtended by the loop. This angle gives rise to a geometric phase, $\exp(i\gamma)$, which depends on the geometry of a loop, but unlike the dynamical phase, Eq. (60), it is independent of the time it takes to complete the transport of the state along the closed loop. If one is now able to form in a physical system a coherent superposition of two states, one accumulating the geometric phase along the adiabatic change of the external field while the other is subject to a constant field, an interference pattern will arise. The Berry phase has been observed in interference experiments involving neutron spin rotation, in molecules, in light transmission through twisted optical-fiber cables, and in the quantum Hall effect.

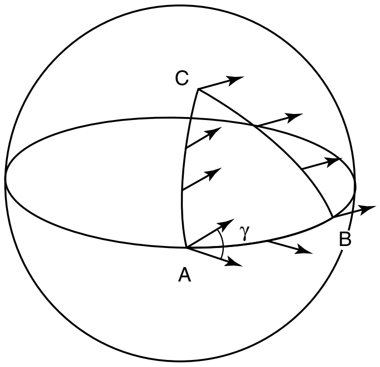

Fig. 1.4 Parallel transport of a vector on a sphere along a closed loop leads to a rotation of the vector. The vector's orientation relative to its local environment remains unchanged during parallel transport. The angle of rotation is related to Berry's phase.

In the opposite limit, where a sudden change of the Hamiltonian from $H(t) = H_0$ for all $t < 0$ to another Hamiltonian $H(t) = \overline{H}_0$ for all $t > 0$ occurs, no dynamical or geometric phase can be accumulated during the instantaneous change of the Hamiltonian at $t = 0$. The initial eigenstate of H_0, ψ_n, in which the system is prepared at $t = 0$, evolves for $t > 0$ as

$$|\psi_n(t)\rangle = \sum_{n'} \exp\left(-\frac{i\overline{\varepsilon}_{n'}t}{\hbar}\right) |\overline{\psi}_{n'}\rangle\langle\overline{\psi}_{n'}|\psi_n\rangle \tag{65}$$

In the sudden limit, the matrix U is nondiagonal. The eigenstate belonging to the "old" Hamiltonian forms a coherent superposition of eigenstates $|\overline{\psi}_n\rangle$ of the new Hamiltonian. The "sudden" formation of coherent states causes "quantum beats," observable oscillations in amplitudes and probabilities.

Consider, for example, an atom that is excited at the time $t = 0$ to a state that is a coherent superposition of a state $|\psi_1\rangle$, with energy E_1, and a state $|\psi_2\rangle$, with energy E_2, that is, $|\psi\rangle = c_1|\psi_1\rangle + c_2|\psi_2\rangle$. At a later point in time, t, the state acquires a phase factor as a function of time according to Eq. (65):

$$|\psi(t)\rangle = c_1 e^{-iE_1 t/\hbar}|\psi_1\rangle + c_2 e^{-iE_2 t/\hbar}|\psi_2\rangle \tag{66}$$

The projection onto a final state $|f\rangle$ representing, for example, the atom in the ground state and the emission of a photon,

$$\begin{aligned} P_f(t) &= |\langle f|\psi(t)\rangle|^2 \\ &= |c_1|^2|\langle f|\psi_1\rangle|^2 + |c_2|^2|\langle f|\psi_2\rangle|^2 \\ &\quad + c_1 c_2^* \exp\left[\frac{it}{\hbar}(E_2 - E_1)t\right] \\ &\quad \times \langle f|\psi_1\rangle\langle f|\psi_2\rangle^* \\ &\quad + \text{complex conjugate} \end{aligned} \tag{67}$$

will display oscillations ("quantum beats") due to the time dependence of the relative phases of the two states. These quantum beats due to dynamical phases have been observed, for example, in the Lyman-α ($n = 2 \rightarrow n = 1$) radiation of hydrogen excited in the $n = 2$ level subsequent to fast collisions with a foil (Figure 1.5).

The standard computational method of solving the time-dependent Schrödinger equation for time-dependent interactions consists of expanding a trial wave function $|\psi(t)\rangle$ in terms of a conveniently chosen truncated time-independent basis of finite size:

$$|\psi(t)\rangle = \sum_{n=1}^{N} a_n(t)|\psi_n\rangle \tag{68}$$

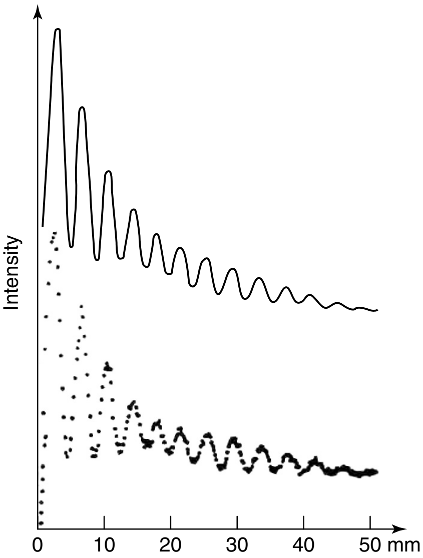

Fig. 1.5 Quantum beats in the Lyman-α photon intensity of hydrogen after collision with a carbon foil: ●, experimental data from Andrä (1974); –, theory from Burgdörfer (1981). The theory curve is shifted relative to the data for clarity.

with unknown, time-dependent coefficients $a_n(t)$. Insertion of Eq. (68) into Eq. (47) leads to a system of coupled first-order differential equations, which can be written in matrix notation as

$$i\hbar\dot{\mathbf{a}} = \mathbf{H}(t)\,\mathbf{a}(t) \tag{69}$$

using the vector notation $\mathbf{a} = (a_1, \dots a_n)$ with $\mathbf{H}$ the matrix of the Hamiltonian in the basis $\{|\psi_n\rangle\}$, $H_{n,n'} = \langle\psi_n | H | \psi_{n'}\rangle$. The solution of Eq. (69) is thereby reduced to a standard problem of numerical mathematics, the integration of a set of N coupled first-order differential equations with variable (time-dependent) coefficients.

1.7.2
Methods for Solving the Time-Independent Schrödinger Equation

The solution of the stationary Schrödinger equation, Eq. (59), proceeds mostly in the $\{|\mathbf{r}\rangle\}$ representation, i.e., using wave functions $\psi(\mathbf{r})$. Standard methods include the method of separation of variables and variational methods.

1.7.2.1 Separation of Variables

The energy eigenvalue problem, Eq. (59), requires the solution of a second-order partial differential equation. It can be reduced to an ordinary second-order differential equation if the method of separation of variables can be applied, i.e., if the wave function can be written in a suitable coordinate system (q_1, q_2, q_3) in factorized form

$$\psi(\mathbf{r}) = f(q_1)g(q_2)h(q_3) \tag{70}$$

with obvious generalizations for an arbitrary number of degrees of freedom. Equation (70) applies only to a very special but important class of problems for which the Hamiltonian possesses as many constants of motion or compatible observables as there are degrees of freedom (in our example, three). In this case, each factor function in Eq. (70) is associated with one "good" quantum number belonging to one compatible observable. This class of Hamiltonians permits an exact solution of the eigenvalue problem and is called *separable* (or *integrable*).

Consider the example of the isotropic three-dimensional harmonic oscillator. The Hamiltonian is

$$H = \frac{p_x^2}{2M} + \frac{p_y^2}{2M} + \frac{p_z^2}{2M} + \tfrac{1}{2}M\omega^2(x^2 + y^2 + z^2) \tag{71}$$

In this case, one suitable set of coordinates for the separation are the Cartesian coordinates ($q_1 = x,\ q_2 = y,\ q_3 = z$). Each of the three factor functions of Eq. (70) satisfies a one-dimensional Schrödinger equation of the form

$$\left(-\frac{\hbar^2}{2M}\frac{\partial^2}{\partial x^2} + \tfrac{1}{2}M\omega^2 x^2\right) f(x) = E_x f(x) \tag{72}$$

and $E = E_x + E_y + E_z$. The simplest solution of Eq. (72) satisfying the boundary conditions $f(x \to \pm\infty) \to 0$ for a normalizable wave function is a Gaussian wave function of the form

$$f(x) = \left(\frac{M\omega}{\pi\hbar}\right)^{1/4} e^{-(M\omega/2\hbar)x^2} \tag{73}$$

It corresponds to the lowest possible energy eigenstate, with $E_x = \frac{1}{2}\hbar\omega$. Ground-state wave functions are, in general, node free, i.e., without a zero at any finite x. The Schrödinger equation possesses an infinite number of admissible solutions with an increasing number $n = 0, 1, \ldots$ of nodes of the wave function and increasing eigenenergies

$$E_x = \hbar\omega\left(n + \tfrac{1}{2}\right) \tag{74}$$

The fact that wave functions belonging to higher states of excitation have an increasing number of zeros can be understood as a consequence of the orthogonality requirement, Eq. (37). Only through the additional change of sign of the wave function can all contributions in the orthogonality integral (Eq. 36) be made to cancel. The wave functions for excited states of a harmonic oscillator are given in terms of Hermite polynomials H_n by

$$f_n(x) = (2^n n!)^{-1/2}\left(\frac{M\omega}{\hbar\pi}\right)^{1/4} \times e^{-(M\omega/2\pi)x^2} H_n\left(\sqrt{\frac{M\omega}{\hbar}}x\right) \tag{75}$$

Examples of the first few eigenstates are shown in Figure 1.6 With increasing n, the probability density $|f_n(x)|^2$ begins to resemble the classical probability density for finding the oscillating particle near the coordinate x, $P_{\mathrm{cl}}(x)$ (Figure 1.7). The latter is proportional to the time the particle spends near x or inversely proportional to its speed:

$$P_{c1}(x) = \left(\frac{\omega}{\pi}\right)\left(2E_x/M - \omega^2 x^2\right)^{-1/2} \tag{76}$$

The increasing similarity between the classical and quantal probability densities as $n \to \infty$ is at the core of the correspondence principle. This example highlights the nonuniformity of the convergence to the classical limit: the quantum probability density oscillates increasingly rapidly around the classical value with decreasing de Broglie wavelengths λ (compared with the size of the classically allowed region). Furthermore, the wave function penetrates the classically forbidden region (''tunneling''). While the amplitude decreases exponentially, $\psi(x)$ possesses significant nonvanishing values outside the domain of classically allowed trajectories of the same energy over a distance of the order of the de Broglie wavelength λ. Only upon averaging over regions of the size of λ can the classical–quantum correspondence be

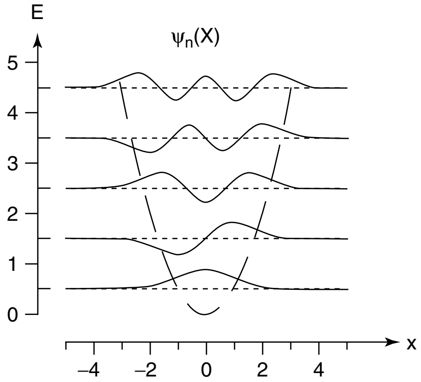

Fig. 1.6 Wave functions $f_n(x)$ for the first five eigenstates of the harmonic oscillator.

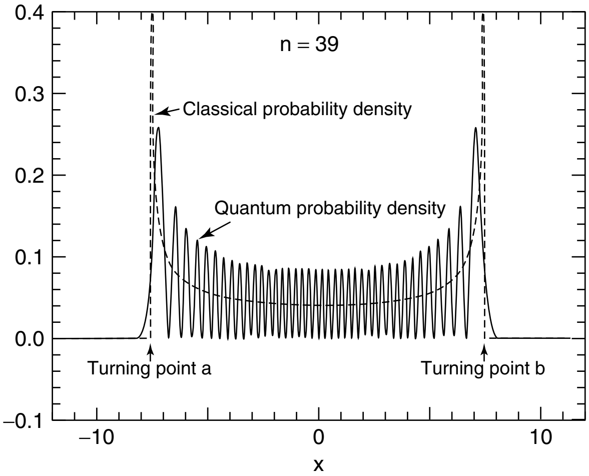

Fig. 1.7 Probability density $|f_n(x)|^2$ of a harmonic oscillator in $n = 39$ compared with the classical probability density $P_{cl}(x) = (\omega/\pi)(2E/M - \omega^2 x^2)^{-1/2}$ indicated by the dashed line. Classical turning points are denoted by a and b.

recovered. As λ tends to zero in the classical limit, classical dynamics emerges. It is the smallness of λ that renders the macroscopic world as being classical for all practical purposes.

The complete wave function for the three-dimensional isotropic oscillator (Eq. 71) consists of a product of three wave functions each of which is of the form of Eq. (75),

$$\psi_{n_x n_y n_z}(x, y, z) = f_{n_x}(x) f_{n_y}(y) f_{n_z}(z) \qquad (77)$$

with eigenenergies

$$E_{n_x n_y n_z} = \hbar\omega \left(n_x + n_y + n_z + \tfrac{3}{2}\right) \qquad (78)$$

The energy depends only on the sum of the three quantum numbers,

$$n = n_x + n_y + n_z \qquad (79)$$

but not on the individual quantum numbers n_x, n_y, and n_z, separately. Different combinations of quantum numbers yield the same energy; the spectrum is therefore degenerate. The degeneracy factor g_n, the number of different states having the same energy E_n, is

$$g_n = \frac{(n+1)(n+2)}{2} \qquad (80)$$

Only the ground state ($n = 0$) is nondegenerate, a feature generic to quantum systems and the origin of the third law (Nernst's theorem) of statistical mechanics. The degeneracy signals that alternative complete sets of commuting observables (instead of the energies in each of the three Cartesian coordinates E_x, E_y, and E_z) and corresponding alternate sets of coordinates should exist in which the problem is separable. One such set of coordinates is the spherical coordinates.

Consider the example of the hydrogen atom. One of the most profound early successes of quantum mechanics was the interpretation of the line spectrum emitted from the simplest atom, the hydrogen atom, consisting of an electron and a proton. The Schrödinger equation (in the center-of-mass frame) for the electron interacting with the proton through a Coulomb potential $V(r) = -e^2/4\pi\varepsilon_0 r$ reads as

$$\left[\frac{-\hbar^2\nabla^2}{2m_e} - \frac{e^2}{4\pi\varepsilon_0 r}\right]\psi(\mathbf{r}) = E\psi(\mathbf{r}) \qquad (81)$$

where $m_e = 9.1 \times 10^{-31}$ kg is the reduced mass of the electron, $\mathbf{r}$ is the vector that points from the nucleus to the electron, $e = 1.6 \times 10^{-19}$ C is the electric charge of the nucleus, and $-e$ is the charge of the electron. If we express the Laplace operator ∇^2 (defined as $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$) in polar spherical coordinates (r, θ, ϕ), the Schrödinger equation becomes

$$\left[\frac{-\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r}\right) + \frac{L^2}{2m_e r^2} - \frac{e^2}{4\pi\varepsilon_0 r}\right]\psi(r,\theta,\phi) = E\psi(r,\theta,\phi) \qquad (82)$$

Since the angular coordinates enter only through the square of the angular momentum operator (see Eq. 28), the Schrödinger equation is separable in spherical coordinates and the wave function can be written as a product $\psi(r,\theta,\phi) = R_{nl}(r)Y_e^m(\theta,\phi)$ with one factor being the spherical harmonics Y_l^m and the $R_{nl}(r)$ being the radial wave function satisfying the second-order differential equation

$$\left[\frac{-\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r}\right) + \frac{\hbar^2 l(l+1)}{2m_e r^2} - \frac{e^2}{4\pi\varepsilon_0 r}\right]R_{nl}(r) = ER_{nl}(r) \qquad (83)$$

The negative-energy eigenvalues of bound states can be found as

$$E_n = -\frac{m_e e^4}{2\hbar^2 n^2 (4\pi\varepsilon_0)^2} = -\frac{E_{\mathrm{H}}}{2n^2} \qquad (84)$$

where $E_H = m_e e^4/\hbar^2(4\pi\varepsilon_0)^2$ is called a *Hartree* or an *atomic unit of energy*. The energy depends only on the "principal" quantum number n, being independent of the angular momentum

$$l = 0, 1, \ldots, n-1 \qquad (85)$$

and of the magnetic quantum number m. The m independence can be found for any isotropic potential $V(|\mathbf{r}|)$ that depends only on the distance of the interacting particles. The degeneracy in l is a characteristic feature of the Coulomb potential (and of the isotropic oscillator), and it reflects the fact that the Schrödinger equation is separable not only in polar spherical coordinates but also in parabolic coordinates. The Coulomb problem possesses a dynamical symmetry that allows the choice of alternative complete sets of compatible observables. The separability in spherical coordinates is related to the set $\{H, L^2, L_z\}$ while the separability in parabolic coordinates is related to the set $\{H, L_z, A_z\}$ where $\mathbf{A}$ is the Runge–Lenz (or perihelion) vector, which, as is well known from

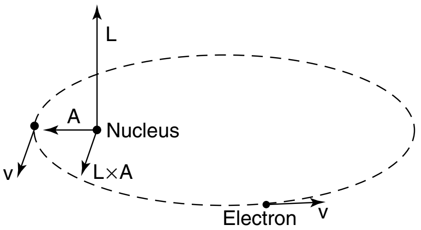

Fig. 1.8 The Runge–Lenz vector **A** and the angular momentum **L** for the classical orbit in an attractive $-1/r$ potential.

astronomy, is a constant of motion for a $1/r$ potential (Figure 1.8). The emission spectrum follows from Eq. (84) as

$$\begin{aligned}\nu &= \frac{(E_n - E_{n_0})}{h} \\ &= \frac{E_\mathrm{H}}{2h}\left(\frac{1}{n_0^2} - \frac{1}{n^2}\right)\end{aligned} \tag{86}$$

with $n_0 = 1$ and $n = 2, 3, \ldots$ giving rise to the Lyman series of spectral lines, $n_0 = 2$ and $n = 3, 4, \ldots$ giving rise to the Balmer series, and so on. The radial probability densities $r^2 R_{nl}(r)^2$ are shown in Figure 1.9

1.7.2.2 **Variational Methods**

For all but the few separable Hamiltonians, the time-independent Schrödinger equation is only approximately and numerically solvable. The accuracy of approximation can, however, be high. It may only be limited by the machine precision of modern computers. The most successful and widely used method in generating accurate numerical solutions is the variational method. The solution of the Schrödinger equation can be recognized as a solution to the variational problem of finding an extremum (in practice, a minimum) of the energy functional $\langle E\rangle = \langle\psi \mid H \mid \psi\rangle / \langle\psi \mid \psi\rangle$ by varying $|\psi\rangle$ until $\langle E\rangle$ reaches a stationary point at an approximate eigenvalue. The wave function at the minimum is an approximate solution to the Schrödinger equation. In practice, one chooses functional forms called *trial functions* $\psi(\mathbf{r})$ that depend linearly and/or nonlinearly on parameters $(c_1, \ldots, c_k)$. The trial function is optimized by minimizing the energy in the k-dimensional parameter space according to

$$\frac{d}{dc_i}\langle E\rangle = 0 \quad (1 \le i \le k) \tag{87}$$

Provided the trial function is sufficiently flexible to approximate a complete set of states in Hilbert space, ψ becomes exact in the limit as $k \to \infty$. The ground state of the helium atom consisting of an α particle as a nucleus (nuclear charge number $Z = 2$) and two electrons provides one of the most striking illustrations of the success of the variational method. The Hamiltonian (neglecting the motion of the nucleus)

$$\begin{aligned}H = &-\frac{\hbar^2}{2m_e}(\nabla_1^2 + \nabla_2^2) - \frac{Ze^2}{4\pi\varepsilon_0 r_1} \\ &-\frac{Ze^2}{4\pi\varepsilon_0 r_2} + \frac{e^2}{4\pi\varepsilon_0 |r_1 - r_2|}\end{aligned} \tag{88}$$

is nonseparable, an analytic solution is unknown, and no perturbation solution is possible since all interactions are of comparable strength. The variational method pioneered by Hylleraas (1929) and further developed by Pekeris (1958, 1959) achieves, however, a virtually exact result for the ground-state energy, $E = 2.903\,724\,377\,03\ldots E_H$, for which the accuracy is no longer limited by the method of solution but rather by the approximate nature of the Hamiltonian itself (for example, the neglect of the finite

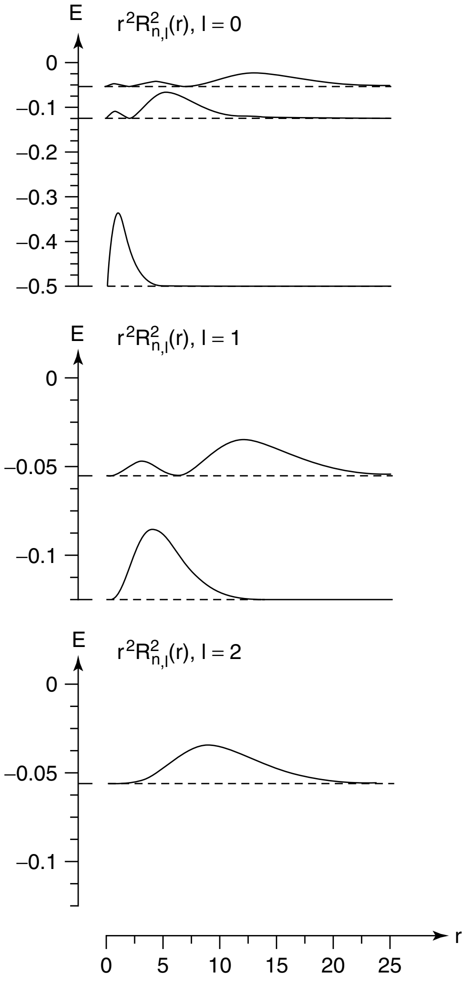

Fig. 1.9 Radial densities $r^2R_{nl}(r)$ for $n=1$, 2, 3 and $l=0$, 1, and 2 of the hydrogen atom.

size of the nucleus and of relativistic effects).

1.7.3
Perturbation Theory

A less accurate method, which is, however, easier to implement, is perturbation theory. The starting point is the assumption that the Hamiltonian H can be decomposed into a "simple," separable (or, at least, numerically solvable) part H_0 plus a perturbation gV,

$$H = H_0 + gV \tag{89}$$

which is nonseparable, but "small" such that it causes only a small modification of the spectrum and of the eigenstates of H_0. The control parameter g $(0 \le g \le 1)$ is used as a convenient formal device for controlling the strength of the perturbation and keeping track of the order of the perturbation. At the end of the calculation, g can be set equal to unity if V itself is small.

Two cases can be distinguished: stationary perturbation theory and time-dependent perturbation theory.

1.7.3.1 **Stationary Perturbation Theory**

The Rayleigh–Schrödinger perturbation theory involves the expansion of both the perturbed energy eigenvalue $E_0(g)$ and the perturbed eigenstate $|\psi_0(g)\rangle$ in powers of the order parameter g (or, equivalently, in powers of V),

$$E_0(g) = E_0 + gE^{(1)} + g^2E^{(2)} + \cdots$$
$$|\psi_0(g)\rangle = |\psi_0\rangle + g|\psi^{(1)}\rangle + g^2|\psi^{(2)}\rangle + \cdots \tag{90}$$

Inserting Eq. (90) into the Schrödinger equation

$$H(g)|\psi_0(g)\rangle = E_0(g)|\psi_0(g)\rangle \tag{91}$$

yields recursion relations ordered in ascending powers of g for the successive corrections to $E_0(g)$ and $|\psi_0(g)\rangle$. In practice, the first few terms are most important: Thus the first-order corrections for a non-degenerate eigenvalue E_0 are

$$E^{(1)} = \langle\psi_0|V|\psi_0\rangle \tag{92}$$

and

$$|\psi^{(1)}\rangle = \sum_{n\neq 0} |\psi_n\rangle \frac{\langle\psi_n|V|\psi_0\rangle}{E_0 - E_n} \tag{93}$$

where the sum over $\{|\psi_n\rangle_{n\neq 0}\}$ extends over the complete set of eigenstates of the unperturbed Hamiltonian excluding the state $|\psi_0\rangle$ for which the perturbation expansion is performed. The second-order correction to the eigenenergy is

$$E^{(2)} = \langle\psi_0|V|\psi^{(1)}\rangle = \sum_{n\neq 0} \frac{|\langle\psi_0|V|\psi_n\rangle|^2}{E_0 - E_n} \tag{94}$$

Alternative perturbation series can be devised. For example, in the Brillouin–Wigner expansion, the perturbed $E_0(g)$, rather than the unperturbed energy E_0, appears in the energy denominator of Eq. (94). The energy is therefore only implicitly given by this equation.

1.7.3.2 **Time-Dependent Perturbation Theory**

Time-dependent perturbation theory deals with the iterative solution of the system of coupled equations, Eq. (69), representing the time-dependent Schrödinger equation. One assumes again that the Hamiltonian consists of an unperturbed part H_0 and a time-dependent perturbation $V(t)$. Expansion in the basis of eigenstates of the unperturbed Hamiltonian (Eq. 68) yields a matrix $\mathbf{H}$ consisting of a diagonal matrix $\langle i\,|\,H_0\,|\,j\,\rangle = E_j\delta_{ij}$ and a time-dependent perturbation matrix $V_{ij} = \langle i\,|\,V(t)\,|\,j\rangle$.

The dynamical phases associated with the unperturbed evolution can be easily included in the perturbative solution of Eq. (69) by making the phase transformation

$$a_j(t) = c_j(t)e^{-iE_jt/\hbar} \tag{95}$$

This transformation, often referred to as the *transformation* to the *interaction representation*, removes the diagonal matrix $\langle i\,|\,H_0\,|\,j\rangle$ from Eq. (69), resulting in the new system of equations

$$i\hbar\frac{d}{dt}\mathbf{C}(t) = \mathbf{V}_I(t)\,\mathbf{C}(t) \tag{96}$$

with matrix elements

$$\langle i|V_I(t)|j\rangle = \exp\left(\frac{i}{\hbar}t(E_i - E_j)\right)\langle i|V(t)|j\rangle \tag{97}$$

and $\mathbf{C} = (c_1,c_2,\ldots,c_N)$. The perturbative solution of Eq. (96) proceeds now by assuming that initially, say at $t = 0$, the

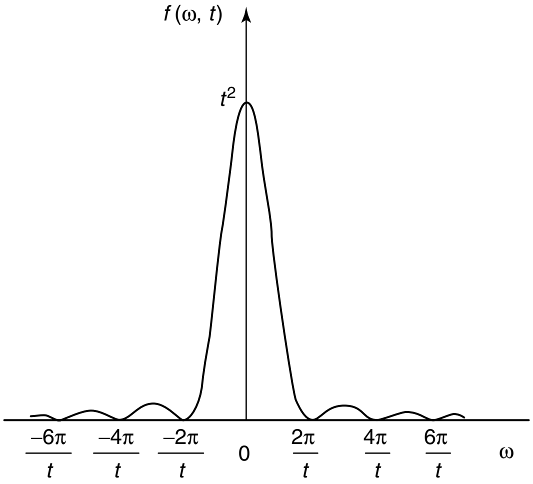

Fig. 1.10 The function $f(\omega, t)$ as a function of ω.

system is prepared in the unperturbed state $|j\rangle$ with unit amplitude, $c_j(0) = 1$. Since the perturbation is assumed to be weak, the system at a later time t will still be approximately in this state. However, small admixtures of other states will develop with amplitudes

$$\begin{aligned} c_i(t) &= \frac{1}{i\hbar}\int_0^t dt' \langle i|V_I(t')|j\rangle c_j(t') \\ &\approx \frac{1}{i\hbar}\int_0^t dt' \langle i|V_I(t')|j\rangle \end{aligned} \tag{98}$$

Therefore, to first order, the time-dependent perturbation induces during the time interval $[0, t]$ transitions $|j\rangle \rightarrow |i\rangle$ with probabilities

$$P_i(t) = |c_i(t)|^2 = \frac{1}{\hbar^2}\left|\int_0^t dt' \langle i|V_I(t')|j\rangle\right|^2 \tag{99}$$

In the special case that V is time independent, Eq. (99) gives

$$\begin{aligned} P_i(t) &= \frac{1}{\hbar^2}|\langle i|V|j\rangle|^2 \frac{|e^{i\omega_{ij}t} - 1|^2}{\omega_{ij}^2} \\ &= \frac{1}{\hbar^2}|\langle i|V|j\rangle|^2 \frac{4\sin^2(\omega_{ij}t/2)}{\omega_{ij}^2} \end{aligned} \tag{100}$$

with $\omega_{ij} = (\varepsilon_i - \varepsilon_j)/\hbar$. Plotted as a function of ω, the function $f(\omega,t) = 4\sin^2(\omega t/2)/\omega^2$ (Figure 1.10) is strongly peaked around $\omega = 0$. The peak height is t^2 and the width of the central peak is given by $\Delta\omega \simeq 2\pi/t$. In other words, f describes the energy–time uncertainty governing the transition: The longer the available time, the more narrowly peaked is the transition probability around $\omega_i - \omega_j = 0$, that is, for transition into states that are almost degenerate with the initial state. In the limit $t \rightarrow \infty$, the time derivative of Eq. (100), that is, the transition probability per unit time, or transition rate w, has the well-defined limit

$$w = \frac{d}{dt}P_i(t)_{t\longrightarrow\infty} = \frac{2\pi}{\hbar}|\langle i|V|j\rangle|^2\delta(\varepsilon_i - \varepsilon_j) \tag{101}$$

where the representation of the δ function, $\pi\delta(\omega) = lim_{t\rightarrow\infty}$ $(\sin\omega t/\omega)$, has been used. Equation (101) is often called *Fermi's golden rule* and provides a simple, versatile tool to calculate transition rates to first order. The physical meaning of the δ function is such that in the limit $t \rightarrow \infty$ only those transitions take place for which energy is conserved, as we would have expected since the interaction in Eq. (100) was assumed to be time-independent (after being switched on at time $t = 0$). For example, in scattering processes, many final states with energies very close to that of the initial states are accessible. The δ function is then evaluated within the sum (or integral) over these final states.

1.8
Quantum Scattering Theory

Scattering theory plays, within the framework of quantum mechanics, a special and important role. Its special role is derived from the fact that scattering deals with unbound physical systems: two (or more) particles approach each other from infinity, scatter each other, and finally separate to an infinite distance. Obviously, one cannot impose upon the wave function the boundary condition $\psi(r = |\mathbf{r}_2 - \mathbf{r}_2| \to \infty) \to 0$ since the probability of finding the scattered particles at large interparticle distances r is, in fact, nonvanishing. This has profound consequences: energies are not quantized since the corresponding boundary condition is missing. The energy spectrum consists of a continuum instead of a set of discrete states. The states describing the unbound motion, the "scattering states," are not square integrable and do not, strictly speaking, belong to the Hilbert space. They can only be orthonormalized in terms of a δ function,

$$\langle \psi_E | \psi_{E'} \rangle = \delta(E - E') \tag{102}$$

Mathematically, they belong to the space of distributions and can be associated with states in Hilbert space only upon forming "wave packets," that is, by convoluting the scattering state with a well localized function. Nevertheless, most of the time one can manipulate scattering states using the same rules valid for Hilbert-space vectors (see Section 1.6) except for replacing the ordinary orthonormalization condition, Eq. (37), by the δ normalization condition, Eq. (102).

The strategy for solving the Schrödinger equation, which governs both bounded and unbounded motion, is different for scattering states. Rather than determining the energy eigenvalues or the entire wave function (which is, in many cases, of no interest), one aims primarily at determining the asymptotic behavior of the wave function emerging from the interaction region, which determines the flux of scattered particles. The central quantity of both classical and quantum scattering is the cross section σ, defined as

$$\sigma = \frac{\begin{array}{c}\text{number of scattered particles}\\ \text{per unit time}\end{array}}{\begin{array}{c}\text{number of incident particles}\\ \text{per unit area and per unit time}\end{array}} \tag{103}$$

A cross section σ has the dimension of an area and can be visualized as an effective area that the target presents to the incoming projectile. Using the probabilistic description of quantum mechanics, one can replace in the definition Eq. (103) all particle currents by corresponding probability currents. Accordingly, σ can be expressed in terms of the transition rate w as

$$\sigma = \frac{w}{j} \tag{104}$$

where $j = |\psi|^2 v$ represents the incoming probability current density. For an incoming plane particle wave (Eq. 4), $j = \hbar k/M$ (with M the reduced mass and the amplitude A set equal to unity). Calculations of total cross sections σ proceed typically by first calculating differential cross sections for scattering into a particular group of final states and then summing over all possible final states. For elastic scattering of particles with incident wave vectors $\mathbf{k}_{\text{in}}$ pointing in the z direction, a group of final states is represented by a wave vector $\mathbf{k}_{\text{out}}$ of the outgoing particles pointing in a solid angle centered around the spherical angles (θ, ϕ),

$$\frac{d\sigma}{d\Omega} = \frac{M}{\hbar k_{in}} w_{\mathbf{k}_{\text{in}} \longrightarrow \mathbf{k}_{\text{out}}} \tag{105}$$

Equation (105) gives the differential cross section per unit solid angle.

1.8.1
Born Approximation

The evaluation of $d\sigma/d\Omega$ is most straightforward in the Born approximation. The first Born approximation is nothing but the application of Fermi's "golden rule," Eq. (101), to scattering:

$$\frac{d\sigma}{d\Omega} = \frac{2\pi M}{\hbar^2 k_{\text{in}}} \int_0^\infty \frac{k_{\text{out}}^2}{(2\pi)^3} dk_{\text{out}} \, |\langle \mathbf{k}_{\text{out}}|V|\mathbf{k}_{\text{in}}\rangle|^2 \times \delta(E_{\text{in}} - E_{\text{out}}) \tag{106}$$

where the integral is taken over the magnitude of k_{out} but not over the solid angle and where $k_{\text{out}}^2 dk_{\text{out}} \; d\Omega/(2\pi)^3$ represents the number of final states available for the scattered particles in the interval $dk_{\text{out}} d\Omega$. Since $k_{\text{out}}^2 dk_{\text{out}} = (M/\hbar^2) k_{\text{out}} dE_{\text{out}}$, we have

$$\frac{d\sigma}{d\Omega} = \frac{M^2}{\hbar^4 (2\pi)^2} |\langle \mathbf{k}_{\text{out}}|V|\mathbf{k}_{\text{in}}\rangle|^2 \tag{107}$$

with $|\mathbf{k}_{\text{out}}| = |\mathbf{k}_{\text{in}}|$. The first Born approximation to elastic scattering, Eq. (107), is only valid if the potential V is sufficiently weak to allow for a perturbative treatment and vanishes sufficiently rapidly at large distances for the matter wave to become a plane wave. In such cases, the matrix element in Eq. (107) can be expressed as the Fourier component of the potential,

$$\langle \mathbf{k}_{\text{out}}|V|\mathbf{k}_{\text{in}}\rangle = \int d^3 r \, e^{i\mathbf{r} \cdot (\mathbf{k}_{\text{out}} - \mathbf{k}_{\text{in}})} V(\mathbf{r}) \tag{108}$$

For a Coulomb potential $V(\mathbf{r}) = Z_1 Z_2 e^2 / 4\pi\varepsilon_0 r$ representing two charged particles with charges $Z_1 e$ or $Z_2 e$ scattering each other, Eq. (107) yields – coincidentally – the Rutherford cross section

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{R}} = \frac{Z_1^2 Z_2^2 e^4}{16 E^2 (4\pi\varepsilon_0)^2 \sin^4(\theta/2)} \tag{109}$$

This expression provided essential clues as to an internal structure and charge distribution of atoms. Two remarkable features should be noted: Prior to the advent of quantum theory, Rutherford (1911) used classical mechanics instead of quantum mechanics to derive Eq. (109). He could do so since, for Coulomb scattering, classical and quantum dynamics happen to agree. Keeping in mind that the classical limit entails the limit $\hbar \to 0$, the QM and classical cross sections should agree, since $(d\sigma/d\Omega)_{\text{R}}$ does not depend on $\hbar$. The equivalence of the classical and the QM Rutherford cross sections is due to the long range (in fact, infinite range) of the Coulomb potential. In this case, the de Broglie wavelength of the particle wave is negligibly small compared to the "size" of the target at all energies. A second coincidence lies in the fact that the first Born approximation yields the exact quantum result even though the Born approximation is, strictly speaking, not even applicable in the case of a Coulomb potential. The infinite range of the Coulomb potential distorts the matter wave at arbitrarily large distances so that it never becomes the plane wave that is assumed in Eq. (108). It turns out that all high-order corrections to the Born approximation can be summed up to give a phase factor that drops out from the expression for the cross section.

1.8.2
Partial-Wave Method

For elastic scattering by a spherically symmetric potential, that is, a potential that depends only on the distance between the particles, $V(\mathbf{r}) = V(|\mathbf{r}|)$, phase-shift analysis provides a versatile nonperturbative method for calculating differential and integral cross sections. For each angular momentum l (which is a good quantum number for a spherically symmetric potential), the phase shift for a radial wave function $u(r) = rR(r)$ can be determined from the radial Schrödinger equation

$$\left(-\frac{\hbar^2}{2M}\frac{d^2}{dr^2} + \frac{\hbar^2}{2M}\frac{l(l+1)}{r^2} + V(r)\right)u(r) = Eu(r) \tag{110}$$

The idea underlying the phase-shift analysis can be best illustrated for the phase shift δ_l for $l = 0$. In absence of the scattering potential $V(r)$, Eq. (110) represents a one-dimensional Schrödinger equation of a free particle in the radial coordinate,

$$-\frac{\hbar^2}{2M}\frac{d^2}{dr^2}u(r) = Eu(r) \tag{111}$$

whose solution is $u(r) = \sin(kr)$ with $k^2 = 2ME/\hbar^2$. Since the matter wave cannot reach the unphysical region of negative r, we have to impose the boundary condition $u(0) = 0$, which excludes the alternative solution $\sim\cos kr$. In the presence of the potential $V(r)$, the wave function will be modified within the region of the nonvanishing potential. At large distances $r \to \infty$, however, when $V(r) \to 0$, the wave function will again become $u(r) = \sin(kr+\delta_0)$ since in this region it must satisfy Eq. (111). The only effect that the potential can have on the scattered wave function at large distances is to introduce a phase shift δ_0 relative to the unperturbed wave.

Simple arguments give a clue as to the origin and the sign of the phase shift. For an attractive potential (negative V), the wave number $k(r) = \sqrt{2M(E - V(r))/\hbar^2}$ increases locally and the de Broglie wavelength $\lambda(r) = 2\pi/k(r)$ becomes shorter compared with that of a free particle of the same energy. The phase of the matter wave is therefore advanced compared with the wave of a free particle and δ_0 is positive (Figure 1.11). Similarly, if V is a repulsive potential, λ increases in the interaction region causing a phase delay and, hence, a negative phase shift δ_0. Including all angular momenta, or all "partial waves," the differential cross section can be expressed in terms of the partial-wave phase shifts δ_l as

$$\frac{d\sigma}{d\Omega} = \frac{1}{k^2}\left|\sum_{l=0}^{\infty}(2l+1)e^{i\delta_l}\sin\delta_l P_l(\cos\theta)\right|^2 \tag{112}$$

A particularly simple expression can be found for the total cross section:

$$\sigma = \frac{4\pi}{k^2}\sum_{l=0}^{\infty}(l+1)\sin^2\delta_l \tag{113}$$

For short-ranged potentials, δ_l decreases with increasing l such that only a small number of terms must be included in this sum. The scattering phase shifts $\delta_l(E)$ depend sensitively on the energy E of the incident particle.

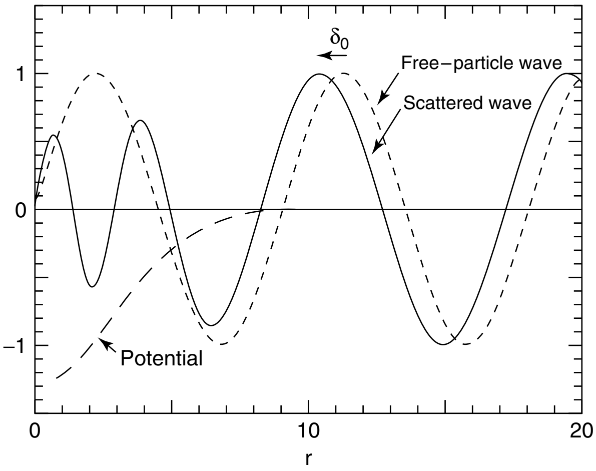

Fig. 1.11 Comparison between the scattered wave in an attractive potential and a free-particle wave (the scattering phase δ_0 is shown modulo π).

1.8.3
Resonances

Often, one phase shift $\delta_l(E)$ increases by π within a narrow energy range. This corresponds to a phase shift of one-half of a wave length, or to the addition of one node to the wave function. A sudden increase of the scattering phase by π is a signature of a "resonance" in the cross section. A resonance is characterized by a sharp maximum in the partial-wave cross section at the energy $E_{\text{res}} = \hbar^2 k_{\text{res}}^2/2M$:

$$(\sigma_l)_{\max} = \left(\frac{4\pi}{k_{\text{res}}^2}\right)(2l+1) \tag{114}$$

where the phase shift passes through $\pi/2$ (or an odd multiple thereof). Resonances appear when the scattering potential allows for the existence of "virtual levels" or quasi-bound states inside the potential well, whose probability density can leak out by tunneling through the potential well. The additional node that the scattering wave function acquires as the energy passes through E_{res} reflects the presence of a quasi-bound state. An isolated resonance can be parametrized by a formula due to Breit and Wigner. One assumes that the rapid change of the scattering phase near the resonance can be modeled by

$$\delta_l(E) \simeq \tan^{-1}\frac{\Gamma}{2(E_{\text{res}} - E)} \tag{115}$$

and that the energy dependence of the nonresonant (smooth part) of the phase shift can be neglected. The term Γ denotes the width over which the phase jump occurs. Inserting Eq. (115) into the lth term of Eq. (113) yields, for the shape of the resonant cross section, the Breit–Wigner formula

$$\sigma_l(E) = (\sigma_l)_{\text{res}}\frac{\Gamma^2/4}{(E_{\text{res}} - E)^2 + \Gamma^2/4} \tag{116}$$

The shapes of resonant cross sections become more complicated when interferences between the resonant and the nonresonant parts of the scattering amplitude come into play. The cross section can then exhibit a variety of shapes (Beutler–Fano profile; Fano, 1961), including asymmetric peaks or dips ("window resonance") depending on the relative phases of the amplitudes. In the limit that a large number of resonances with energies $E_{\text{res},i}\,(i = 1, \ldots, N)$

are situated within the width Γ ("overlapping resonances"), the cross section displays irregular fluctuations ("Ericson fluctuations") (*see* Chapter 10). These play an important role in scattering in complex systems, for example, in nuclear compound resonances (Ericson and Meyer-Kuckuk, 1966) as well as in scattering in chaotic systems Burgdörfer *et al.*, 1995).

1.9
Semiclassical Mechanics

While the correspondence principle postulates that in the limit of large quantum numbers (or, equivalently, $\hbar \to 0$), quantum mechanics converges to classical mechanics, the approach to this limit is highly nonuniform and complex. The description of dynamical systems in the limit of small but nonzero $\hbar$ is called *semiclassical mechanics*. Its importance is derived not only from conceptual but also from practical aspects since a calculation of highly excited states with large quantum numbers involved becomes difficult because of the rapid oscillations of the wave function (see Figure 1.7). Semiclassical mechanics has been developed only recently. The old Bohr–Sommerfeld quantization rules that preceded the development of quantum mechanics are now understood as an approximate form of semiclassical mechanics applicable to separable (or integrable) systems.

The wave function of the time-independent Schrödinger equation for a single particle,

$$E\psi(\mathbf{r}) = -\left(\frac{\hbar^2}{2M}\right)\nabla^2\psi(\mathbf{r}) + V(\mathbf{r})\psi(\mathbf{r}) \tag{117}$$

can be written as

$$\psi(\mathbf{r}) = A\exp\left[\frac{iS(\mathbf{r})}{\hbar}\right] \tag{118}$$

where the unknown function $S(\mathbf{r})$ replaces the exponent $\mathbf{k}\cdot\mathbf{r}$ of a plane wave (Eq. 4) for a free particle in the presence of the potential. The idea underlying the semiclassical approximation is that in the limit $\hbar \to 0$, or likewise, in the limit of small de Broglie wavelength $\lambda \to 0$ (compared with the distance over which the potential changes), $\psi(\mathbf{r})$ should behave like a plane wave with, however, a position-dependent de Broglie wavelength. Inserting Eq. (118) into Eq. (117) leads to

$$E = \frac{1}{2M}[\nabla S(\mathbf{r})]^2 + V(\mathbf{r}) - \frac{i\hbar}{2M}\nabla^2 S(\mathbf{r}) \tag{119}$$

with $\mathbf{p} = \nabla S$. Equation (119) is well suited for taking the classical limit $\hbar \to 0$ and yields the classical Hamilton–Jacobi equation. In this limit, S is the action or Hamilton's principal function. Quantum corrections enter through the term linear in $\hbar$. Approximate solutions of Eq. (119) can be found by expanding S in ascending powers of $\hbar$. The apparent simplicity of the classical limit is deceiving: the principal function S appears inside the exponent Eq. (118) with the prefactor $\hbar^{-1}$ and this causes the wave function to oscillate infinitely rapidly as $\hbar \to 0$.

1.9.1
The WKB Approximation

For problems that depend only on one coordinate, retention of the first two terms of the expansion of Eq. (119),

$$S(x) = S_0(x) + \hbar S_1(x)$$

with

$$S_0(x) = \pm \int^x p(x')dx'$$
$$S_1(x) = \tfrac{1}{2} i \ln|p(x)| + c \qquad (120)$$

leads to the Wentzel–Kramers–Brillouin (WKB) approximation where c is an integration constant to be determined by normalization of the wave function,

$$\psi^{\mathrm{WKB}}(x) = \frac{A}{\sqrt{|p(x)|}} \exp\left[\frac{\pm i}{\hbar} \int^x p(x')dx'\right] \qquad (121)$$

Several features of Eq. (121) are worth noting: the WKB wave function is an asymptotic solution of Schrödinger's equation in the limit of small λ and satisfies all rules of QM, including the superposition principle. All quantities in Eq. (121) can be calculated, however, purely from classical mechanics. In particular, the quantum probability density $|\psi^{\mathrm{WKB}}(x)|^2$ can be directly associated with the inverse classical momentum $\sim |p(x)|^{-1}$ or, equivalently, the time the particle spends near x. This result was already anticipated for the highly excited state of the harmonic oscillator (Figure 1.7). Furthermore, $S_0(x)$ is a double-valued function of x corresponding to the particle passing through a given point moving either to the right or to the left with momentum $\pm p(x)$. It is the multiple-valuedness of $p(x)$ or $S(x)$ that is generic to semiclassical mechanics and that poses a fundamental difficulty in generalizing the WKB approximation to more than one degree of freedom.

For describing bound states, a linear combination of ψ^{WKB} with both signs of the momentum in Eq. (121) is required in order to form a standing rather than a traveling wave:

$$\psi^{\mathrm{WKB}}(x) = \frac{A}{\sqrt{|p(x)|}} \sin \times \left(\frac{1}{\hbar}\int_a^x p(x')dx' + \frac{\pi}{4}\right) \qquad (122)$$

Here a is the left turning point, the boundary of the classically allowed region (Figure 1.7). The additional phase of $\pi/4$ is required to join $\psi(x)$ smoothly with the exponentially decaying solution in the classically forbidden region where $p(x)$ becomes purely imaginary ("tunneling"). With equal justification, we could have started from the classically forbidden region to the right of the turning point b and would find

$$\psi^{\mathrm{WKB}}(x) = \frac{A}{\sqrt{|p(x)|}} \sin \times \left(\frac{1}{\hbar}\int_x^b p(x')dx' + \frac{\pi}{4}\right) \qquad (123)$$

The uniqueness of $\psi^{\mathrm{WKB}}(x)$ mandates the equality of Eqs (122) and (123). The two are equal if the integral over the whole period of the trajectory (from a to b and back to a) equals

$$\left(\int_a^b + \int_b^a\right) p(x)dx = \oint p(x)dx = (n + \tfrac{1}{2})2\pi\hbar \qquad (124)$$

Equation (124) can be recognized as the Bohr–Sommerfeld quantization rule of the "old" quantum theory put forward prior to the development of quantum mechanics. Quantization rules were successful in exploring the discrete spectrum of hydrogen, one of the great puzzles that classical dynamics could not resolve. The additional term $\frac{1}{2} \times 2\pi\hbar$ in Eq. (124) was initially introduced as an empirical correction. Only within the semiclassical limit of QM does

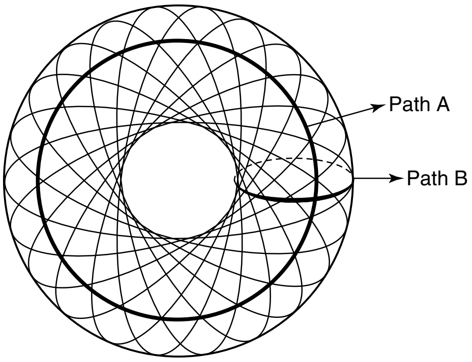

Fig. 1.12 Confinement of trajectories of an integrable Hamiltonian for constant energy E to the surface of a torus, shown here for a system with two degrees of freedom ($N = 2$) (after Noid and Marcus, 1977).

its meaning become transparent: it is the phase loss in units of $h = 2\pi\hbar$ of a matter wave upon reflection at the turning points (in multidimensional systems, at caustics). These phase corrections are of the form $\alpha(\pi/4)$ with $\alpha = 2$ in the present case. The quantity α is called the *Maslov index* and it is used to count the number of encounters with the caustics (in general, the number of conjugate points) during a full period of the classical orbit.

1.9.2
The EBK Quantization

The generalization of the WKB approximation to multidimensional systems faces fundamental difficulties: the momentum vector $\mathbf{p}(\mathbf{r})$ is, in general, not smooth but it is a highly irregular function of the coordinate vector $\mathbf{r}$ and takes on an infinite number of different values. Take, for example, a billiard ball moving in two dimensions on a stadium-shaped billiard table. A ball of a fixed kinetic energy $T = p^2/2M$ can pass through any given interior point $\mathbf{r}$ with a momentum vector $\mathbf{p}$ pointing in every possible direction. Consequently, the generalization of Eq. (121),

$$\psi(\mathbf{r}) = \sqrt{|D(\mathbf{r})|} \times \exp\left[\frac{i}{\hbar}\int_{\mathbf{r}_0}^{\mathbf{r}} \mathbf{p}(\mathbf{r}') \cdot d\mathbf{r}'\right] \tag{125}$$

is well defined only under special circumstances, that is, when $\mathbf{p}(\mathbf{r})$ is smooth and the action $S(\mathbf{r}_0, \mathbf{r}) = \int_{\mathbf{r}_0}^{\mathbf{r}} \mathbf{p} \cdot d\mathbf{r}'$ is either single valued or (finite-order) multiple valued (called a *Lagrangian manifold*; Gutzwiller, 1990). Einstein pointed out, as early as 1917, that the smoothness applies only to integrable systems, i.e., systems for which the number of constants of motion equals the number of degrees of freedom, N. For such a system, classical trajectories are confined to tori in phase space (as shown in Figure 1.12 for $N = 2$) and give rise to smooth vector fields $\mathbf{p}(\mathbf{r})$ (Figure 1.13). The corresponding quantization conditions are

$$\oint_{C_i} \mathbf{p}(\mathbf{r}) \cdot d\mathbf{r} = 2\pi\hbar\left(n + \frac{\alpha}{4}\right) \quad (i = 1, \ldots, N) \tag{126}$$

where C_i $(i = 1, \ldots, N)$ denote N topological distinct circuits on the torus, that is, circuits that cannot be smoothly deformed into each other without leaving the torus (for example, the paths A and B in Figure 1.12). The conditions of Eq. (126) are called the *Einstein–Brillouin–Keller* (*EBK*) quantization rules and are the generalization of the WKB approximation (Eq. 124). The amplitude of Eq. (125) is given by the projection of the point density of the torus in phase space onto the coordinate space. Since the point density is

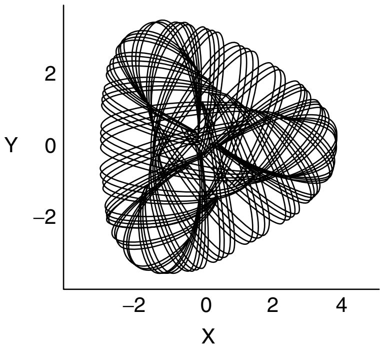

Fig. 1.13 Regular trajectory in coordinate space for an integrable system. The vector field **p**(**r**) is multiple valued but smooth (after Noid and Marcus, 1977).

uniform in the classical angle variables θ_i conjugate to the action (Goldstein, 1959), the amplitude is given by

$$|D(\mathbf{r})| \propto \det\left|\frac{\partial\theta_1\partial\theta_2\partial\theta_3}{\partial x\partial y\partial z}\right| \tag{127}$$

For a system with one degree of freedom ($N = 1$), Eq. (125) reduces to Eq. (121) since

$$\begin{aligned}\left|\frac{\partial\theta}{\partial x}\right|^{1/2} &= \left|\frac{\partial t}{\partial x}\frac{\partial\theta}{\partial t}\right|^{1/2}\\ &= \left|\frac{M}{p}\omega\right|^{1/2} \propto \frac{1}{|p|^{1/2}}\end{aligned} \tag{128}$$

1.9.3
Gutzwiller Trace Formula

As already anticipated by Einstein (1917), tori do not exist in many cases of practical interest – for example, for the motion of an electron in a stadium-shaped semiconductor heterostructure (Marcus *et al.*, 1992). WBK or EBK approximations are not applicable since the classical motion of such an electron is chaotic, destroying the smooth vector field **p**(**r**) as in the billiard discussed above. The semiclassical mechanics for this class of problems was developed only recently (Gutzwiller, 1967, 1970, 1971). The starting point is the semiclassical Van Vleck propagator (Van Vleck, 1928),

$$\begin{aligned}K^{\mathrm{SC}}&(\mathbf{r}_1,\mathbf{r}_2,t_2-t_1)\\ &= \sqrt{|D(\mathbf{r}_1,\mathbf{r}_2,t_2-t_1)|}\\ &\quad\times\exp\left[\frac{i}{\hbar}\int_{t_1}^{t_2} L(\mathbf{r}(t'))dt' - \frac{i\alpha\pi}{2}\right]\end{aligned} \tag{129}$$

where L is the classical Lagrange function for the particle traveling along the classically allowed path from $\mathbf{r}_1$ at time t_1 to $\mathbf{r}_2$ at time t_2 and α counts the number of singular points of the amplitude factor D (similar to the Maslov index). If more than one path connects $\mathbf{r}_1(t_1)$ with $\mathbf{r}_2(t_2)$, the coherent sum of terms of the form in Eq. (129) must be taken. The Van Vleck propagator was recognized only 20 years later (Feynman, 1948) as the semiclassical limit of the full Feynman quantum propagator

$$\begin{aligned}K&(\mathbf{r}_1,\mathbf{r}_2,t_2-t_1)\\ &= \int\{D\mathbf{r}\}\exp\left[\frac{i}{\hbar}\int_{t_1}^{t_2} L(\mathbf{r},t')dt'\right]\end{aligned} \tag{130}$$

where $\{D\mathbf{r}\}$ stands for the path integral, that is the continuous sum over all paths connecting $\mathbf{r}_1$ and $\mathbf{r}_2$ including all those that are classically forbidden. In the semiclassical limit $\hbar \to 0$, the rapid oscillations in the phase integral cancel all contributions except for those stemming from the classically allowed paths for which the actions $\int L dt$ possess an extremum or, equivalently, for which the phase in Eq. (130) is stationary.

Equation (129) provides a method for investigating the semiclassical time evolution of wave packets in time-dependent problems. The Fourier–Laplace transform of Eq. (129) with respect to t yields the semiclassical Green's function $G(\mathbf{r}_1, \mathbf{r}_2, E)$. The spectral density of states of a quantum system can be shown to be

$$n(E) = \sum_i \delta(E - E_i) = -\frac{1}{\pi}\mathrm{Tr}\,\mathrm{Im}\, G(\mathbf{r}_1 = \mathbf{r}_2, E) \qquad (131)$$

where the trace implies integration over the variables $\mathbf{r}_1, \mathbf{r}_2$ with constraint $\mathbf{r}_1 = \mathbf{r}_2$. Note that each of these eigenenergies causes a sharp peak (resembling the singularity of the δ function) in $n(E)$. Calculation of $n(E)$ therefore allows the determination of eigenenergies of quantum systems. It is possible to evaluate Eq. (131) in the semiclassical limit by using the semiclassical Green's function and evaluating the trace in the limit $\hbar \to 0$ by the stationary-phase method. The result is the trace formula

$$n(E) = n_{\mathrm{av}}(E) + \mathrm{Im}\frac{1}{i\hbar\pi} \times \sum_{\substack{\text{periodic}\\ \text{orbits}}} \frac{T_i}{2\sinh(T_i\lambda_i/2)} \times \exp\left[i\left(\frac{S_i}{\hbar} - \alpha_i\frac{\pi}{2}\right)\right] \qquad (132)$$

The sum extends over all unstable classical periodic orbits, each characterized by the period T_i, the instability (or ''Lyapunov'') exponent λ_i, and the action S_i, all of which are functions of the energy E. An orbit is unstable if its Lyapunov exponent is positive. The term λ_i measures the rate of exponential growth of the distance from the orbit when the initial condition is ever so slightly displaced (Gutzwiller, 1990). The smooth average density of states,

$$n_{\mathrm{av}}(E) = \frac{d}{dE}\left(\frac{V(E)}{(2\pi\hbar)^N}\right) \qquad (133)$$

is given by the rate of the change of the classical phase-space volume with energy in units of the volume of Planck's unit cell $(2\pi\hbar)^N$ associated with each quantum state. The derivation of Eq. (132) assumes two degrees of freedom and makes explicit use of the fact that the physical system is completely chaotic and integrable regions are absent. Only (hyperbolic) unstable periodic orbits are assumed to exist, each with a positive Lyapunov exponent $\lambda_i > 0$ that measures the instability of each periodic orbit. Equation (132) is therefore complementary to the EBK quantization formula (Eq. 126). This formula of ''periodic orbit quantization'' is an asymptotic series, that is, the sum over all periodic orbits is, in general, divergent. For several systems, the sum over the first few orbits has been shown to reproduce the position of energy levels quite well. The mathematical and physical properties of the Gutzwiller trace formula are still a topic of active research in quantum mechanics.

1.10
Conceptual Aspects of Quantum Mechanics

QM has proved to be an extraordinarily successful theory and, so far, has never been in contradiction to experimental observation. The Schrödinger equation has cleared every test carried out so far, including a precision test of its linearity: the upper bound for corrections due to nonlinear terms in the wave functions,

$\psi(x)^n$ ($n > 1$), in the Schrödinger equation stands currently at one part in 10^{27} (Majumder *et al.*, 1990). Even so, the conceptual and philosophical aspects of QM have remained a topic of lively discussion stimulated, to a large part, by the counterintuitive consequences of QM that apparently defy common-sense interpretation. The debate, which can be traced to the origins of QM and Einstein's objections summarized in his famous quote "Gott würfelt nicht" ("God does not play dice"), is centered around two aspects: the superposition principle, Eq. (15), and the probability interpretation of the wave function, Eq. (39).

1.10.1
Quantum Mechanics and Physical Reality

The counterintuitive aspects of the superposition principle are highlighted by the thought experiment of "Schrödinger's cat." The coherent superposition of two states, each of which is presumably an eigenstate of an extremely complex many-body Schrödinger equation, describes the state of the cat, being either dead, $|d\rangle$, or alive, $|a\rangle$:

$$|\psi_{\text{cat}}\rangle = c_d|d\rangle + c_a|a\rangle \tag{134}$$

with $|c_d|^2+|c_a|^2=1$. Only by way of measurement, that is, by projection onto the states $|a\rangle$ or $|d\rangle$,

$$P_a = |\langle a|\psi_{\text{cat}}\rangle|^2, \quad P_d = |\langle d|\psi_{\text{cat}}\rangle|^2 \tag{135}$$

can we find out about the fate of the cat. While the meaning of two sharply different outcomes of Eq. (135), "dead" or "alive," is deeply engraved in our classical intuition, the quantum state of a coherent superposition, Eq. (134), defies any classical interpretation. Yet it is an accessible state of the system. The point to be emphasized is that it is not our incomplete knowledge of an independently existing objective reality, but the fate of the cat itself, that can only be resolved by the measurement. Such a measurement is therefore, quite literally, a "demolition" measurement leading to the "collapse" of the wave function to one of the two possible states. In hypothetical thought experiments for macroscopic systems such as Schrödinger's cat problem, the average over a huge number ($\sim 10^{23}$) of uncontrolled degrees of freedom will, for all practical purposes, destroy any well-definded phase relation or coherence between the "states" dead and alive. In contrast, the axioms of QM can be put to a rigorous test for microscopic systems, for example, by performing correlation measurements on two particles emitted from the same source. Examples along these lines were, for example, put forward by Einstein, Podolsky and Rosen (1935) to challenge the purely probabilistic interpretation of QM.

Consider the emission of two electrons from, for example, a helium atom (Figure 1.14). The spin of each electron $i = 1,2$ can be in a coherent superposition state of spin up $|+\rangle$ and spin down $|-\rangle$,

$$|\psi_i\rangle = \alpha_i|+\rangle + \beta_i|-\rangle \tag{136}$$

relative to one particular Cartesian axis, for example, the z axis. One possible spin state of the electron pair (ignoring here the antisymmetrization requirement for fermions) would be an uncorrelated product state,

$$|\psi\rangle = |+\rangle_1|-\rangle_2 \tag{137}$$

Already Schrödinger pointed out that quantum theory allows to be alternatively

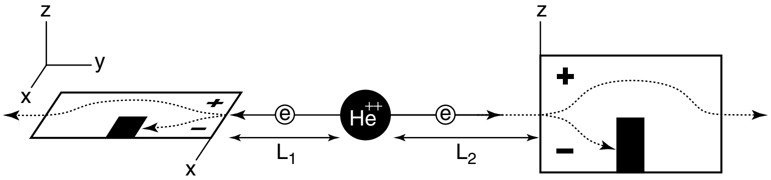

Fig. 1.14 Two-electron emission from helium with the electrons being spin-analyzed in two Stern–Gerlach-type filters with different orientations (along the x and z axis, respectively). The difference in length, $L_1 < L_2$, makes the spin selection in the left detector happen first (inducing a "wave function collapse") and in the right detector later.

in an entangled (or quantum-correlated) superposition state,

$$|\psi\rangle = \alpha|+\rangle_1|-\rangle_2 + \beta|-\rangle_1|+\rangle_2 \qquad (138)$$

In fact, the electron pair in the (singlet) ground state of helium with total spin $S = 0$ forms such an entangled pair with $\alpha = -\beta = 1/\sqrt{2}$. The hallmark of entangled states of the form Eq. (138) is that they cannot be represented as a factorized product in the form of Eq. (137).

The consequences of such quantum correlations are profound: when measuring the spin of particle 1 to be up (+), we know with certainty that particle 2 has its spin down (−). The "collapse" of the entangled wave function when measuring particle 1 forces particle 2 to switch its spin from a completely undetermined state to a well-defined value. We therefore obtain information about the orientation of spin 2 without actually performing a measurement on this particle. This correlation, often referred to as the *nonlocality of QM*, is a consequence of the probabilistic description and superposition of wave functions in QM. The emergence of a definite physical property or physical reality by "postselection" through the measurement of an entangled state goes even further. For example, the entangled state Eq. (138) with $\alpha = -\beta = 1/\sqrt{2}$,

$$|\psi\rangle = \frac{1}{\sqrt{2}}(|+\rangle_1|-\rangle_2 - |-\rangle_1|+\rangle_2) \qquad (139)$$

is rotationally symmetric and equally applies when we inquire about the spin orientation along the x rather than along the z axis. If we postselect the spin-up direction (+) along the x axis for the first particle, the second particle will have spin down (−) along the same axis. If we, instead, measured for the second particle the polarization relative to the z axis as before (Figure 1.14), we would find both spin up and down with 50% probability, and thus a vanishing average spin. Different projection protocols for the first spin imply entirely different results for the second. The emergence of a specific "physical reality" out of a specific measurement context is often referred to as *quantum contextuality* and is unknown in classical physics. It has therefore been questioned whether the quantum mechanical description of a state such as in Eq. (138) can be considered a complete picture of physical reality (Einstein, Podolsky and Rosen, 1935). In particular, it was conjectured that particles may have additional properties that are underlying the quantum-mechanical picture but which are hidden from our view. Such "hidden variables" would ensure that physical systems have only properties that are "real," that is, independent of a measurement and that the result of any measurement is only dependent on "local" system properties rather than on a remote detection of another observable. The knowledge of "hidden variables" would allow one to remove the probabilistic aspects of QM. The role of probability in QM could then be the same as in statistical mechanics: a convenient way to quantify our incomplete knowledge of the state of a system. The hidden-variable hypothesis, or alternatively, the quantum correlation built into entangled states, Eq. (138), has been probed by testing the violation of Bell's inequality (Bell, 1969; Clauser *et al.*, 1969). Experiments with correlated pairs of particles, in particular photon pairs – for example, by Aspect and coworkers (1982) – have falsified the hidden-variable hypothesis by showing that entangled states can violate Bell's inequality while being in full agreement with the predictions of QM. More recent experiments have succeeded in measuring entangled photons at a distance of several hundred meters apart and with light polarizers (used as photon analyzers), which switch their axes so rapidly that during the photons' time of flight the polarizers have no chance to exchange information on their respective orientation. (The "collapse" of the wave function by measuring one of the two photons occurs instantaneously for both photons, but cannot be used to transmit any information and therefore does not violate the relativistic causality relations.) Even under such stringent conditions, a violation of Bell's inequality by more than 30 standard deviations was observed experimentally (Weihs *et al.*, 1998). Also so-called noncontextual hidden-variable theories and realistic models that assume a certain type of "nonlocality" are untenable (Hasegawa *et al.*, 2006; Gröblacher *et al.*, 2007).

1.10.2
Quantum Information

The most fundamental unit of information in classical information theory is the so-called bit, which can take on only one of two mutually exclusive values (typically labeled as "0" and "1"). In conventional computers, all numbers and operations with them are encoded in this binary system. The corresponding quantum analog of the bit – named *qubit* – is given by a two-state system with the two states $|+\rangle$ and $|-\rangle$ from Eq. (136), now labeled as $|0\rangle$ and $|1\rangle$. What sets the qubit apart from the conventional classical bit is precisely the ability to be in a coherent superposition of both basis states,

$$|Q\rangle = \alpha|0\rangle + \beta|1\rangle \tag{140}$$

with $|\alpha|^2 + |\beta|^2 = 1$. In quantum information theory, the intrinsic indeterminacy of the qubit's value before a measurement is exploited as a resource rather than treated as a deficiency.

One potential application of qubits is subsumed under the name "quantum computation". The basic building block of a so-called quantum computer would be a number of N entangled qubits that can be in any superposition of 2^N basis states. An example for $N = 2$ is just the maximally entangled pair in Eq. (139). While a collection of N classical bits can only be in a single one of the 2^N possible states at a given time, N qubits can be in any superposition state and thus can clearly have a much higher information content. Owing to the superposition principle, any of the (unitary) logic operations of the quantum computer performed on the initial state could process all the involved 2^N basis states simultaneously. Several algorithms have been suggested (Shor, 1994; Grover, 1996) for how this inherently quantum feature of ''parallel processing'' could be used to solve fundamental computational problems much faster, i.e., with much fewer operations than with the corresponding classical computations.

The manipulation of quantum states within the framework of quantum computation and quantum information processing involves a set of rules as, for example, the so-called no cloning theorem (Wootters and Zurek, 1982), which states the impossibility to create identical copies of an arbitrary unknown quantum state. Although only imperfect ''clones'' of a quantum state are possible, a transfer of a quantum state from one system to a second, possibly distant, system is allowed according to QM. Such a ''teleportation'' of a quantum state involves the destruction of the original state during the teleportation procedure and is typically performed through an intermediate entangled state of three particles (Bennett *et al.*, 1993; Bouwmeester *et al.*, 1997).

The laws of QM can also be used for secure information transfer. In classical cryptography, secret messages are enciphered by way of a code that the recipient of a message must know in order to decipher a message's content. To prevent the breaking of the code by a third unauthorized party, the key for the encoding algorithm is preferably defined as a random sequence of numbers, which is generated anew for each message transmitted.

Challenges to classical cryptography are the need of a truly random key and the risk of key corruption through the interception by a third party. Both of theses challenges can be met by intrinsic quantum features. A truly random sequence of numbers can be generated, for example, by repeatedly measuring the spin orientation (or photon polarization) of an unpolarized spin, a situation that may be realized by first projecting the first spin of an entangled pair along a perpendicular direction (see the example of Fig. 1.14 above).

Interception of a message shared with the recipient through an entangled pair by a third party would require a measurement, which leads to a wave function collapse and to a detectable reduction in quantum correlations. Using the principles of QM for the generation and transmission of a secure encryption key – a technique that is referred to as *quantum cryptography* – has been successfully implemented for setups involving very large distances (144 km) between the sender and recipient (Ursin *et al.*, 2007).

1.10.3
Decoherence and Measurement Process

One fundamental obstacle in practically implementing quantum computation and quantum information protocols is the challenge to keep the coherent superposition of a quantum state, in particular of entangled pairs, ''alive'' for extended periods of time. Any unintentional or intentional interaction of the system inevitably and irreversibly converts the quantum superposition into a classical probability distribution and destroys the operating principle of a quantum information device. The measurement process and the destruction of coherence, frequently called *decoherence*, are closely intertwined. In the early days of quantum theory, the measurement device that caused the ''collapse'' of the wave function was considered to be a ''classical'' apparatus decoupled from the quantum dynamics to be observed

(Bohr, 1928). The notion of open quantum systems has superseded this view and provides a widely accepted unified description of measurement and decoherence within the realm of quantum theory. The starting point here is the fundamental insight that the quantum system (S) to be observed is never completely isolated from the environment (E), which itself is quantum rather than classical. The Hamiltonian describing both system and environment is given by $H = H_S + H_E + H_{S-E}$, containing the Hamiltonian of the system (H_S) and its environment (H_E), as well as the interaction between the two (H_{S-E}). A state describing both system and environment, $|\psi\rangle$, even when at the initial time $t = 0$ prepared in a factorizable state, $|\psi(t=0)\rangle = |\psi_S^i\rangle|\psi_E^j\rangle$, will evolve in the course of time under the influence of the interaction H_{S-E} into an entangled, nonfactorizeable state

$$|\psi(t)\rangle = \sum_{i,j} a_{ij}|\psi_S^i\rangle|\psi_E^j\rangle(t) \tag{141}$$

Here, $|\psi_S^i\rangle$ (and $|\psi_E^j\rangle$) are basis states of the system (of the environment), which often, but not always, are eigenstates of the Hamilton operator of the system H_S (of the environment H_E). "Tracing out" the (unobserved) environment degrees of freedom of the entangled state by taking expectation values leads to decoherence in the (observed) system and mimics the effect of a classical measurement device.

Consider, as an illustrative example, a situation in which the system and the environment are each represented by a two-dimensional Hilbert space and described by the following entangled state:

$$|\psi(t)\rangle = \alpha|+\rangle_S|-\rangle_E + \beta|-\rangle_S|+\rangle_E \tag{142}$$

The expectation value of any physical observable represented by an operator A_S acting only on the states in the Hilbert space of the system S gives in the presence of entangled environmental degrees of freedom,

$$\begin{aligned}\langle A_S\rangle &= \langle\psi|A_S|\psi\rangle \\ &= |\alpha|_S^2\langle+|A_S|+\rangle_S \\ &\quad +|\beta|_S^2\langle-|A_S|-\rangle_S \\ &= Tr(\rho A_S)\end{aligned} \tag{143}$$

with $\rho = |\alpha|^2|+\rangle_S\,{}_S\langle+| + |\beta|^2|-\rangle_S\,{}_S\langle-|$. It is the coherent entanglement with the environment, Eq. (142), that leads to (partial) decoherence within the system (S) and to a statistical mixture described by the density operator introduced above (Eq. 40) with probabilities $P_+ = |\alpha|^2$ and $P_- = |\beta|^2$. The ubiquitous coupling of a physical system to the environment provides the natural setting for the transition from the quantum indeterminism of superpositions to the definiteness of the classical measurement. The classical limit induced by decoherence is conceptually different from the classical limit of quantum systems of large quantum numbers, which is the focus of semiclassical mechanics (see Section 1.9). In spite of recent progress, it is generally still considered an open question if decoherence concepts alone can fully explain the quantum-to-classical transition and provide definite answers to the widely discussed questions regarding the "quantum measurement problem."

The above considerations demonstrate that it is very unlikely for a macroscopic object such as Schrödinger's cat to ever be in a superposition state "dead and alive" as in Eq. (134) because it is extremely difficult to isolate the cat from its environment. For all practical purposes, an exchange of particles and heat between the cat and its environment will prevent the cat, for itself, to be in a pure quantum state. It will rather be described by a density matrix with strongly reduced quantum correlations. As both the cat and the environment are macroscopic objects with many degrees of freedom, decoherence sets in at an extremely short timescale. Recent experiments have been able to sufficiently decouple "mesoscopic" objects as superconducting rings (Friedman *et al.*, 2000) from their environment to observe these systems in superposition states.

1.11
Relativistic Wave Equations

When the characteristic speed v of particles in a physical system becomes comparable to the speed of light, $v \leq c$, the Schrödinger equation, which incorporates nonrelativistic quantum dynamics, fails. Generalizations to relativistic wave equations face, however, fundamental difficulties due to the possibility of particle creation and destruction in relativistic dynamics (*see* Chapter 2). For example, if photons have energies in excess of twice the relativistic rest energy of electrons, $E_\gamma > 2m_e c^2$, a pair consisting of an electron and its antiparticle, a positron, can be created. Therefore, the interpretation of $|\psi(\mathbf{r})|^2$ as a single-particle probability density is no longer possible. A consistent resolution of the difficulties can be accomplished within the framework of quantum field theory, which is outside the scope of this chapter. The relativistic analogs to the Schrödinger equation discussed in the following section are only applicable to relativistic systems in which particle production and destruction are not yet important.

1.11.1
The Klein–Gordon Equation

We use the same recipe that led us in Section 1.3 to the Schrödinger equation, i.e., we replace the quantities H and $\mathbf{p}$ by differential operators (Eq. 11), motivated by the de Broglie hypothesis. In this case, however, we use the relativistic relation between energy and momentum (*see* Chapter 2) instead of the nonrelativistic one, Eq. (9):

$$E - V(\mathbf{r}) = \sqrt{M^2c^4 + p^2c^2} \tag{144}$$

Following this recipe, we are led to

$$i\hbar\frac{d}{dt}\psi(\mathbf{r},t) = \left[\sqrt{-\hbar^2\nabla^2c^2 + M^2c^4} + V(\mathbf{r})\right]\psi(\mathbf{r},t) \tag{145}$$

Equation (145) has a major drawback: it treats the space and time derivatives asymmetrically. The Lorentz invariance of relativistic dynamics requires, however, that space and time coordinates be treated on equal footing. We thus start with the square of Eq. (144) and arrive at

$$\left[i\hbar\frac{\partial}{\partial t} - V(\mathbf{r})\right]^2\psi(\mathbf{r},t) = (-\hbar^2\nabla^2c^2 + M^2c^4)\psi(\mathbf{r},t) \tag{146}$$

This is the time-dependent Klein–Gordon equation, applicable to particles with integer spin. The corresponding stationary Klein–Gordon equation follows by replacing $i\hbar\partial/\partial t$ by E. Equation (146) gives an eigenvalue equation in E^2 rather than in E itself. Consequently, upon taking the square root of the eigenvalue, solutions with both signs, $\pm\sqrt{p^2c^2 + M^2c^4}$, will appear. The physical meaning of negative-energy solutions is discussed below. For a charged particle with charge q in the presence of an electromagnetic field, both the scalar potential $\phi (V = q\phi)$ and the electromagnetic vector potential $\mathbf{A}$ must be included by "minimum coupling":

$$\mathbf{p} \longrightarrow \mathbf{p} - q\mathbf{A} = \left(\frac{\hbar}{i}\right)\nabla - q\mathbf{A} \tag{147}$$

With this coupling, the Klein–Gordon equation is invariant under gauge transformations of the electromagnetic field as well as under Lorentz transformations.

1.11.2
The Dirac Equation

Instead of taking the square of Eq. (144), Dirac pursued a different approach in developing a Lorentz-invariant relativistic wave equation. He "linearized" the square root

$$\sqrt{c^2p^2 + M^2c^4} \longrightarrow \left(c\,\boldsymbol{\alpha}\cdot\mathbf{p} + \beta Mc^2\right) \tag{148}$$

with the subsidiary condition that the square of the linearized operator satisfies

$$\left(c\boldsymbol{\alpha}\cdot\mathbf{p} + \beta Mc^2\right)^2 = c^2p^2 + M^2c^4 \tag{149}$$

It turned out that solutions to this equation can be found only if all α_i $(i = x,\ y,\ z)$ and β are taken as matrices of minimum dimension 4×4. Equation (149) is satisfied if the matrices α_i, β satisfy the relations

$$\begin{aligned}\alpha_i\alpha_k + \alpha_k\alpha_i &= 2\delta_{ik}\\ \alpha_i\beta + \beta\alpha_i &= 0\end{aligned} \tag{150}$$

Accordingly, ψ is now a four-component entity (called a *spinor*), $\psi = \{\psi_i,\ i = 1, \ldots, 4\}$. The resulting Dirac equation describes spin $\frac{1}{2}$ particles. When a charged spin $\frac{1}{2}$ particle interacts with an electromagnetic field as described by minimal coupling, the stationary Dirac equation becomes

$$\begin{aligned}&[E - q\phi(\mathbf{r})]\psi(\mathbf{r})\\ &= \left[c\boldsymbol{\alpha}\left(\frac{\hbar}{i}\nabla - q\mathbf{A}\right) + \beta Mc^2\right]\psi(\mathbf{r})\end{aligned} \tag{151}$$

Dirac spinors permit the probability-density interpretation, that is, $|\psi(x)|^2 = \sum_{i=1}^{4} |\psi_i(x)|^2$. The physical meaning of the four components can be easily understood by considering a free particle. The energy eigenvalues are $E = \pm\sqrt{p^2c^2 + M^2c^4}$. In addition to the positive energies we find negative eigenenergies, which are a feature of relativistic quantum mechanics and which result from the fact that the square-root operator permits both the positive and negative sign of E. The four-spinor can be decomposed into two 2-spinors $\psi = (\phi_1,\ \phi_2)$ one of which represents the positive-energy solution and the other the negative-energy solution. Each component of the two-spinor wave function can be understood as a product of a configuration-space wave function $e^{i\mathbf{kr}}$ and a spin 1/2 eigenstate $|m_s = \pm 1/2\rangle$. A major success of the Dirac theory was that the intrinsic degree of an electron spin, which was a mere add-on within the Schrödinger theory, is incorporated into the Dirac equation from the outset. Furthermore, the g factor for the magnetic moment of the electron as well as the spectrum of the hydrogen atom can be derived from the Dirac equation to a very high degree of approximation. The pieces still missing are the quantum electrodynamic (QED) corrections that lead to small energy shifts of atomic levels ("Lamb shift") and the deviations of the g factor for the anomalous magnetic moment from

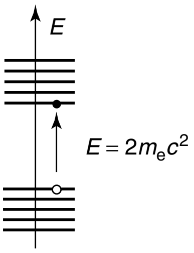

Fig. 1.15 Particle–antiparticle production visualized as the excitation of a negative-energy particle to positive energies leaving behind a hole.

2, $g = 2 \times 1.001\,16$. These corrections can be determined only within quantum field theory, the theory of the interactions of charged particles with the quantized electromagnetic field.

The negative-energy states, according to Dirac, can be interpreted in terms of antiparticle states. The vacuum state of empty space is represented by a fully occupied "sea" of negative-energy states. While this "sea" itself is not observable, "holes" created in the sea by exciting negative-energy electrons to positive energies (Figure 1.15) are observable and appear as antiparticles. For example, a missing electron with charge $-e$, energy $-E$, and momentum $\mathbf{p}$ represents a positron with charge e, energy E, and momentum $-\mathbf{p}$. The negative-energy states of electrons therefore offer a simple explanation of particle–antiparticle pair production in terms of the excitation of a negative-energy particle to a positive-energy state (the particle) leaving a hole in the negative-energy "sea" (the antiparticle) behind.

Glossary

Coherence and Decoherence: In QM, the term *coherence* stands for the ability of a particle's state to interfere. Perfectly coherent states ("pure states") are subject to the superposition principle of QM, whereas imperfections in the coherence are described by a density matrix with (partially) classical correlations. Decoherence stands for the loss of coherence as induced, for example, by coupling an isolated quantum system to its environment.

Correspondence Principle: The principle that quantum-mechanical and classical description of physical phenomena should become equivalent in the limit of vanishing de Broglie wavelength $\lambda \to 0$, or equivalently, of large quantum numbers.

de Broglie Wave: According to de Broglie, the motion of a particle of mass M and velocity v is associated with a matter wave with wavelength $\lambda = h/(Mv)$. h is Planck's quantum.

Delta (δ) Function: A particular case of a distribution, frequently used in quantum mechanics to formulate the orthogonality and normalization conditions of states with a continuous spectrum of eigenvalues.

Distributions: Also called *generalized functions*. Linear-continuous functionals operating on a metric vector space. They form the dual space of the metric vector space. In the context of quantum mechanics, the space is a Hilbert space and the operation of the functional on an element of the Hilbert space is called *formation of a wave packet*.

Eigenvalue Problem: The solution of the eigenvalue equation for the matrix A, $A\psi = \lambda\psi$ where λ is a number called an *eigenvalue* and ψ is the *eigenvector*. In quantum mechanics, ψ is a vector in Hilbert space.

Entanglement: An intrinsic feature of QM, occurring when particles or subsystems (in either case more than one), are correlated beyond a degree allowed by classical physics. Entangled systems, even when far apart, cannot be described independently of each other.

Hamilton–Jacobi Equation: A particular canonical transformation in classical dynamics that leads to the vanishing of the Hamiltonian function in the new coordinates. The transformation equation for the original Hamiltonian function is called the *Hamilton–Jacobi equation* and is equivalent to equations of motion.

Hilbert Space: Infinite-dimensional complete vector space over the complex numbers endowed with a metric induced by a scalar product that satisfies Schwartz's inequality.

Laser: Light amplication by stimulated emission of radiation. Modern source for high-intensity coherent electromagnetic radiation in the infrared, visible, and ultraviolet spectral region.

Schrödinger Equation: Fundamental equation governing the dynamics of a nonrelativistic quantum system, playing a similar role in quantum mechanics as do Newton's equations of motion in classical dynamics.

State: A mechanical system is at any given time completely characterized in quantum mechanics by the state ψ. The projection onto coordinate space, $\psi(\mathbf{r})$, is called a *wave function*. States are vectors in Hilbert space.

Superposition Principle: Any superposition in Hilbert space, $\psi = a\psi_1 + b\psi_2$, of two states ψ_1 and ψ_2 forms another physically realizable state of a physical system.

Uncertainty Principle: Two canonically conjugate variables, such as position x and momentum p, can be simultaneously measured only with an intrinsic uncertainty of at least $\Delta x \Delta p \gtrsim \hbar/2$.

Wave Function: The representation of the state $|\psi\rangle$ in coordinate space, $\psi(\mathbf{r}) = \langle \mathbf{r} \mid \psi \rangle$.

INTRODUCTION

A coherent state of light has identical noise on two quadrature components, which are cosine and sine components of the oscillating field. The product of the two quadrature noise components satisfies a (Heisenberg) minimum-uncertainty product, $\langle \Delta \hat{a}_1^2 \rangle \langle \Delta \hat{a}_2^2 \rangle = \frac{1}{16}$. Thus, a coherent state of light is a minimum-uncertainty state. A laser pumped at far above the oscillation threshold produces a coherent state of light, if the phase diffusion (Schawlow–Townes linewidth) caused by spontaneous emission is suppressed by an appropriate phase reference beam. Preparation of the phase reference beam is possible by dividing a laser output into two arms or by using an optical phase-locked-loop (PLL) technique. These techniques are standard in various optical precision measurements and communications. Indeed, the performance limits of various optical precision measurements are all attributed to the quantum noise of a coherent state of light mentioned above. For instance, when a laser intensity or phase is measured, so-called shot noise appears and determines a signal-to-noise ratio. The origin of this shot noise is the in-phase component noise $\langle \Delta \hat{a}_1^2 \rangle = \frac{1}{4}$ for an intensity measurement and the quadrature-phase component noise $\langle \Delta \hat{a}_2^2 \rangle = \frac{1}{4}$ for a phase measurement, if only

cosine component $\hat{a}_1$ carries a coherent (dc) amplitude. Such performance limits are often referred to as standard quantum limits (SQL).

A ground state of light ("darkest state") is also a coherent state, whose average field is zero, $\langle \hat{a}_1 \rangle = \langle \hat{a}_2 \rangle = 0$, but quadrature noise is still $\langle \Delta \hat{a}_1^2 \rangle = \langle \Delta \hat{a}_2^2 \rangle = \frac{1}{4}$. This quadrature noise of a ground state is often referred to as a quantum-mechanical zero-point fluctuation, and the ground state itself is called a vacuum state.

Electromagnetic fields with the noise on one quadrature component reduced to below the quantum-mechanical zero-point fluctuation level and the noise on the other quadrature component enhanced to above it are currently of great interest in quantum optics because of their potential applications to various precision measurements. Such quadrature squeezed states of light are usually produced by imposing nonlinear unitary evolution on coherent (or vacuum) states.

Slusher and co-workers at AT&T Bell Laboratories produced quadrature squeezed states for the first time in 1985. A most successful generation scheme for quadrature squeezed states has been a parametric amplifier. Kimble and co-workers at California Institute of Technology produced a cw squeezed state by a resonant cavity $\mathrm{LiNbO_3}$ parametric amplifier. Kumar and co-workers at Northwestern University generated a pulse squeezed state by a traveling-wave–type $\mathrm{LiNbO_3}$ parametric amplifier. An alternative generation scheme is a four-wave mixer. Levenson and co-workers at IBM Laboratories produced quadrature squeezed states by four-wave mixing in a fiber. Haus and co-workers at Massachusetts Institute of Technology observed a pulsed squeezed state in a Sagnac fiber-loop mirror.

A coherent state of light is also a minimum-uncertainty state for photon number and phase. The photon-number noise $\langle \Delta \hat{n}^2 \rangle = \langle \hat{n} \rangle$ and the phase noise $\langle \Delta \hat{\phi}^2 \rangle = 1/4\langle \hat{n} \rangle$ of a coherent state satisfy a (Heisenberg) minimum-uncertainty product, $\langle \Delta \hat{n}^2 \rangle \langle \Delta \hat{\phi}^2 \rangle = \frac{1}{4}$. Electromagnetic fields with the photon-number noise reduced to below that of a coherent state and the phase noise enhanced to above it or vice versa are called number-phase squeezed states. Number-phase squeezed states with reduced photon-number noise and enhanced phase noise are generated directly by a constant-current–driven semiconductor laser. This is the simplest scheme for the generation of nonclassical light, and so far it has yielded the largest photon-number-noise reduction. The mutual coupling between a lasing junction and an external electrical circuit provides opportunities for exploring the macroscopic and microscopic quantum effects in open optoelectronic systems.

A quadrature squeezed state has been discussed in detail in recent monographs (Meyster and Sargent, 1991; Walls and Milburn, 1994; Vogel and Welsch, 1994), and so we do not reproduce it in this article. We concentrate here on a number-phase squeezed state.

Cavity quantum electrodynamics (QED) is also an important subject of quantum optics which has been studied intensively for the last two decades. Spontaneous emission by an atom is not an immutable property of the atom but is a consequence of atom–vacuum-field coupling. The zero-point fluctuation of a vacuum field is continuous over a relevant frequency range for an atom and also isotropic in propagation direction in free space. This is why the spontaneous emission of an atom in free space is an irreversible process with a unique decay time. If an atom is enclosed by a cavity, the distributions of the vacuum-field fluctuations in frequency and space are modulated. For instance, if the atomic transition frequency is below the cutoff frequency of the cavity, the vacuum field that is responsible for spontaneous emission is expelled from the cavity and spontaneous emission is inhibited. If the atomic transition frequency is just on resonance of the cavity, the vacuum field that is responsible for spontaneous emission is resonantly trapped in the cavity and spontaneous emission is enhanced. Moreover, when the cavity has a high enough Q value (long photon lifetime), spontaneous emission can be made even a reversible process. Such cavity QED effects have been demonstrated for a two-level atomic system.

A new class of optical microresonators is making possible the exploration of such quantum-electrodynamic phenomena in condensed-matter systems and providing microlasers with a wide range of potential applications. The coupling efficiency of spontaneous emission into a lasing mode and the spontaneous emission rate can be modified by various semiconductor microcavity structures. By increasing the coupling efficiency, semiconductor lasers with a very low threshold current and semiconductor lasers and light-emitting diodes with a high quantum efficiency, broad modulation bandwidth, and low noise can be realized. Atomic cavity QED effects have been discussed in a recent monograph (Berman, 1994), and so we concentrate here on semiconductor cavity QED effects and microlasers.

Quantum nondemolition (QND) measurements are the repeated measurements of an observable without changing the free evolution of the observable. The measurement error of the observable and the back-action noise imposed on the conjugate observable satisfy the Heisenberg uncertainty relationship. The measurement back action on the measured observable can be eliminated by choosing an observable and constructing a measuring device appropriately. The concept of QND measurements was created for improving the sensitivity of gravitational wave detection, but various QND measurement schemes have been actively studied in quantum optics.

The quantum-mechanical properties of long-lived optical pulses in a fiber known as solitons have recently been studied theoretically and observed experimentally. These experiments suggest effective ways of reducing quantum noise (squeezing) in signal transmission and of performing quantum-mechanical nondemolition measurements without destroying the signal. We discuss such soliton quantum effects with special emphasis on squeezing and QND measurements.

1. SQUEEZING—CONTROL OF QUANTUM STATES OF LIGHT

1.1 Introduction

Quantum statistical properties of laser light have been extensively studied during the last 30 years. A laser is a nonequilibrium open system. A nonequilibrium cavity internal field and population inversion, which are referred to as "systems," are coupled to thermal-equilibrium cavity external fields and pump source, etc., which are referred to as "reservoirs." Separation of system dynamics from reservoir dynamics is usually employed in the theoretical analysis of such an open system. Indeed, a quantum-mechanical reservoir theory has been successfully applied to a laser (Haken, 1970; Sargent *et al.*, 1974; Louisell, 1973). Coherent states of light, which feature quantum-mechanical zero-point fluctuations around the average field excitation, have also been extensively studied in quantum optics (Glauber, 1963). The ordinary shot noise usually observed on direct detection of the laser output light has been attributed to the quantum-mechanical zero-point fluctuations. An ideal laser pumped at well above the oscillation threshold generates a coherent state of light with the exception of random-walk phase-diffusion noise (Loudon, 1973). Various experimental facts, such as Poissonian photoelectron statistics, shot-noise–limited photocurrent spectra, and Gaussian homodyne detection output statistics, supported the above conclusion. It was also suggested that the quantum statistical properties of a semiconductor laser are essentially the same as those of other lasers (Haug and Haken, 1967). However, a semiconductor *pn*-junction laser converts electrons injected via an electrical current to coherent photons by stimulated emission.

Recent theoretical and experimental studies on quantum-noise properties of a semiconductor laser have revealed that the semiconductor *pn*-junction laser produces photon-number squeezed states with photon-number noise reduced to below the standard quantum limit (SQL) $\langle \Delta\hat{n}^2 \rangle = \langle \hat{n} \rangle$ (Yamamoto *et al.*, 1992). The conventional quantum reservoir theory cannot describe the result. We must take into account the mutual coupling between the pump electrical circuit and the lasing junction. This generation scheme of photon-number squeezed states is in sharp contrast to the conventional means of generating squeezed states of light, in which coherent states produced by a laser are unitarily transformed to squeezed states by various nonlinear optical processes (Kimble and Walls, 1987).

1.2 Brief Review of Squeezed States

The Heisenberg uncertainty principle for two conjugate observables $\hat{O}_1$ and $\hat{O}_2$ is the direct consequence of the commutation relation between them (Messiah, 1961). It can be derived by the Schwartz inequality

$$[\hat{O}_1,\hat{O}_2] = i\hat{O}_3 \Rightarrow \langle \Delta\hat{O}_1^2\rangle\langle \Delta\hat{O}_2^2\rangle \geq \tfrac{1}{4}\,|\langle \hat{O}_1,\hat{O}_2\rangle|^2 = \tfrac{1}{4}\,\langle \hat{O}_3\rangle^2, \tag{1}$$

where $\Delta\hat{O}_i = \hat{O}_i - \langle \hat{O}_i\rangle$, $i = 1,2$. A state that exactly satisfies the equality in Eq. (1) is called a minimum-uncertainty state and is mathematically defined as an eigenstate of the operator

$$\hat{O}(r) = e^r\hat{O}_1 + ie^{-r}\hat{O}_2, \tag{2}$$

where r is a squeezing parameter. That is, r determines the distribution of quantum noise between $\hat{O}_1$ and $\hat{O}_2$:

$$\begin{aligned}\langle \Delta\hat{O}_1^2\rangle &= \langle \Delta\hat{O}_1^2\rangle_{r=0}e^{-2r},\\ \langle \Delta\hat{O}_2^2\rangle &= \langle \Delta\hat{O}_2^2\rangle_{r=0}e^{2r}.\end{aligned} \tag{3}$$

A quadrature-squeezed state of the electromagnetic field is a minimum-uncertainty state, in which $\hat{O}_1$ and $\hat{O}_2$ correspond to the two quadrature phase components $\hat{a}_1 = \frac{1}{2}(\hat{a} + \hat{a}^\dagger)$ and $\hat{a}_2 = (1/2i)(\hat{a} - \hat{a}^\dagger)$. The term $\hat{O}_3$ is then a c-number ($= \frac{1}{2}$). The squeezed state features reduced quantum noise in one quadrature and enhanced quantum noise in the other quadrature. In the special case of $r = 0$, the two quadrature components share the same amount of quantum noise, namely, $\langle \Delta\hat{a}_1^2\rangle = \langle \Delta\hat{a}_2^2\rangle = \frac{1}{4}$. This is a characteristic of a coherent state (Glauber, 1965). The electromagnetic field generated by a classical oscillating current is a coherent state (Glauber, 1965). Its quadrature-component quantum noise is sometimes referred to as the standard quantum limit (SQL). In order ultimately to reduce the noise in one of the quadratures to zero, the electromagnetic-field mode must have an infinite photon number and thus an infinite energy. This is because the enhanced quadrature noise component will require part of the total photon number (Yuen, 1976):

$$\langle \hat{n}\rangle_{SS} = \langle \hat{a}_1\rangle^2 + \langle \hat{a}_2\rangle^2 + \sinh^2(r) \underset{(r\to\infty)}{\longrightarrow} \infty. \tag{4}$$

That is, there is a trade-off relation between quantum-noise reduction and the required photon number.

A number-phase squeezed state of the electromagnetic field is defined as

$$\hat{O}_1 = \hat{n} \equiv \hat{a}^\dagger\hat{a}, \tag{5}$$

$$\hat{O}_2 = \hat{S} \equiv (1/2i)[(\hat{n} + 1)^{-1/2}\hat{a} - \hat{a}^\dagger(\hat{n} + 1)^{-1/2}], \tag{6}$$

and

$$\hat{O}_3 = \hat{C} \equiv \tfrac{1}{2}[(\hat{n} + 1)^{-1/2}\hat{a} + \hat{a}^\dagger(\hat{n} + 1)^{-1/2}], \tag{7}$$

where $\hat{n}$, $\hat{S}$, and $\hat{C}$ are the photon-number operator, the sine operator, and the cosine operator, respectively (Jackiw, 1968). When r is equal to $-\frac{1}{2}\ln(2\langle \hat{n}\rangle)$ and the average photon number is much larger than one, the photon-number noise and the sine-operator noise (which corresponds to the classical phase noise) are reduced to $\langle(\Delta\hat{n})^2\rangle = \langle \hat{n}\rangle$ and $\langle(\Delta\hat{S})^2\rangle = \langle \hat{C}\rangle^2/4\langle n\rangle \simeq \frac{1}{4}\langle \hat{n}\rangle$. This photon-number and sine-operator noise is also referred to as the SQL. A number-phase squeezed state with r greater than $-\frac{1}{2}\ln(2\langle \hat{n}\rangle)$ features smaller photon-number noise and larger sine-operator (phase) noise than the SQL, while the minimum-uncertainty relationship $\langle(\Delta\hat{n})^2\rangle\langle(\Delta\hat{S})^2\rangle = \frac{1}{4}\langle \hat{C}\rangle^2$ is preserved. The photon-number noise can ultimately be reduced to zero (photon-number state) without requiring an infinite photon number, because the enhanced phase noise does not consume energy at all.

The above various photon states are described by the quasi-probability density (Q representation)

$$Q(\alpha) \equiv \langle \alpha|\hat{\rho}|\alpha\rangle = |\langle \alpha|\psi\rangle|^2, \tag{8}$$

where $|\psi\rangle$ is a state vector, $\hat{\rho}$ is a density operator, and $|\alpha\rangle$ is a coherent state with the complex eigenvalue α, and the real and imaginary parts of α correspond to $\langle \hat{a}_1\rangle$ and $\langle \hat{a}_2\rangle$, respectively. Neither a squeezed state or a number-phase squeezed state possesses a positive-definite diagonal $P(\alpha)$ function (Glauber, 1963) for the density operator, which implies that these states cannot be realized by a classical mixture of coherent states. The term "nonclassical photon states" for characterizing squeezed states has been coined because of this fact. Figure 1 compares the quasi-probability densities $Q(\alpha)$ of various quantum states of light.

An unmistakable mark of squeezed-state generation is the observation of quadrature amplitude squeezing. That is, a homodyne-

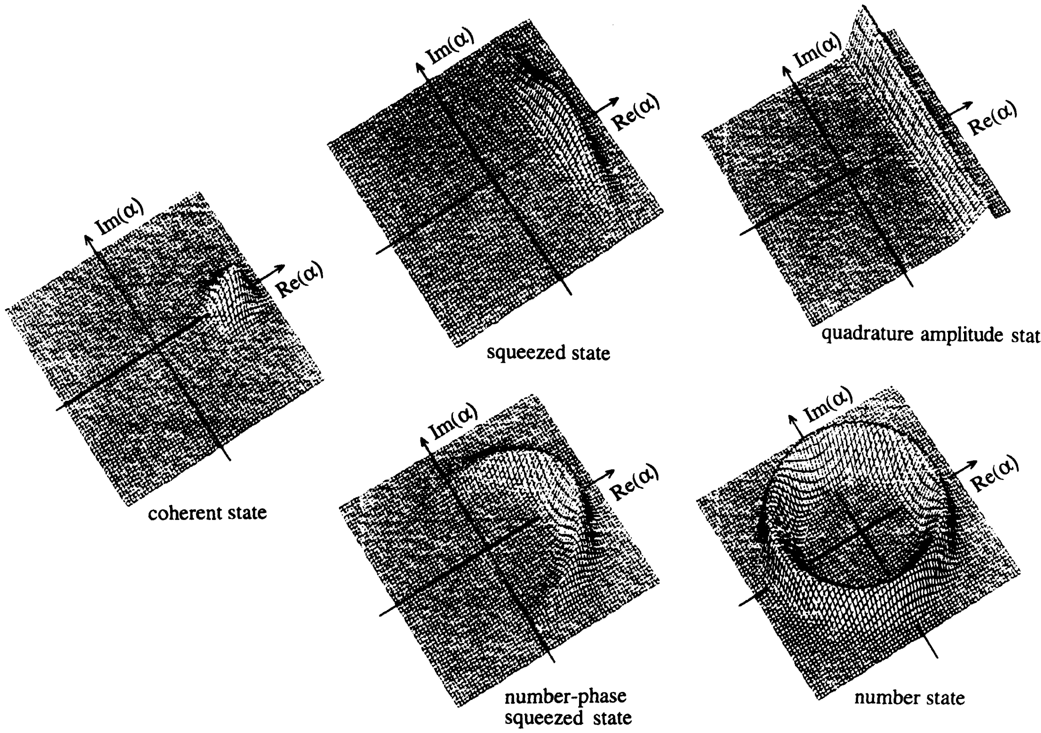

FIG. 1. Quasi-probability densities $Q(\alpha)$ of various quantum states of light.

detector output current will feature a reduced noise level below that for vacuum fields (Slusher *et al.*, 1985; Shelby *et al.*, 1986; Wu *et al.*, 1986). An unmistakable mark of number-phase squeezed-state generation, on the other hand, is the observation of amplitude squeezing. That is, a photon-counting detector output will feature a noise below the shot-noise level and thus sub-Poissonian photon statistics.

1.3 Principle of Squeezed-State Generation in Semiconductor Lasers

The macroscopic coherence of light and matter in a laser is established by the balance between the ordering force of "systems" (gain saturation in the case of a laser) and fluctuating forces from external "reservoirs." The conventional quantum-mechanical reservoir theory for a laser treats only three degrees of freedom as "systems": cavity internal field, population inversion, and dipole moment. All of the other degrees of freedom are considered as "reservoirs" and eliminated by use of the quantum-mechanical fluctuation–dissipation theorem.

A fluctuating force pertinent to our discussion is that from an external pump source. The pump fluctuating force for optically pumped lasers is usually shot-noise limited, because the pump light absorption by a gain medium is considered as a random Poisson point process. Of course, this is not a fundamental limit imposed by quantum mechanics. We may consider a thought experiment in which a gain medium is excited by photon-number states of light with a perfect absorption efficiency. The pump fluctuating force determined by the photon-number noise of pump light is reduced to zero for such a case (Golubev and Sokolov, 1984). The phase noise of pump light does not contribute to the pump noise of a laser at all, because a laser oscillator is an incoherently pumped device, in contrast to a parametric oscillator, which is a coherently pumped device.

The photon-number noise spectra for a pump-noise–suppressed laser are reduced to below SQL at frequencies below the cavity cutoff frequency at pump rates well above the threshold. The physical interpretation for the result is rather straightforward. Every absorbed pump photon is emitted sooner or later as a coherent lasing photon from the cavity, in which the stimulated emission by a strong laser field is much stronger than a random spontaneous emission at high pump rates. Therefore, if the emitted photon number is counted for a measurement time interval longer than the population lifetime and the photon lifetime, the photon statistics of the laser output should be the same as the photon statistics of the pump light. A high conversion efficiency is indeed only one criterion for such preservation of the absorbed pump-photon statistics to the emitted coherent photon statistics.

However, the phase noise spectra are increased to above SQL at frequencies below the cavity cutoff frequency because of the so-called Schawlow–Townes phase-diffusion process. The product of reduced photon-number spectrum $S_{\Delta N}(\Omega)$ and increased phase spectrum $S_{\Delta\psi}(\Omega)$ satisfies the Heisenberg uncertainty principle,

$$S_{\Delta N}(\Omega) S_{\Delta\psi}(\Omega) \geq 1. \tag{9}$$

In the limit of high pump rates, the product is higher by only a factor of 2 over the minimum-uncertainty product. A finite photon lifetime introduces the residual photon-number noise $S_{\Delta N}(\Omega)$ by a stochastic photon output process, and at the same time, it stores coherent photons inside the cavity, which leads to the stabilization of the phase noise $S_{\Delta\psi}(\Omega)$ by stimulated emission. This result suggests that the output field from a pump-noise–suppressed laser is not far from the number-phase squeezed state shown in Fig. 1. Similar states are also produced by either the quantum phase diffusion in a Kerr nonlinear medium (Kitagawa and Yamamoto, 1986) or the state reduction induced by a quantum nondemolition measurement (Kitagawa *et al.,* 1987) or by an idler photon-number measurement for a parametric amplifier output (Watanabe and Yamamoto, 1988).

Several schemes have been proposed to suppress the pump fluctuating force of a laser. One scheme utilizes sub-Poissonian space-charge–limited electron beams to obtain the Franck–Hertz effect (Teich and Saleh, 1985). Another utilizes three-level atoms as a gain medium, in which the pump process is self-regulated by a limited number of ground-state atoms (Bergou *et al.,* 1989; Haake *et al.,* 1989). The most practical and direct way of suppressing the pump fluctuating force is to use a constant-current source for a semiconductor injection laser.

The junction-current noise of a *pn* diode driven by a constant-voltage source is shot-noise limited. This fact has been erroneously identified as a "shot-noise–limited pump fluctuating force" for a semiconductor laser. The mistake in this argument is twofold. First, the junction-current noise is not a pump fluctuating force (cause) but a relaxation-current pulse (result) for the radiative recombination (photon emission) event in a junction. Second, a semiconductor laser usually operates under a constant-current mode rather than a constant-voltage mode.

The difference between constant-voltage mode and constant-current mode is schematically shown in Fig. 2. When a *pn* junction is driven by a constant-voltage source with a source resistance R_S much smaller than the diode's differential resistance R, that is, $R_S \ll R = k_B T/eI$, where k_B is the Boltzmann constant and T is temperature, the junction-voltage drop resulting from the radiative recombination of an electron–hole pair is quickly eliminated by an external circuit relaxation-current pulse. By the time the next radiative recombination event occurs, the junction voltage (number of electron–hole pairs in a junction) has recovered to the original value. In such a memoryless system, photon emission events follow a Poisson point process and the junction current carries full shot noise. On the other hand, when a *pn* junction is driven by a constant-current source with a source resistance much larger than the diode's differential resistance, that is, $R_S \gg R$, the junction voltage is not pinned by a source but is free to fluctuate. The fluctuation in the junction voltage caused by the radiative recombination has not recovered at the time of the next radiative recombination event. In such a system with memory, the photon emission events follow a sub-Poissonian process and the junction current carries noise below the shot-noise level because of self-stabilization.

The pump fluctuating force of a semiconductor laser is identified as the thermal noise

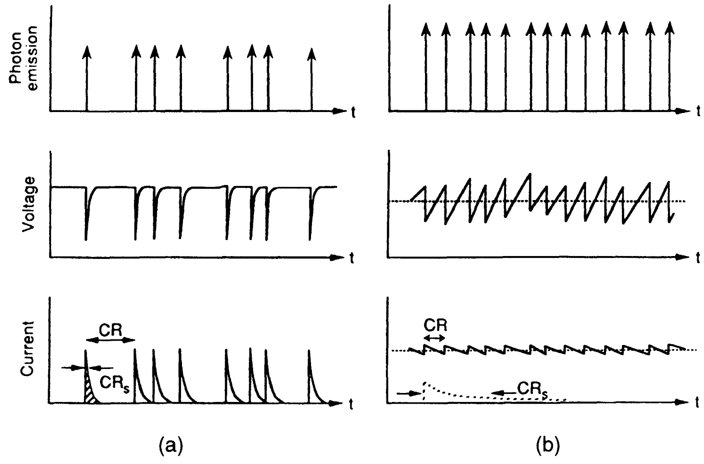

FIG. 2. The junction-voltage fluctuation and the relaxation-current pulse caused by a photon emission event for (a) $R \gg R_s$ (constant-voltage driving case) and (b) $R \ll R_s$ (constant-current driving case). C is the diffusion capacitance of a *pn* junction. The time constant CR corresponds to the electron lifetime, and CR_s is the external circuit relaxation time constant.

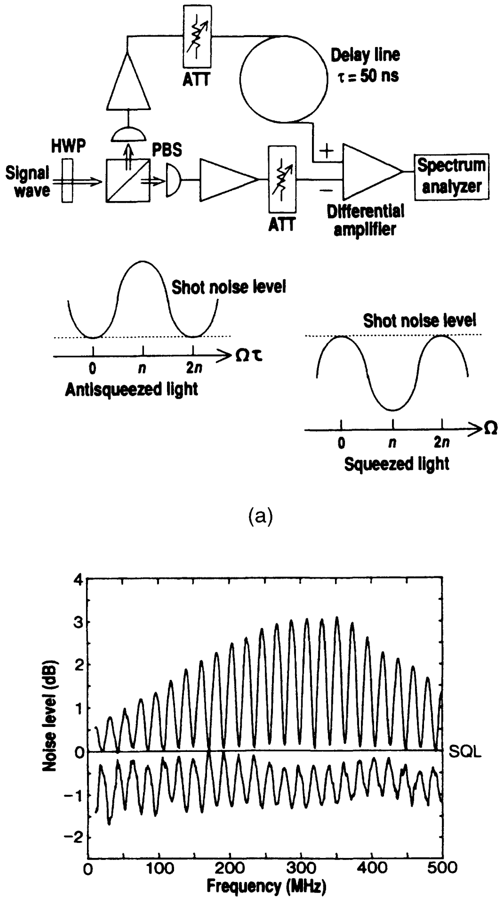
generated in the source resistance R_S, whose spectral density is $4k_BT/R_S$. The thermal noise is much higher than the shot-noise value $2eI$ for a constant-voltage source with $R_S \ll R$, but is much smaller than the shot-noise value for a constant-voltage source with $R_S \gg R$. The thermal-noise–limited pump fluctuating force and the dissipation rate of the junction voltage through the pump circuit satisfy the fluctuation–dissipation theorem exactly (Yamamoto *et al.*, 1991). In the case of a constant-current source, the dissipation rate $(CR_S)^{-1}$ of the junction voltage through a pump circuit is very slow and the fluctuating force from the pump circuit $4k_BT/R_S$ is also small. The two conditions necessary for the generation of photon-number squeezed states in semiconductor lasers, that is, the free voltage fluctuation and the pump-noise suppression, are satisfied simultaneously by $R_S \gg R$.

There is an analogy between the quantum states established in a *pn*-junction laser and in a superconductor tunnel junction. A Bloch oscillation at a frequency $f = I/2e$ is achieved in an ultrasmall superconductor tunnel junction driven by a constant-current source I, in which the number of tunneled electron pairs is regulated but the relative phase of the two superconductors is randomized (Likharev and Zorin, 1985). This is similar to the present scheme for the generation of photon-number squeezed states in a *pn*-junction laser driven by a constant-current source. On the other hand, an ordinary Josephson oscillation at a frequency $f = 2eV/h$ (h is Planck's constant) is observed in a macroscopic superconductor tunnel junction driven by a constant-voltage source V, in which the relative phase of two superconductors is fixed, but the number of tunneled electron pairs is random. This is similar to coherent-state generation in a conventional laser oscillator.

1.4 Squeezed-State Generation Experiments

Figure 3(a) shows a dual-balanced detector setup for measuring the photon-number noise spectrum from a semiconductor laser. A semiconductor laser output is split equally into the two arms by a half-wave plate and polarization beam splitter. One detector output current I_1 is delayed by a coaxial cable and combined with the other, undelayed, detector output current I_2 by a differential amplifier or 180° hybrid. For a fluctuation frequency Ω_{in} satisfying $\Omega_{\text{in}}\tau = 2N\pi$, where τ is the delay time and N is an integer, the differential amplifier output $I_1 - I_2$ calibrates the shot-noise value. For a fluctuation frequency Ω_{out} satisfying $\Omega_{\text{out}}\tau = (2N + 1)\pi$, the differential amplifier output $I_1 + I_2$ measures the photon-number noise of the laser output. Thus, the differential amplifier output simultaneously displays the laser noise and corresponding shot-noise values with a frequency period of $\Delta\Omega = 2\pi/\tau$ on a spectrum analyzer.

The measured noise spectra at two different pump rates for a GaAs transverse-junction stripe semiconductor laser are shown in Fig. 3(b). The noise spectra are normalized



(a)

(b)

FIG. 3. (a) A dual–balanced-detector setup for measuring the intensity noise of a semiconductor laser: HWP, half-wave plate; PBS, polarization beam splitter; and ATT, attenuator and equalizer. (b) The measured intensity-noise spectra normalized by the shot-noise value for two pump rates, I/I_{th} = 1.03 (upper curve) and I/I_{th} = 13.6 (lower curve). The solid line represents the standard quantum limit (SQL).

by the shot-noise value, which is independently calibrated by a light-emitting diode with the same wavelength as the laser. The noise spectrum at the pump rate just above the threshold, $I/I_{th} = 1.03$, shows a lower noise value at Ω_{in} and a higher noise value at Ω_{out}, where I_{th} is the threshold current. This is a characteristic of antisqueezed (super-Poissonian) light. The noise spectrum at the pump rate well above the threshold, $I/I_{th} = 13.6$, shows a higher noise value at Ω_{in} and a lower noise value at Ω_{out}, which is a characteristic of squeezed (sub-Poissonian) light.

The degree of squeezing is degraded by the Poissonian partition noise associated with optical loss. To increase the light-collection efficiency, a GaAs transverse-junction stripe laser, with less than 10% front-facet reflectivity R_1 and more than 90% rear-facet reflectivity R_2, is operated at 66 K to minimize the free-carrier absorption loss and is directly coupled to a Si photodetector to minimize the coupling loss. Figure 4(a) shows theoretical and experimental photon-number noise values normalized by the shot-noise value vs the normalized pump rate $I/I_{th} - 1$. The experimental results are corrected for a detection quantum efficiency of about 89%, so that the degree of squeezing shown in Fig. 4 corresponds to that of the laser output. The experimental maximum degree of squeezing, −14 dB (≃0.04), is in reasonable agreement with the theoretical limit imposed by the output coupling efficiency,

$$\eta = \frac{\ln(1/R_1)}{\ln(1/R_1R_2)} \simeq 0.97, \tag{10}$$

of the laser.

1.5 Poissonian Optical-Partition Noise versus Sub-Poissonian Electrical-Partition Noise

If a photon-number state of light is attenuated by an optical loss, random deletion of photons introduces a so-called partition noise. In the limit of large attenuation, photon statistics approach a Poisson distribution. This is often referred to as "Poissonian partition noise."

The overall quantum efficiency [(detector output current)/(laser driving current)] in the experiment demonstrated in Fig. 4 was only 48%. If all loss processes that are responsible for this quantum efficiency could commonly introduce a Poissonian partition noise, squeezing of more than 3 dB would be impossible. However, the observed degree of squeezing was 8.5 dB. An explanation of the counterintuitive experimental result has been worked out. The GaAs laser used in the experiment has a nonlasing junction in parallel with the lasing junction [Fig. 4(b)]. Under the operating conditions of $T \simeq 66$ K and $I \simeq 30$ mA, the leakage current is estimated to be approximately equal to the current in-

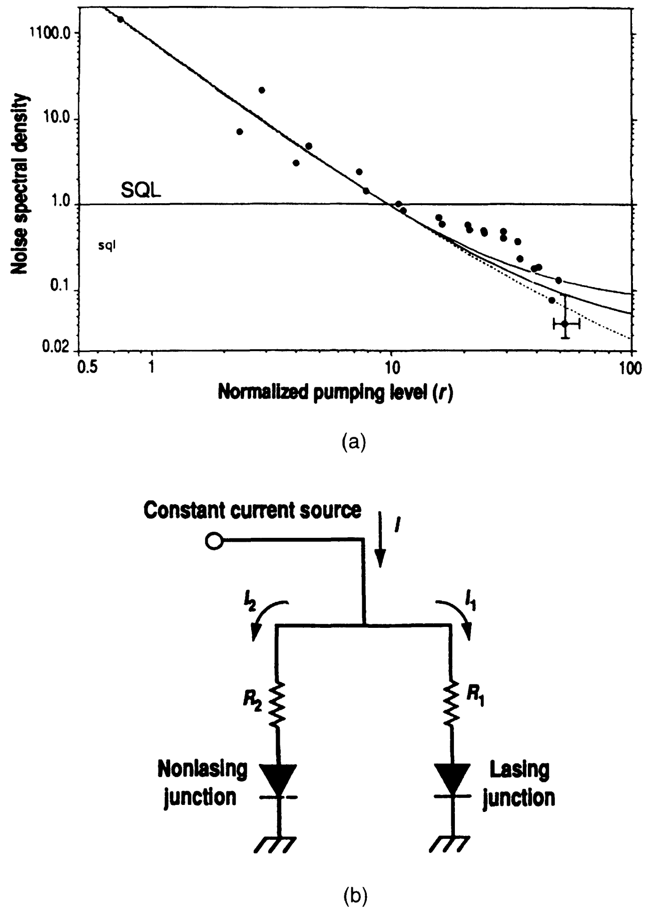


FIG. 4. (a) The theoretical (lines) and experimental (dots) intensity-noise values normalized by the shot-noise value vs the normalized pump rate $R \equiv I/I_{th} - 1$. The experimental results are corrected for a detection quantum efficiency of 89%. The three curves correspond to different internal absorption losses (the dotted line represents an ideal case of no absorption). (b) A model for current division into a lasing junction and a nonlasing junction.

jected into the lasing junction. That is, the overall quantum efficiency is degraded mainly by current division. This current division introduces a new noise source, which serves as a pump fluctuating force for the lasing junction.

A unified circuit theory has been developed for treating optical-partition noise and electrical-partition noise in the same circuit language. The current noise in two branching arms driven by a constant-current source is given by

$$i_1 = -i_2 = \frac{v_2 + v_{d2} - v_1 - v_{d1}}{2(R + R_d)}, \tag{11}$$

where it is assumed for simplicity that the two series resistances connected to the two (lasing and nonlasing) junctions are equal, $R_1 = R_2 = R$, and that the differential resistances of the two junctions are also equal, $R_{d1} = R_{d2} = R_d$. Here, v_i and v_{di} are the noise voltages associated with R and R_d. The spectra of i_1 and i_2 are given by

$$S_{i_1} = S_{i_2} = \begin{cases} 2k_BT/R & (R \gg R_d), \\ \frac{1}{2}eI & (R \ll R_d). \end{cases} \tag{12}$$

Here the quantum zero-point fluctuation $2\hbar\Omega R$ associated with R is neglected because it is much smaller than the thermal noise $4k_BTR$. Thus, if $R \ll R_d$, the current noise is only 3 dB below the shot-noise value. That is, current division introduces a Poissonian electrical-partition noise. On the other hand, if $R \gg R_d$, the current noise is much smaller than the shot-noise value. This condition is satisfied at a high current level $I \gg 2k_BT/eR$ for any small series resistance R. In this way, the sub-Poissonian character of a constant-current source is preserved against current division. The theoretical curve in Fig. 4(a) assumes a series resistance $R = 50\ \Omega$. In the case of photon flux division, the quantum zero-point fluctuation $2\hbar\omega R$ is much larger than the thermal noise $4k_BTR$ for which a Poissonian partition noise is always associated. Although such a macroscopic (circuit) theory successfully explains the experimental results, a microscopic theory, that is, a quantum theory of transport and division of charged particles in conducting wires, has yet to be worked out.

1.6 Quantum Correlation between Photon Number and Junction Voltage

The product of the reduced photon-number noise and the increased phase noise is generally higher than the minimum uncertainty product, $S_{\Delta N}(\Omega)S_{\Delta\phi}(\Omega) = 1$. The increased phase noise due to a random-walk phase diffusion is a noise inherent in any negative-conductance oscillators that do not have a restoring force for phase. On the other hand, there is a possibility that there is a hidden measurement for photon number in semiconductor lasers, which could lead to a further reduction in photon-number noise to the minimum value required by the uncertainty product.

In a constant-current–driven semiconductor laser, the junction-voltage fluctuation is related to the electron-number fluctuation through a junction capacitance. The electron-number fluctuation and the photon-number fluctuation are negatively correlated through the spontaneous emission, stimulated emission, and absorption. Consequently, it is expected that the photon-number noise can be determined by measuring the junction-voltage noise.

An experimental setup for measuring the quantum correlation between photon-number noise and junction-voltage noise is shown in Fig. 5(a). The photon-number noise of a semiconductor laser is measured by detector D2, and the shot-noise value is calibrated by a light-emitting diode and detector D1. The junction-voltage noise is measured independently and combined with the delayed photon-number noise by a wideband 180° hybrid. Figure 5(b) shows the measured junction-voltage noise (trace a), laser-intensity noise (trace b), shot noise (trace c), and combined noise of junction voltage and laser intensity (trace d). The sinusoidal variation shown by trace d manifests the correlation between the photon-number noise and the junction-voltage noise. In the absence of the correlation, trace d would be flat and the noise power numerically equal to the sum of the two noise powers given by traces a and b. The squeezed intensity noise is further reduced by the adding of the junction-voltage noise, which indicates that the correlation is negative and penetrates into a quantum region.

The junction voltage can be used as a quantum measurement probe of the photon number. Conditioned on the junction-voltage measurement result, the photon-number noise can be reduced to nearly the minimum value dictated by the uncertainty principle. This fact can be interpreted from the viewpoint of a "quantum watchdog effect" (Wheeler and Zurek, 1983). That is, the photon number is always monitored by the external pump circuit (the watchdog), even though an experimentalist does not actually read out the junction voltage. Partial (or perfect) reduction of a wave packet continuously occurs irrespective of readout actions made by the experimentalist. Such a hidden measurement introduces back-action noise on the observable conjugate to the measured observable. This inevitable back-action noise emerges as Schawlow–Townes phase-diffusion noise caused by the dephasing of dipole moments, that is, random-phase spontaneous emission.

1.7 Future

Photon-number squeezed states cannot be directly used to improve interferometric phase measurements such as a gravitational-wave–detection laser interferometer and a laser gyroscope. Such measurements require a reduced phase noise rather than a reduced photon-number noise, or more generally they require squeezed vacuum states. It is possible to change photon-number squeezed states into squeezed vacuum states (Lai *et al.,* 1991). A constant-current–driven semiconductor laser is injection-locked by an external master-laser oscillator. The phase correlation between the squeezed slave-laser output and the master-laser output is established without sacrificing appreciably the de-

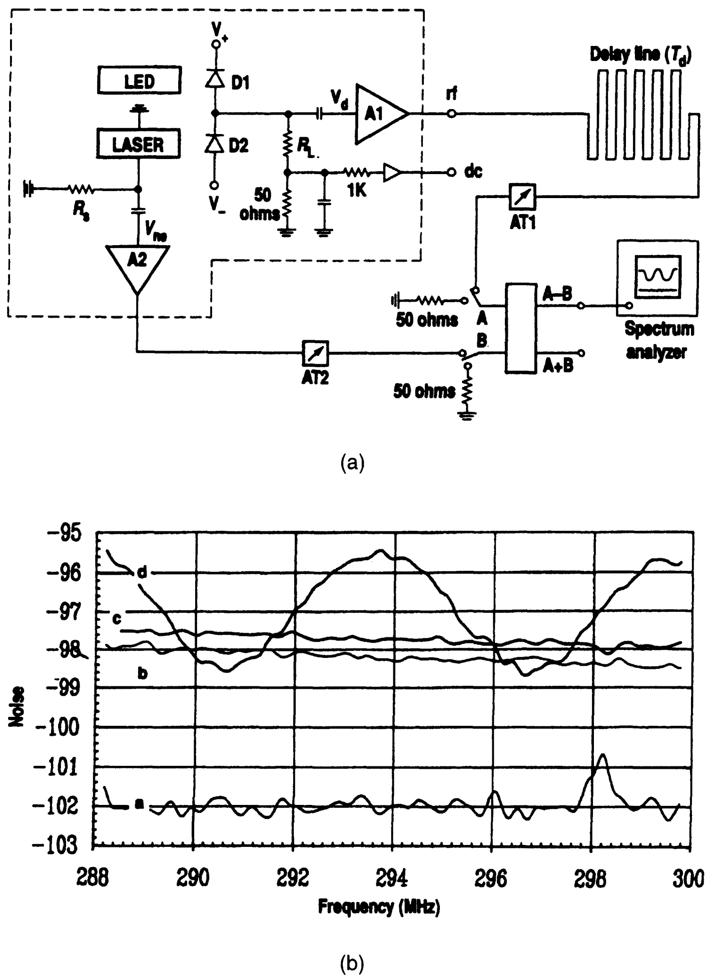

FIG. 5. (a) An experimental setup for measuring the quantum correlation between the photon-number noise and the junction-voltage noise; LED, light-emitting diode. (b) The measured junction-voltage noise (trace a), laser-intensity noise (trace b), shot noise produced by a light-emitting diode (trace c), and combined noise of junction voltage and laser intensity (trace d). The ordinate is the noise power P_n expressed as $(\mathrm{dB}_m) \equiv 10 \log_{10} P_n$ (nW). A1, A2: Amplifiers. AT1, AT2: Attenuators.

gree of photon-number squeezing. The classical signal part of the squeezed output from the slave laser can be canceled interferometrically; here, the quantum noise of the master-laser output can be suppressed with the use of a high-transmission mirror. Because a semiconductor laser emission wavelength can be chosen at any wavelength region from 0.45 to 1.7 μm, this squeezed vacuum-state generation technique can be applied to any laser interferometer system.

Photon-number squeezed states can be generated only at pump rates well above the threshold, because constantly injected electron–hole pairs are spontaneously emitted mainly into nonlasing modes at pump rates below and near the threshold. Random deletion due to such spontaneous emission introduces a Poissonian partition noise, which is even amplified at pump rates near the threshold. However, it is possible to confine all spontaneous emission into a single lasing mode by using a cavity quantum-electrodynamic technique, as described in the next section. The photon-number spectra for such a microcavity semiconductor laser with a unity coupling efficiency of spontaneous emission are reduced to below SQL at any pump rate. Only one criterion for generating photon-number squeezed states in a constant-current–driven semiconductor laser, a high conversion efficiency from electrons to photons, is satisfied by the microcavity without requiring the stimulated emission. Low-intensity squeezed light generated by such a light-emitting diode may find applications to the optical interconnection inside a large-scale integrated circuit, in which the energy dissipation for communication is already much larger than that for signal processing.

If we can decrease the current level I to less than e/τ_{sp} and satisfy the constant-current operation condition, where τ_{sp} is the spontaneous-emission lifetime, the charging time for one electron–hole pair into a junction can become longer than the radiative recombination lifetime. In such a case, coexistence of continuous uniform charging into the junction and discrete radiative recombination of an electron–hole pair will achieve the junction-voltage oscillation and single-photon emission at a frequency of $f = I/e$ (Imamoglu and Yamamoto, 1994). This is an optical analog of the Coulomb blockade, or single-electron (electron-pair) tunneling oscillation in an ultrasmall-capacitance tunnel junction. It is expected to open up a new field of combined single electronics and single photonics.

2. CAVITY QUANTUM ELECTRODYNAMICS—CONTROL OF SPONTANEOUS EMISSION

2.1 Introduction

Spontaneous emission is not a fixed property of an atom but a consequence of atom–vacuum-field coupling. It has been known for some time that the decay rate, transition energy, and radiation pattern of spontaneous emission can be altered by modifying vacuum-field fluctuations by a cavity wall. The principle, often referred to as cavity quantum electrodynamics (cavity QED), is a classic theoretical problem. Cavity-enhanced and -suppressed spontaneous decay rates were predicted by Purcell (1946). A cavity-induced radiative energy shift was pointed out by Casimir (Casimir and Polder, 1948). The nonlinear coupling of atom and vacuum fields was formulated by Jaynes and Cummings (1963), in which it was predicted that spontaneous emission becomes even reversible if an atom is put in a high-Q single-mode cavity. However, those effects have been observed only recently using either Rydberg atoms in microwave superconductor cavities or atoms in optical microcavities (Haroche and Kleppner, 1989, and references therein). The only exception is the pioneering work by Drexhage (1974), in which he demonstrated that the decay rate and radiation pattern of spontaneous emission are modified by a metal mirror.

Since spontaneous emission is a major source of energy loss, speed limitation, and noise in semiconductor optical devices, the possibility of employing cavity QED to control spontaneous emission is expected to improve the device performances fundamentally.

In this section, we review the principle of cavity QED, the performance of various microcavity structures, and the applications to semiconductor optical devices, such as light-emitting diodes and semiconductor lasers.

2.2 Brief Review of Atomic Cavity Quantum Electrodynamics

There are two distinct regimes in atomic cavity QED, i.e., a low-Q regime and a high-Q regime. A decisive parameter separating the two regimes is the vacuum Rabi frequency,

$$\Omega_R = \frac{p_{12}}{\hbar}\mathscr{E}_{\text{vac}} = \frac{p_{12}}{\hbar}\sqrt{\frac{\hbar\omega}{2\epsilon_0 V_0}}, \tag{13}$$

where p_{12} is an atomic dipole moment, $\mathscr{E}_{\text{vac}}$ is a vacuum-field amplitude, and V_0 is an optical cavity volume. When Ω_R is much smaller than the escape rate of a photon from the cavity and the decay rate of an atomic dipole moment, i.e., $\Omega_R \ll \gamma_{\text{photon}}, \gamma_{\text{dipole}}$, the atom–vacuum-field coupling is only weakly perturbed by the cavity and spontaneous emission remains an irreversible and incoherent process. Nevertheless, a cavity can modify the radiation pattern and decay rate. Spontaneous-emission rate is either inhibited or enhanced.

On the other hand, when $\Omega_R \gg \gamma_{\text{photon}}, \gamma_{\text{dipole}}$, the atom–vacuum-field coupling is strongly perturbed by the cavity and spontaneous emission becomes a reversible and coherent process. A coupled atom–field system, often referred to as a "dressed state," has two split eigenfrequencies. This vacuum Rabi splitting corresponds to a periodic energy exchange between the atom and field.

When N atoms collectively couple with the cavity field, the atom–field coupling strength is enhanced in proportion to $\sqrt{N}$. In a low-Q regime, the cavity enhances a so-called cooperative superradiant decay (Dicke, 1954). The decay rate is enhanced and the emission pattern is highly concentrated because of the formation of a gigantic dipole moment. In a high-Q regime, it corresponds to a collective Rabi splitting. The difference between the two eigenfrequencies is increased to $\Omega_R\sqrt{N}$ from Ω_R for a single-atom case.

Enhanced and inhibited spontaneous-emission rates at microwave frequencies have been demonstrated with either Rydberg atoms or cyclotron electrons. Enhanced and inhibited spontaneous emission rates at optical frequencies have also been demonstrated with either dye molecules or Rb atoms. Collective Rabi splitting has been demonstrated at both microwave and optical frequencies. Cavity QED experiments in semiconductors require a microcavity structure with an optical wavelength size (Yamamoto and Slusher, 1993, and references therein). This is because the spontaneous-emission spectral width in semiconductors is much broader than that of an atom in vacuum as a result of a very short dephasing time and a very large inhomogeneous broadening of an electron–hole pair dipole. The cavity structures used for cavity-QED experiments in semiconductors are quite similar to those utilized in vertical-cavity surface-emitting lasers. In fact, a major thrust in the study of cavity-QED effects in semiconductors is the development of small-sized, ultra-low-threshold, high-speed lasers and light-emitting diodes for applications in optical communication, parallel optical signal processing, and optical computing.

Because spontaneous emission is a major source of energy loss, speed limitation, and noise in lasers, the capability to control spontaneous emission is expected to improve laser performance. New phenomena are expected if the radiation pattern is highly directed toward a lasing mode and the fraction of spontaneous emission coupled into the lasing mode is made close to 1. The fraction of the total spontaneous emission that is coupled into the single lasing mode at low excitation rates is defined to be the spontaneous-emission coefficient β. An example of the new phenomena expected as β approaches 1 is the "thresholdless laser" (DeMartini and Jacobovitz, 1988), in which the light output increases nearly linearly with pump power instead of exhibiting a sharp turn-on at a pump threshold.

Consider a single atom centered in an optical cavity between two confocal mirrors, each with reflectivity R. This cavity radiates into a mode that subtends a solid angle $\Delta\Omega$. If the atom is located at an antinode of the vacuum field in the cavity, the spontaneous-emission rate into $\Delta\Omega$ is enhanced by a factor $4/(1 - R)$ because the vacuum field at that point is strongly enhanced relative to its free-space value. Correspondingly, when the atom is located at a node of the cavity field, the spontaneous-emission rate into $\Delta\Omega$ is inhibited by a factor of $(1 - R)/4$. If atoms are distributed over many wavelengths, strong spatial modulation of the spontaneous decay rates is not expected. Note that although the spontaneous-emission rate into the cavity mode can be strongly modified, the total spontaneous-emission rate integrated over all angles may change only a modest amount if $\Delta\Omega \ll 4\pi$.

The most important effect of modified spontaneous emission for possible applications is the altered radiation pattern and the enhanced spontaneous-emission coefficient β. The strong reflectivity dependence of the spontaneous-emission rate into a cavity mode clearly indicates that β can be increased when an atom is located at the antimode of the mode field. As the reflectivity approaches unity, the β value approaches the ideal limit of 1. Such high β values can be used to enhance the efficiency of light-emitting diodes and lower the thresholds of lasers.

2.3 Microcavity Laser Physics

The spontaneous-emission coefficient β for the relatively large-volume solid-state and gas lasers in common use today can be approximated by

$$\beta = \lambda^4/4\pi^2 V \Delta\lambda n^3. \qquad (14)$$

Here $\Delta\lambda$ is the emission linewidth, n the refractive index, and V the mode volume. This expression accounts for the number of modes in the system, which is roughly equal to the number of cubic wavelengths in the system, and the number of modes within the emission linewidth, which is proportional to

$\Delta\lambda/\lambda$. For example, even a semiconductor laser the size of a grain of salt has a β value of only 10^{-5}. One can reduce both V and $\Delta\lambda$ to obtain a larger β value. In principle, one can increase the β value to close to 1. For this purpose, one does not necessarily require a true single-mode cavity. One needs only to enhance the spontaneous-emission rate into a single mode relative to the many existing modes over the spectral-emission bandwidth, which is typically less than a few percent of the transition frequency.

One of the most important consequences of the increased spontaneous-emission coefficient is the reduction of the threshold pump rate of a laser. In a simple atomic model, where the spontaneous-emission rate and the emission spectral width are constant as functions of excitation level, the threshold pump rate as a function of β is given by (Björk and Yamamoto, 1991)

$$P_{th} = \frac{\gamma_{\text{photon}}}{2\beta}[1 + \beta + \xi(1 - \beta)]. \tag{15}$$

Here γ_{photon} is the rate of photon emission from the cavity. The quantity $\xi = N\beta V\Gamma/2\gamma_{\text{photon}}$ is the average photon number in the lasing mode when half of the atoms are in the excited state; N is the atomic density and Γ is the spontaneous-emission rate. The excitation level where the excited-atom density N_{ex} is $N/2$ is called the transparency carrier density in semiconductors, because there is no absorption and no net gain at this point. The gain G at excitation levels higher than the transparency point is assumed here to be a linear function of the excited-atom density N_{ex}: $G = \beta V\Gamma(N_{ex} - N/2)$.

The threshold pump rate in Eq. (15) includes the two distinct regions that are being studied in present semiconductor microresonator experiments, $\xi \ll 1$ and $\xi \gg 1$. When $\xi \ll 1$ and $\beta \ll 1$, P_{th} is equal to $\gamma_{\text{photon}}/2\beta$ and the threshold pump rate decreases linearly with $1/\beta$. Figure 6 shows the light output power as a function of pump rate for a set of β values in this regime. The lasing threshold, characterized by the jump in the efficiency of converting pump power to light output power, decreases with increasing β. When $\xi \gg 1$ and $\beta \ll 1$, P_{th} is independent of β and is fixed at the pump rate required to obtain transparency. One must keep the total number of atoms NV and the spontaneous decay rate Γ small to satisfy the condition $\xi \ll 1$ and obtain a decrease in the threshold pump rate with an increase in β. Of course, we are assuming that the active material can be pumped to emit a sufficient number of photons to achieve threshold at these low gain volumes. In practice, the linear gain dependence assumed in this analysis cannot be achieved if the gain volume is too small. An-

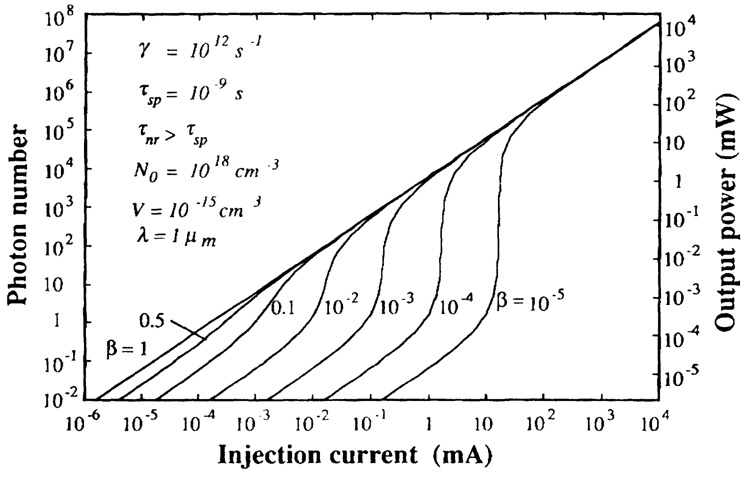

FIG. 6. Photon flux and power. The curves show the average flux in the mode (left axis) and the corresponding output power (right axis) for microcavity lasers with various spontaneous-emission coefficients β. Parameters used for the theoretical model that generated these curves are $\gamma_{\text{photon}} = 10^{12}$/s, $\Gamma = 10^{9}$/s, $N/V = 10^{18}$/cm^3, $V = 10^{-15}$ cm^3, and $\lambda = 1$ μm.

other consequence of experimental reality is that β can vary with excitation level if the spectral-emission width is not a constant.

In Fig. 6, we see that when the spontaneous-emission coefficient β is 1 there is no jump in the quantum efficiency of the conversion of pump photons to light output. This is the "thresholdless" laser, or "zero-threshold" laser. However, there is a well-defined threshold, $P_{th} = \gamma_{\text{photon}}$, even in this case, according to Eq. (15). At pump rates below threshold, the average photon number in the cavity is less than 1, so that the dominant emission process is incoherent spontaneous emission. At pump rates above threshold, the average photon number becomes greater than 1, resulting in a dominance of coherent stimulated emission. With the onset of stimulated emission, the population inversion is "pinned" at its threshold value, because each newly generated electron–hole pair very rapidly recombines in a stimulated process. The dominance of stimulated emission above threshold is also expected to result in an increased coherence of the light output and a narrowing of the output spectrum even in the $\beta = 1$ limit, as shown in Fig. 7(a).

Fluctuations of the light intensity emitted by a microlaser exhibit a resonance increase at threshold, as shown in Fig. 7(b). These light fluctuations, similar to the fluctuations found in a second-order phase transition, are a measure of threshold behavior that also persists in the limit of $\beta = 1$. Note that as β approaches 1, these fluctuations decrease and their relative width in pump power increases, thus providing another indicator of the unique characteristics in the high-β microlaser limit.

We conclude from an examination of carrier-density pinning, linewidth narrowing, and light-level fluctuations—present even when there is only approximately one photon in the cavity—that there is a well-defined threshold even for $\beta = 1$. This threshold discriminates between regions that can be described as a linear amplifier and a nonlinear laser oscillator.

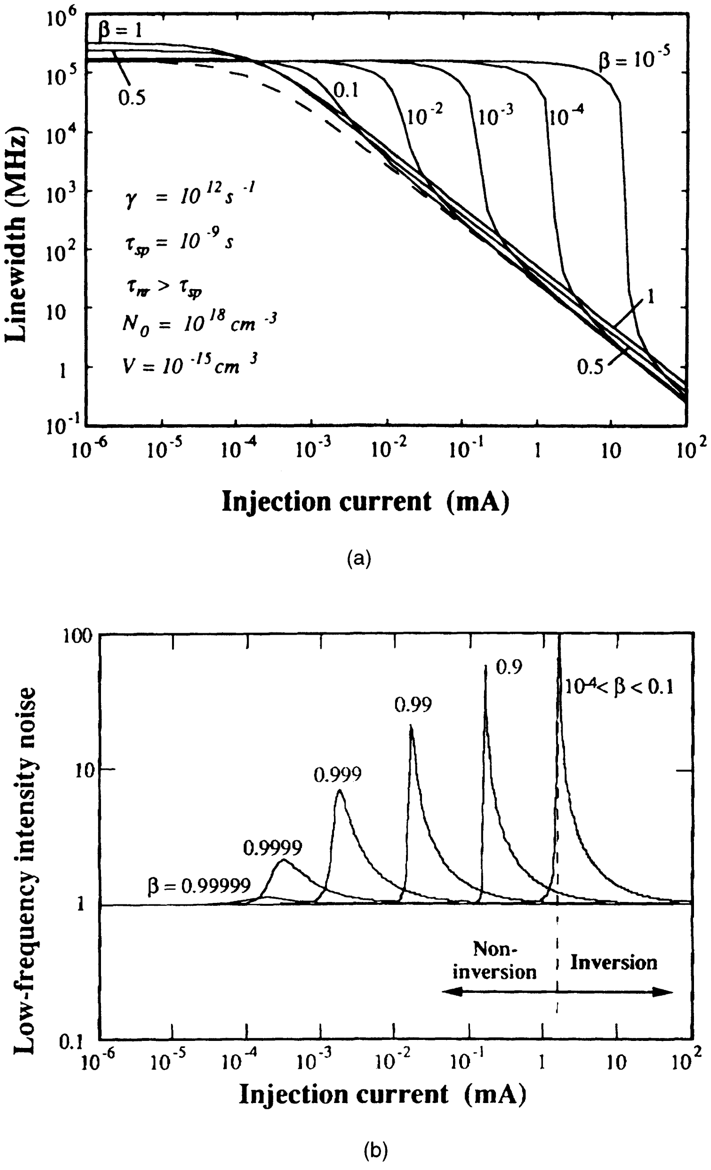
2.4 Fabry–Pérot Microcavities

The simplest approach to fabricating an optical microcavity is to shrink the spacing between the mirrors of a Fabry–Pérot resonator to λ/n while reducing the lateral dimensions to the same range. This structure provides a single dominant longitudinal field mode that radiates into a narrow range of angles around the cavity axis. The first optical microcavity experiments used dye molecules between high-reflectivity dielectric mirrors in the Fabry–Pérot configuration.

Semiconductor microcavities provide high-Q Fabry–Pérot cavities for both basic studies and potential applications. The Q of a cavity is the number of radian cycles required for the optical-field energy in the cavity to decay by a factor of $1/e$. Molecular-beam epitaxy or organometallic chemical vapor deposition techniques are used to deposit high-reflectivity mirrors consisting of alternating quarter-wavelength layers of lattice-matched semiconductors. For example, 15 to 20 pairs of quarter-wave layers of $Al_{0.2}Ga_{0.8}As$ and AlAs result in a reflectivity greater than 99% and Q values greater than 500. The optically active layer in such a microcavity is typically a GaAs quantum well located at the midplane of the cavity, where the field strength is a maximum.

Planar Fabry–Pérot microcavities have been studied theoretically and experimentally in some detail. The two important parameters for laser performance, γ_{photon} and β, depend on the cavity geometry and the spectral-emission width of the quantum-well gain material. Even if the dimensions of the cavity in the plane between the mirrors are much larger than an optical wavelength, the planar cavity structure will give rise to discrete spatial modes with a finite mode radius r_m. The mirror spacing and reflectivities determine the radiating solid angle of the mode. This solid angle is inversely proportional to the coherence radius and directly proportional to the cold-cavity linewidth $\Delta\lambda_m$—the linewidth of the cavity resonance without the gain material. For example, a GaAs microcavity with a spacing of λ/n between the mirrors and with mirror reflectivities of 99% corresponds to a mode radius $r_m \simeq 7\ \mu\text{m}$, a cavity resonance linewidth $\Delta\lambda_m \simeq 0.43$ nm, and a far-field angular radiation angle of 5.7°.

The maximum β achievable with a large-area planar GaAs Fabry–Pérot microcavity is estimated to be 0.05, assuming dipole moments oriented in the plane of the cavity and negligible spectral broadening. However, the



(a)

(b)

FIG. 7. Linewidth and noise. (a) The laser linewidth and (b) the intensity-noise spectral density in the light output from a microlaser as functions of the pump current are plotted here for a series of β values. The noise shown here is normalized with respect to the mean number of photons in the cavity. The parameters used in the theoretical model that generated these curves are the same as in Fig. 6.

GaAs quantum-well emission linewidth is 30 nm at room temperature and 2.5 nm at 4 K, much broader than the cold-cavity linewidth of 0.43 nm. As soon as the emission linewidth exceeds the cold-cavity bandwidth, β starts to decrease with the ratio of the two widths; β is thus estimated to be 0.05(0.43/2.5) $\simeq$ 0.01 at 4 K. The quantum efficiency for conversion of pump photons to output light is close to unity above the threshold, while it is equal to β below it, assuming negligible absorption in the cavity. Therefore β can be experimentally deduced from the step at threshold, yielding a β of 10^{-2}, as shown in Fig. 8.

The β values achievable with the large-area planar microcavities are limited by the leakage of spontaneous emission into directions centered around the plane of the cavity. A postlike structure, fabricated by wet or dry etching, can suppress this leakage of spontaneous emission and increase the β values up to 0.5 if the post diameter is on the order of the wavelength in the material and

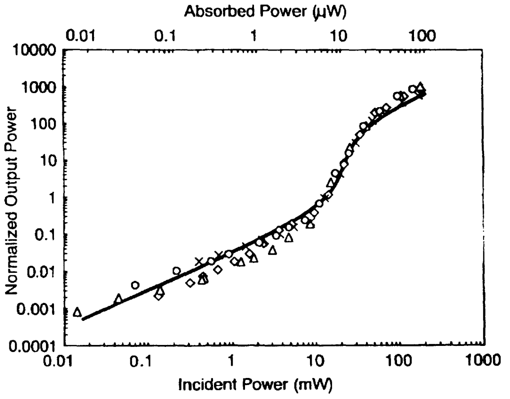


FIG. 8. Power transfer. The normalized output power from a GaAs Fabry–Pérot microcavity is plotted here as a function of incident pump power (bottom axis) and absorbed pump power (top axis). The solid line is the theoretical curve for $\beta = 0.01$.

if the quantum-well emission linewidth is much narrower than the cold-cavity linewidth. The factor-of-2 degradation in β stems from the fact that the two degenerate orthogonal polarization modes capture an equal amount of spontaneous emission below threshold, but only one of them oscillates above threshold. Such a high β has not yet been observed experimentally, in part because the emission linewidths are often broader than the cold-cavity linewidths.

An alternative way to increase β is to use a hemispherical structure with an integrated curved mirror (Matinaga *et al.,* 1993). To fabricate each of these curved mirrors, researchers formed a photoresist disk on a planar GaAs-AlGaAs optical cavity. They then melted this photoresist by heat treatment, forming it into a hemispherical disk. Finally, they transferred the curved geometry of the photoresist disk to the semiconductor by dry etching using an ion beam. They controlled the curvature and diameter of the structures by varying the diameter and the thickness of the resist disk; the resulting curvatures ranged from 5 to 20 μm. The hemispherical microcavity has a measured β value of 0.05, which compares with the theoretical prediction of 0.1.

A variety of condensed-matter Fabry–Pérot microcavities have exhibited modifications of the spontaneous-emission patterns and rates. Modified radiation patterns have been observed for the exciton emission from GaAs microcavities (Yamamoto *et al.,* 1989). Dye-molecule experiments have demonstrated both enhanced and inhibited spontaneous-emission rates (DeMartini *et al.,* 1991). One easily controls inhibition or enhancement in these experiments by adjusting the Fabry–Pérot cavity spacing to set the position of the field node in the active dye layer. Narrowing of the emission angle and enhancement of the intensity of the emitted radiation have been observed (Schubert *et al.,* 1992) from erbium-doped glass in a Fabry–Pérot cavity with mirrors formed from four alternate quarter-wave layers of silicon and SiO_2: The intensity of 1.54-μm radiation from the Er-doped glass along the cavity axis was enhanced by between one and two orders of magnitude, and the spectral width was narrowed by a factor of 10.

2.5 Microdisk Cavities

"Whispering-gallery" modes are a second successful route to achieving high-*Q* microcavities. Total internal reflection along a curved boundary between two materials with different optical indices results in high-*Q* modes propagating within a half-wavelength of the boundary. Lord Rayleigh conceived these modes over a century ago as an explanation of the efficient propagation of sound—even of whispers—along the walls of St. Paul's Cathedral in London. In fact, the ratio of the sound wavelength to the cathedral diameter is very similar to the ratio of the light wavelength to the diameter of optical microcavities being studied today.

Whispering-gallery modes in condensed-matter microstructures were pioneered using nearly spherical liquid droplets (Tzeng *et al.,* 1984). Cavities with *Q* values as high as 10^8 can be obtained because of the nearly perfect smoothness of the droplet boundaries, which in many cases is limited only by thermal fluctuations at the surface. Spectacular enhancements of the spontaneous decay rates of dye molecules—by a factor of 120—have been demonstrated in these microcavities (Campillo *et al.,* 1991). Polymer spheres have now been fabricated with the optical smoothness required for high-*Q* whispering-gallery–mode microcavities (Kuwata-Gonokami *et al.,* 1992): Optically pumping a dye-doped polystyrene sphere results in a red microlaser.

Researchers have demonstrated semiconductor whispering-gallery–mode microresonators as microlasers in the disk and cylindrical geometries (McCall *et al.*, 1992). The thickness of the disk is only 100 nm, less than a half-wavelength in the semiconductor, thus allowing only one transverse-optical mode to propagate in the plane of the disk. This microcavity geometry allows an excellent overlap of the optical gain region with the mode volume. Large overlap factors are important for achieving low microlaser thresholds. This geometry avoids the complexity of multilayer mirrors and allows the fabrication of high-Q microcavities in systems like InGaAs-InGaAsP, where the index contrast for layered mirrors is not high enough to permit fabrication of high-reflectivity distributed Bragg reflectors. For a 1-μm-radius disk and an optical wavelength of 1.5 μm, there are approximately eight optical nodes arranged around the disk edge in a whispering-gallery mode. The spectral spacing of modes with differing numbers of nodes is large enough that only one mode dominates the InGaAs quantum-well emission spectrum centered near 1.5-μm wavelength. The measured Q values for these 1-μm-radius microdisks range from 200 to 1000, and the β values are near 0.1, compared with the theoretically predicted value of 0.3.

2.6 Low-Threshold Microlasers

Optical microresonators promise ultralow-threshold laser behavior primarily because the threshold should scale down with the gain volume and with the increased coupling of spontaneous emission into the cavity mode—that is, with increased values of β. As the gain volume approaches a fraction of a cubic wavelength in the material and as β approaches 1, threshold powers below 1 μW are expected for sufficiently high Q values. This is a factor of nearly a thousand less than the thresholds near 1 mW that are typical for semiconductor lasers in common use today with volumes of several hundred cubic wavelengths and β values that range from 10^{-4} to 10^{-5}.

Estimated thresholds have been demonstrated in the 5–10-μW range for Fabry–Pérot semiconductor microlasers with one quantum well and in the 10–20-μW range for whispering-gallery–mode microlasers with six quantum wells (Yamamoto and Slusher, 1993). These experiments used optical pumping and temperatures below that of liquid nitrogen. The actual pump-light levels incident on the structures in these experiments range from 700 μW to 1 mW for the Fabry–Pérot microcavities and from 30 to 100 μW for the whispering-gallery–mode microcavities. Only the fraction of this power actually absorbed in the active region is used to obtain the estimated thresholds. Nonlasing modes reduce the β values in these microlaser experiments to the 0.01–0.1 range, because the total volumes of the cavities are still considerably larger than the ideal limit.

2.7 Future

The present trends toward smaller-scale nanostructures and the continuous development of new and improved materials should result in steady progress toward more ideal optical microcavities. Examples of new material include quantum wires and dots in semiconductor or organic systems. An interesting approach for achieving a truly isolated optical mode is the fabrication of three-dimensional photonic bandgap systems that exclude all optical modes over a limited optical spectrum (Everitt, 1992, and references therein). An "acceptor" or "donor" optical mode with a frequency in this isolated spectral region can then be formed as a dielectric defect. These defect modes can in principle form high-Q resonant modes with β values very close to 1. With advances in experimental systems, we may soon see a more substantial basis in experiment for the novel physics of QED, lasing without inversion, cavity-assisted excitonic superradiance, and squeezed-light generation (Yamamoto *et al.*, 1993, and references therein).

The limit of isolated field modes in microresonators may also have a significant impact in applied areas. For example, if visible microlasers can be developed, their many potential applications include fast holographic memories, laser projection displays, plastic fiber-optic communications, and applications where He-Ne lasers are used at present.

3. QUANTUM NONDEMOLITION MEASUREMENT—CONTROL OF MEASUREMENT BACK ACTION

3.1 Introduction

The quantum theory of measurement has been widely regarded as a problematic and dubious subject of little relevance to real physics. The reason for this irrelevance of the quantum theory of measurement is, however, only because experimentalists could not make repetitive measurements at a quantum limit on a single quantum object until very recently. In the 1980s, the experimentalists' interest has shifted from the single destructive measurement of an ensemble of microscopic systems to the repeated nondestructive measurements of a single macroscopic system. An experimentalist in quantum optics finally began to catch up with the measurement concepts such as "collapse of the wave function" of the creators of quantum mechanics.

The standard quantum theory based on unitary time evolution cannot describe the process of a measurement. A measurement is a nonunitary and indeterministic process, for which a so-called "projection postulate" is applied. This is a very reasonable postulate, but there has been no direct experimental evidence for the postulate so far. A quantum nondemolition measurement is the first experiment to confirm directly such a nonunitary collapse of the wave function by a measurement process.

3.2 General Quantum Measurement and QND

In a general quantum measurement, the observable of the signal system, $\hat{A}_s$, is measured by means of the change in the observable of the probe system, $\hat{A}_p$, after the proper interaction between the signal and probe systems, as shown in Fig. 9. The Heisenberg equations of motion for $\hat{A}_s$ and $\hat{A}_p$ are written as

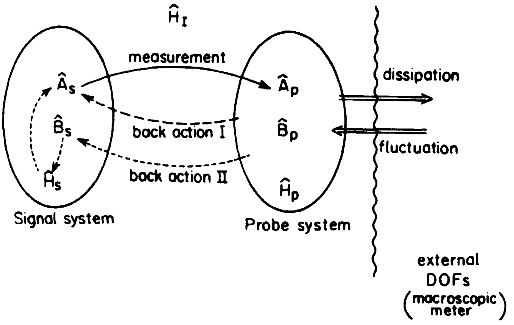

FIG. 9. QND measurement model with a probe system and a macroscopic meter. Signal observable $\hat{A}_s$ is nondemolitionally measured through demolitional measurement of probe observable $\hat{A}_p$, whose motion is affected by $\hat{A}_s$ by means of interaction Hamiltonian $\hat{H}_I$. If $\hat{H}_I$ does not commute with $\hat{A}_s$, the motion of $\hat{A}_s$ is kicked by $\hat{H}_I$ (back action I). If $\hat{H}_s$ contains $\hat{B}_s$, the motion of $\hat{A}_s$ is also kicked by the uncertainty principle between $\hat{A}_s$ and $\hat{B}_s$ (back action II).

$$-i\hbar \frac{d}{dt}\hat{A}_s = [\hat{H}_s,\hat{A}_s] + [\hat{H}_I,\hat{A}_s] \tag{16}$$

and

$$-i\hbar \frac{d}{dt}\hat{A}_p = [\hat{H}_p,\hat{A}_p] + [\hat{H}_I,\hat{A}_p], \tag{17}$$

where $\hat{H}_s$ is the unperturbed Hamiltonian of the signal system, $\hat{H}_p$ is that of the probe system, and $\hat{H}_I$ is the interaction Hamiltonian between the two. The first commutators in Eqs. (16) and (17) represent the free motion of $\hat{A}_s$ and $\hat{A}_p$. The second commutators represent the contribution of the interaction between the signal and probe systems.

In order to measure $\hat{A}_s$ using $\hat{A}_p$, $[\hat{H}_I,\hat{A}_p]$ in Eq. (17) should not be zero and H_I should be a function of $\hat{A}_s$. These are the requirements for a general quantum measurement:

1. $\hat{H}_I$ is a function of $\hat{A}_s$.
2. $[\hat{H}_I, \hat{A}_p] \neq 0$

In general, a measurement of $\hat{A}_s$ affects the motion of $\hat{A}_s$ itself in two ways (measurement back action). One way is the change of $\hat{A}_s$ due to $[\hat{H}_I,\hat{A}_s]$ in Eq. (16). Such an example is photoelectron emission in a photodetector. When a signal photon number is measured by a conventional photodetector, the photon absorption process naturally changes the signal photon number. Such a back action is shown by the dashed line in Fig. 9. If the interaction Hamiltonian H_I commutes with $\hat{A}_s$,

$$[H_I, \hat{A}_s] = 0, \tag{18}$$

H_I is called a "back-action evading" type, and this first source of back action can be eliminated.

The other way of changing $\hat{A}_s$ is through the uncertainty that is introduced on the observable conjugate to $\hat{A}_s$ by the measurement. The Heisenberg uncertainty principle dictates that when the observable $\hat{A}_s$ is measured with accuracy $\langle \Delta \hat{A}_s^2 \rangle$, the uncertainty imposed on the conjugate observable $\hat{B}_s$ should be larger than

$$\langle \Delta \hat{B}_s^2 \rangle \geq \frac{1}{4\langle \Delta \hat{A}_s^2 \rangle} |\langle [\hat{A}_s, \hat{B}_s] \rangle|^2. \tag{19}$$

If the unperturbed Hamiltonian H_s contains the conjugate observable $\hat{B}_s$, the motion of $\hat{A}_s$ is affected by this uncertainty of $\hat{B}_s$. An example is the position measurement of a free particle. When a free particle's position is measured by a γ-ray microscope, the measurement accuracy is proportional to the photon wavelength, $\Delta q \simeq \lambda$. A photon scattered by a free particle changes the particle's momentum. This back action imposed on the particle's momentum is of the order of the photon's momentum itself, $\Delta p \simeq h/\lambda$. The kicked momentum then perturbs the free motion of the particle's position according to the following relation:

$$H_s = \frac{\hat{p}^2}{2M} \Rightarrow \hat{q}(t) = \hat{q}(0) + \frac{\hat{p}(0)}{2M} t. \tag{20}$$

Here $\hat{q}(0)$ and $\hat{p}(0)$ are the position and momentum just after the first measurement. This back action is shown by the dotted line in Fig. 9.

If $\hat{A}_s(0)$ commutes with $\hat{A}_s(t)$,

$$[\hat{A}_s(0), \hat{A}_s(t)] = 0, \tag{21}$$

$\hat{A}_s$ is called a "QND observable" and the second source of back action can be eliminated. Equations (18) and (21) are the conditions for a QND measurement (Caves *et al.*, 1980, and references therein).

In a QND measurement, the observable $\hat{A}_s$ is not affected at all, even though the measurement accuracy of $\hat{A}_s$ is increased arbitrarily. In optical communication, this means that the information carried by a signal wave is fully extracted at one receiver but the signal wave still can transport exactly the same information to the other receivers.

3.3 QND Measurement for Photon Number

When the observable of the signal wave is a photon number $\hat{A}_s = \hat{n}_s$, condition (21) is satisfied, since the system free Hamiltonian is given by $H_s = \hbar\omega_s(\hat{n}_s + \frac{1}{2})$ and $[H_s, \hat{n}_s] = 0$; that is, a photon number is a "QND observable."

Let us consider the configuration shown in Fig. 10 (Imoto *et al.*, 1985). The signal wave at frequency ω_s propagates along an optical Kerr medium with a probe wave at frequency ω_p in which the phase of the probe wave is modulated by the photon number of the signal wave. The phase modulation of the probe wave is detected by a homodyne receiver, and thus the information about the signal photon number can be extracted. If the signal wave is not attenuated, the signal photon number is preserved.

The readout observable of the probe wave is a quadrature component $\hat{A}_p \equiv \hat{a}_{p2} = (\hat{a}_p - \hat{a}_p^\dagger)/2i$. The interaction Hamiltonian for the measurement is that for the interphase modulation between the signal and probe waves:

$$H_I = \hbar\chi\hat{n}_s\hat{n}_p. \tag{22}$$

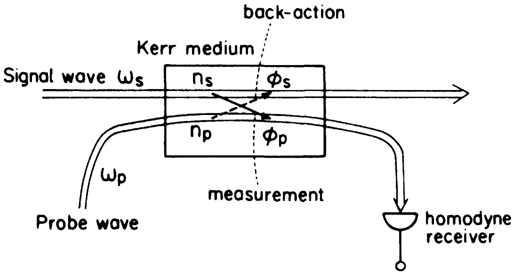

FIG. 10. Schematical view of a QND measurement scheme with an optical Kerr medium. The signal photon number is nondemolitionally measured through the homodyne detection of the probe phase, which carries the signal photon-number information by means of the optical Kerr effect.

The constant χ is equal to $(\hbar/2V\epsilon^2)\omega_p\omega_s\chi^{(3)}$, where V is the mode volume and $\chi^{(3)}$ is the third-order susceptibility; ϵ is the dielectric constant of the medium.

It is easily verified that the interaction Hamiltonian [Eq. (22)] satisfies the general quantum measurement conditions **1** and **2** in Sec. 3.2. The QND condition [Eq. (18)] is also satisfied, and thus the interaction Hamiltonian [Eq. (22)] is a "back-action evading" type.

3.3.1 Heisenberg Picture The unitary evolution for the signal- and probe-wave annihilation operators resulting from the onset of Eq. (22) is expressed by

$$\hat{a}_s(L) = \exp(i\sqrt{F}\hat{n}_p)\hat{a}_s(0), \tag{23}$$

and

$$\hat{a}_p(L) = \exp(i\sqrt{F}\hat{n}_s)\hat{a}_p(0). \tag{24}$$

Here $\sqrt{F} = \chi L/c$, L is the length of the Kerr medium, and c is the light velocity. The optical homodyne receiver with a proper local oscillator phase (90° out of phase for the coherent excitation of the probe wave) measures the quadrature phase component of $a_p(L)$,

$$\begin{aligned}\hat{a}_{p2}(L) &= (1/2i)[\hat{a}_p(L) - \hat{a}_p^\dagger(L)]\\ &= \hat{a}_{p1}(0)\sin(\sqrt{F}\hat{n}_s) + \hat{a}_{p2}(0)\cos(\sqrt{F}\hat{n}_s).\end{aligned} \tag{25}$$

Since the probe wave has the coherent excitation only along $\hat{a}_{p1}(0)$, that is, $\langle\hat{a}_{p1}(0)\rangle \neq 0$ and $\langle\hat{a}_{p2}(0)\rangle = 0$, and the phase modulation $\sqrt{F}\hat{n}_s$ is a small quantity, Eq. (25) is reduced to

$$\hat{a}_{p2}(L) \simeq \langle\hat{a}_{p1}(0)\rangle\sqrt{F}\hat{n}_s + \Delta\hat{a}_{p2}(0). \tag{26}$$

The signal photon number to be measured is expressed by

$$\hat{n}_s^{(\text{obs})} \equiv \frac{\hat{a}_{p2}(L)}{\sqrt{F}\langle\hat{a}_{p1}(0)\rangle} = \hat{n}_s + \frac{\Delta\hat{a}_{p2}(0)}{\sqrt{F}\langle\hat{a}_{p1}(0)\rangle}. \tag{27}$$

Taking the expectation value and variance of Eq. (27), we obtain

$$\langle\hat{n}_s^{(\text{obs})}\rangle = \langle\hat{n}_s\rangle, \tag{28}$$

$$\langle(\Delta\hat{n}_s^{(\text{obs})})^2\rangle = \langle\Delta\hat{n}_s^2\rangle + \frac{\langle\Delta\hat{a}_{p2}(0)^2\rangle}{F\langle\hat{n}_p\rangle}. \tag{29}$$

The second term of Eq. (29), $\langle\Delta\hat{n}_s'^2\rangle = \langle\Delta\hat{a}_{p2}(0)^2\rangle/F\langle\hat{n}_p\rangle$, represents the measurement error, which is determined by the probe-wave phase noise $\langle\Delta\hat{\psi}_p^2\rangle \simeq \langle\Delta\hat{a}_{p2}(0)^2\rangle/\langle\hat{n}_p\rangle$ and the nonlinear interaction strength $\sqrt{F}$. It can be decreased arbitrarily by increasing $\sqrt{F}$ and/or decreasing $\langle\Delta\hat{\psi}_p^2\rangle$. This QND measurement is ideal, since the expectation value and variance, that is, the statistics of measurement results, are equal to those of the signal wave itself. When the probe wave is in a coherent state, $\langle\Delta\hat{\psi}_p^2\rangle$ is given by $1/4\langle\hat{n}_p\rangle$. When the probe wave is in an optimum squeezed state, $\langle\Delta\hat{\psi}_p^2\rangle$ can be reduced to $1/4\langle\hat{n}_p\rangle(\langle\hat{n}_p\rangle + 1)$.

The phase noise of the signal wave is increased by the other interaction represented by Eq. (23). The quadrature phase component of the signal wave is similarly calculated as

$$\hat{a}_{s2}(L) \simeq \langle\hat{a}_{s1}(0)\rangle\sqrt{F}\hat{n}_p + \Delta\hat{a}_{s2}(0). \tag{30}$$

The phase noise is thus given by

$$\langle\hat{\Delta}\psi_s^2\rangle \equiv \frac{\langle\Delta\hat{a}_{s2}(L)^2\rangle}{\langle\hat{a}_{s1}(0)\rangle^2} = \langle\Delta\hat{\psi}_s^2(0)\rangle + F\langle\Delta\hat{n}_p^2\rangle. \tag{31}$$

Here $\langle\Delta\hat{\psi}_s(0)^2\rangle = \langle\Delta\hat{a}_{p2}(0)^2\rangle/\langle\hat{a}_{p1}(0)\rangle^2$ is the initial phase noise of the signal wave. The second term, $\langle\Delta\hat{\psi}_s'^2\rangle = F\langle\Delta\hat{n}_p^2\rangle$, is the back-action noise added by the measurement. With decrease of the measurement error, the back-action noise increases. When the probe wave satisfies the minimum uncertainty product, $\langle\Delta\hat{a}_{p1}(0)^2\rangle\langle\Delta\hat{a}_{p2}(0)^2\rangle = \frac{1}{16}$, the measurement error and the back-action noise satisfy the Heisenberg minimum uncertainty product:

$$\langle\Delta\hat{n}_s'^2\rangle\langle\Delta\hat{\psi}_s'^2\rangle = \tfrac{1}{4}. \tag{32}$$

The preceding argument concerning the measurement error and back-action noise suggests that the signal wave after QND measurement is "reduced" to a number-phase squeezed state. This can be easily shown by using the projection postulate.

3.3.2 Schrödinger Picture Suppose the signal and probe waves are initially in coherent states $|\alpha\rangle_s$ and $|\beta\rangle_p$. The density operator after the interphase modulation is expressed by the unitary operator $\hat U = \exp(i\sqrt{F}\hat n_s \hat n_p)$,

$$\hat\rho_{sp} = \hat U|\alpha_0\rangle_{ss}\langle\alpha_0| \otimes |\beta_0\rangle_{pp}\langle\beta_0|\hat U^\dagger. \qquad (33)$$

The density operator after the measurement of the quadrature amplitude of the probe wave is given by (for the specific readout β_2)

$$\hat\rho_s^{(\mathrm{meas},\beta_2)} = \mathrm{Tr}_p(|\beta_2\rangle_{pp}\langle\beta_2| \otimes \hat\rho_{sp}). \qquad (34)$$

The quasi-probability density $\langle\alpha|\hat\rho_s^{(\mathrm{meas},\beta_2)}|\alpha\rangle$ is shown in Fig. 11. The variances for photon-number and sine operators,

$$\begin{aligned}\langle\Delta\hat n^2\rangle &= \mathrm{Tr}_s[\hat\rho_s^{(\mathrm{meas},\beta_2)}(\hat n - \langle\hat n\rangle)^2] \\ &\simeq (1/|\alpha|^2 + 4F|\beta|^2)^{-1} \qquad (35)\end{aligned}$$

and

$$\begin{aligned}\langle\Delta\hat S^2\rangle &= \mathrm{Tr}_s[\hat\rho_s^{(\mathrm{meas},\beta_2)}(\hat S - \langle\hat S\rangle)^2] \\ &\simeq 1/4|\alpha|^2 + \tfrac{1}{2}[1 - \exp(-2F|\beta|^2)], \qquad (36)\end{aligned}$$

satisfy the number-phase minimum uncertainty product, $\langle\Delta\hat n^2\rangle\langle\Delta\hat S^2\rangle = \frac{1}{4}\langle\hat C\rangle^2$, as shown in Fig. 12.

The initial coherent state is transformed to a number-phase squeezed state by the nonunitary state reduction. QND measurement is considered as the generation process of nonclassical light. This QND measurement was experimentally demonstrated with a Kerr nonlinear medium (Friberg *et al.*, 1992, and references therein).

Two similar but slightly different configurations for QND measurement of photon number have been proposed. One utilizes a microwave photon in a high-Q superconductor cavity as a probe system (Braginsky and Vyatchanin, 1981). The other employs a nonlinear coupler based on four-wave mixing (Milburn and Walls, 1983).

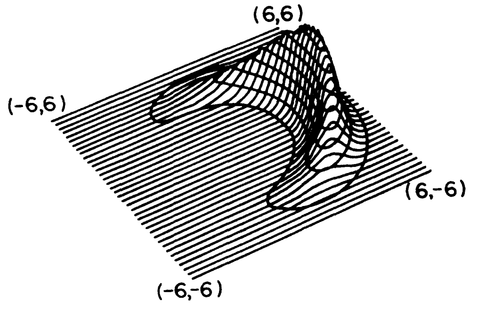

FIG. 11. Quasi-probability density $Q(\alpha)$ of the state after the measurement in the α_1-α_2 phase space, where α_1 and α_2 are the two quadrature amplitudes.

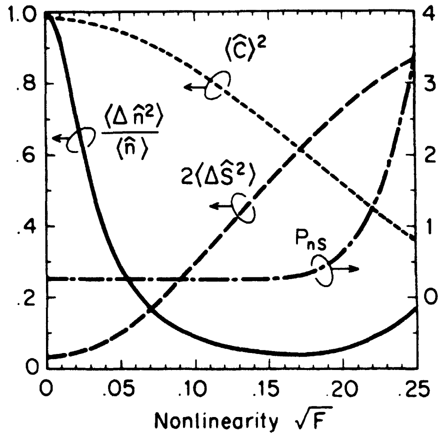

FIG. 12. Uncertainties $\langle\Delta\hat n^2\rangle$, $\langle\Delta\hat S^2\rangle$ and uncertainty product $P_{ns} = \langle\Delta\hat n^2\rangle\langle\Delta\hat S^2\rangle/\langle\hat C\rangle^2$ of the state after the measurement ($|\alpha_0| = |\beta_0| = 4$, $\beta_2 = 0$).

3.4 Other QND Measurements

The quadrature amplitude $\hat a_1$ or $\hat a_2$ is also a QND observable. A degenerate parametric amplifier with two orthogonal polarization channels can perform such a QND measurement of the quadrature amplitude (Shelby and Levenson, 1987). This QND measurement was experimentally demonstrated with a type II nonlinear crystal (Pereira *et al.*, 1994, and references therein). In this QND measurement, the back-action noise is imposed on the conjugate observable ($\hat a_2$ for the measurement of $\hat a_1$) and requires an increased energy. The repeated QND measurements leave the measured quadrature amplitude unchanged but amplify the system energy.

4. OPTICAL-SOLITON QUANTUM EFFECT—MACROSCOPIC QUANTUM EFFECT

4.1 Introduction

The first reported soliton was a water wave in a canal, observed by John Scott-Russell (Scott-Russell, 1844). A wave or "lump" of water was seen to travel over long distances without spreading out or breaking up. Since then, numerous examples of solitons have been found in various physical, chemical, and biological environments, all propagating without spreading out or breaking up. Recently, there has been great interest in solitons in optical fibers. Such solitons, predicted in 1973 (Hasegawa and Tappert, 1973) and first demonstrated in 1980 (Mollenauer *et al.*, 1980), offer advantages for high-speed, long-distance communication: propagation distances of more than 10^6 km have been demonstrated (Nakazawa *et al.*, 1991). The stability of optical solitons in fibers makes them interesting not just for optical communication systems, but also for fundamental tests of quantum mechanics.

Solitons are persistent, "solitary waves" or pulses that are particularly resistant to the disruptions that ordinarily distort a pulse as it propagates. A short pulse is made up of a range of oscillation frequencies: The shorter the pulse, the broader its spectrum. In any physical medium, the propagation velocity depends on frequency, an effect known as group-velocity dispersion. By itself, this causes different portions of the pulse spectrum to travel with different velocities, leading to pulse broadening. Temporal solitons exist in nonlinear media in which the velocity also depends on the amplitude of the pulse. If the signs of these two effects are opposite, a soliton can form that (in classical physics) would propagate without distortion. Spatial optical solitons form in a similar manner, opposing diffraction against self-focusing in a nonlinear medium (Zakharov and Shabat, 1971).

In the case of solitons in optical fibers, the balance is between the wavelength dependence and the intensity dependence of the refractive index of the fiber waveguide. Group-velocity dispersion causes shorter wavelengths to travel faster (for the case of interest here) than the longer wavelengths. Normally, the leading edge of the pulse becomes blueshifted and the trailing edge redshifted. However, the intensity dependence of the refractive index causes the phase of the pulse to be time dependent. This results in a frequency shift toward the red on the leading edge and toward the blue on the trailing edge, tending to cancel the effect of group-velocity dispersion. When these opposing effects balance, an optical-fiber soliton is formed.

Classical arguments predict that a soliton is invariant as it propagates. However, the classical picture of solitons is not correct quantum mechanically: A true quantum soliton undergoes phase diffusion and wave-packet spreading. A quantum soliton consists of a linear superposition of solitons with different photon-number and momentum eigenstates. Each component soliton has a different phase velocity and group velocity, causing the phase and the wave packet of quantum solitons to spread out as they propagate. This fact, implicit in an early work by Bethe (1931), has been explored recently in much more detail in the quantum theory of optical solitons (Haus and Lai, 1990, and references therein). We now know that solitons in optical fibers are superpositions of macroscopic quantum states that correspond to clusters of 10^8 or more photons, bound together. Nevertheless, intrinsically quantum-mechanical effects emerge and can be detected even for such macroscopically large objects. Recently, theoretical predictions of quantum phase diffusion have been confirmed experimentally in one of the few experimental tests of a simple, exactly soluble quantum-field theory. These experiments give direct evidence of the quantum nature of soliton propagation.

When two optical solitons collide, the phase and position of each soliton are correlated with the photon number and momentum, respectively, of the other soliton. This has been shown theoretically in the quantum theory of soliton collisions and has now been confirmed experimentally (Drummond *et al.*, 1993, and references therein). These experimental results not only extend our understanding of single quantum solitons to the collision of two solitons but also provide an experimental realization of a quantum nondemolition (QND) measurement of the photon number of an optical soliton.

QND measurements were first discussed by Landau and Peierls (1931). Lately, there has been renewed interest in developing various techniques for the realization of QND measurements because of their unique importance to quantum theories of measurement, and practical implications for precision measurements. Optical solitons propagate and collide with unchanging pulse shape, momentum, intensity, and energy. Consequently, the photon number of a soliton is not altered when its energy is measured by means of the phase shift of a soliton with which it collides. Accordingly, the conditions necessary for a QND measurement are met, and a QND measurement can be used to determine the number of photons in a soliton pulse with an accuracy better than the shot-noise limit.

4.2 Quantization of Optical Solitons

An optical soliton in a fiber can be described classically using the nonlinear Schrödinger equation, which is applicable to single-mode propagation in nonlinear dispersive fibers or waveguides. This is an approximate wave equation, which ignores quantum effects. In this section, we review the predictions of a quantum version of this equation, in which operators replace the classical field variables. Classically the most unexpected behavior is the existence of quantum solitons of discrete particle number and undetermined phase. More readily observable quantum effects include phase and position diffusion, in which classically stable observables have increasing quantum uncertainties with propagation. For soliton collisions, quantum theory predicts that information about phase and position is transferable from one soliton to another, allowing QND measurements.

In a reference frame moving at the group velocity v, the corresponding quantum operator equation for the photon density amplitude $\hat{\psi}$ in dimensionless form is

$$\frac{\partial}{\partial T}\,\hat{\psi}(T,X) = i\left\{\pm\tfrac{1}{2}\frac{\partial^2}{\partial X^2} + \frac{2\hat{\psi}^\dagger\hat{\psi}}{\bar{N}}\right\}\hat{\psi}(T,X), \qquad (37)$$

where

$$[\hat{\psi}(T,X),\hat{\psi}^\dagger(T,X')] = \delta(X - X'). \qquad (38)$$

The variable T represents elapsed time and is therefore proportional to the distance propagated. It is defined relative to a characteristic pulse duration t_0 and group-velocity dispersion $k_0'' = \partial^2 k/\partial\omega^2|_{\omega=\omega_0}$, so that

$$T = vt|k_0''|/t_0^2. \qquad (39)$$

The variable X represents spatial location relative to the moving reference frame:

$$X = (x/v - t)/t_0. \qquad (40)$$

The ± sign in Eq. (37) is positive for anomalous-dispersion ($k_0'' < 0$) optical fibers that support solitons, typically at wavelengths greater than ~1.4 μm. The quantity $\bar{N}$ is a scaling constant inversely proportional to n_2, the nonlinear refractive index per unit intensity:

$$\bar{N} = 2|k_0''|\mathcal{A}_c/n_2\hbar\omega_0^2 t_0. \qquad (41)$$

Here $\mathcal{A}_c$ is the effective modal cross section of the fiber. The operator $\hat{\psi}^\dagger(T,X)\hat{\psi}(T,X)$ directly represents the photon density in dimensionless units.

The operator equations show that photons propagate with a nonzero effective mass $m = \hbar/(|k''|v^3)$ in the moving reference frame. Similar changes in effective mass are observed in electrons traveling in solids. The nonlinear term in the equation is equivalent to a localized delta-function attractive force acting between the particles.

The energy eigenstates of this quantum nonlinear Schrödinger equation are known from early theoretical work on interacting Bose gases. The simplest quantum soliton is an eigenstate consisting of a cluster of photons with a well-defined energy and photon number—a photonic atom. Such a state is predicted to propagate stably, without distortion or breaking up into its component photons, just as an atom does in free space. There are forces predicted to act between two such quantum solitons, as there are between two atoms. Quantum states of this type can be pulses of macroscopic size, with 10^9 or more photons. Despite this, an isolated quantum soliton-number eigenstate has yet to be experimentally observed.

Fiber soliton experiments start with the input field in a coherent state, rather than in a state of well-defined particle number. In a coherent state, the quantum fluctuations of the electric field are identical to those of a vacuum state. As shown in Fig. 13, the variance is the same for either amplitude or phase fluctuations. Thus, the photon number N must have fluctuations such that $\langle(\Delta\hat{N})^2\rangle = \langle\hat{N}\rangle$. This means that an input field will be a superposition of quantum solitons of differ-

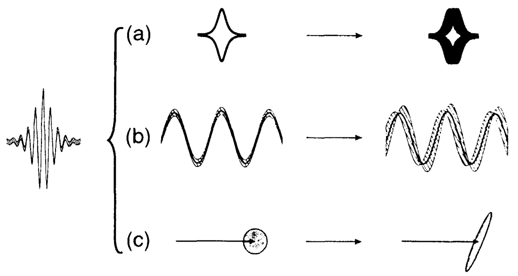

FIG. 13. Evolution of a quantum soliton. A coherent soliton, shown schematically at the left, is a superposition of a classical hyperbolic secant light pulse and quantum noise due to the zero-point fluctuations of the field. The presence of the zero-point fields imposes uncertainties in the soliton's position in time and space, its central frequency, its photon number or electric-field amplitude, and the phase of its electric field. The frequency uncertainty, coupled with the frequency dependence of the group velocity of the fiber, causes quantum spreading of the envelope of the pulse as shown in (a). The uncertainty in photon number obeys a Poisson distribution and is responsible for the "shot noise" observed when coherent light is detected. The photon-number uncertainty, along with the intensity dependence of the phase velocity, causes a spreading of the phase as shown in (b). The electric field and noise are shown for an optical period. The phase and position spreading are not due simply to an increase in uncertainty, but also to correlations with the amplitude and frequency of the pulse, respectively. This results in interference effects. The destructive interference of the noise occurs at certain phases of the optical cycle, as shown in (b). This is known as quantum-noise squeezing and can also be represented as a narrowing of the phase-space diagram of the field as shown in (c). There, the vector represents the average electric-field amplitude and the shaded area the quantum noise. The left side is a coherent state—the superposition of the field and zero-point fluctuations with equal and uncorrelated amplitude and phase uncertainties yields a circular distribution. At the right, the soliton is shown after evolving into a squeezed state. The noise is reduced in certain directions because of the correlations, yielding an elliptical distribution with a minor axis smaller than the width of the original coherent noise distribution.

ent photon number, along with some unbound "continuum" photons.

Even for superpositions of this type, there are large differences between the classical and quantum theories. We first note that the classical equations predict that coherent pulse will propagate essentially unchanged if injected with an initial amplitude of $\sqrt{\bar{N}/2} \times \operatorname{sech}(X)$. The time-dependent classical solution is given by

$$\psi_0(T,X) = \sqrt{\bar{N}/2}\,\operatorname{sech}(X)\exp[i(\theta_0 + T/2)], \tag{42}$$

where θ_0 is the initial phase. The parameter $\bar{N}$ corresponds to the mean photon number $\langle N\rangle$. Thus, the only change predicted classically is that the total phase $\theta(T) = \theta_0 + T/2$ increases linearly with distance down the fiber.

The classical result of a soliton as a phase-shifted, undistorted pulse never occurs in quantum theory. Even for a quantum soliton with a well-defined photon number, the center-of-mass position obeys the Heisenberg uncertainty principle. Position and momentum are conjugate observables and thus not simultaneously measurable, and so a soliton with some given velocity cannot have a well-defined position at all times. This holds as well for the conjugate observables of phase and photon number. Momentum and photon number are invariant during propagation. Their conjugates (position and phase) are predicted to show a quantum-mechanical time dependence—leading to increasing fluctuations as time progresses. This is the quantum diffusion of position and phase.

In order to understand quantum phase diffusion better, consider a simplified model of the input coherent pulse as a superposition of quantum solitons of different photon numbers. The classical phase shift of a soliton with N photons at elapsed time T is

$$\theta_N(T) = \frac{TN^2}{2\bar{N}^2} = \frac{x|k_0''|N^2}{2t_0^2\bar{N}^2}\,. \tag{43}$$

This phase shift can also be calculated directly from quantum theory, using the fact that the optically measured phase is the difference between the quantum phases of the N-photon and the $(N + 1)$-photon states. As many photon-number states are superimposed to give an initially coherent soliton, this leads to a corresponding diffusion of phase shifts after an elapsed time T. The enhanced phase fluctuations can be roughly estimated from the known fluctuations in photon number N, giving $\langle\Delta\theta(T)^2\rangle \approx T^2/\bar{N}$. More rigorously, the initial coherent-state phase fluctuations should also be included. This gives the final result that

$$\langle\Delta\theta(T)^2\rangle = (0.607 + T^2)/\bar{N}. \tag{44}$$

A similar result holds for the quantum diffusion of the center-of-mass position.

As a result of phase diffusion, the distribution of the amplitude fluctuations narrows, or is squeezed, for certain phases. This leads to quantum-noise reduction, as illustrated in Fig. 13. Its physical origin is the correlation of photon number and phase for each component of the superposition. Quantum noise reduction due to soliton squeezing has possible applications in low-noise measurements.

We now turn to soliton-collision experiments, which have been analyzed using quantum inverse-scattering methods. In fact, it is possible to understand soliton collisions using classical inverse-scattering results together with stochastic noise sources representing vacuum fluctuations. After two solitons collide, the position and phase of one soliton are modified by an amount that depends on the velocity and photon number of the other soliton. Quantitatively, we find

$$\Delta\theta_P^{\mathrm{COL}} = 2\left(\tan^{-1}\left[\frac{N_P + N_s}{\bar{N}|V_P - V_s|}\right] - \tan^{-1}\left[\frac{N_P - N_s}{\bar{N}|V_P - V_s|}\right]\right). \tag{45}$$

For large relative velocity differences, the result for the phase reduces to

$$\Delta\theta_P^{\mathrm{COL}} = 4N_s/\bar{N}|V_P - V_s|, \tag{46}$$

where $\Delta\theta_P^{\mathrm{COL}}$ is the phase shift experienced by a probe soliton, V_P and V_s are the velocities of the probe and signal solitons in dimensionless units, and N_P and N_s are the corresponding numbers of photons. The physical explanation of this effect is that as the solitons pass through each other, they experience a more intense field. Because of the nonlinearity of the refractive index, this increases the phase shift experienced by each soliton. The phase shift is proportional to the photon number of the other soliton—but is smaller at large relative velocities, as this reduces the interaction time.

A probe-soliton phase measurement after a collision of probe and signal solitons allows the photon number of the signal soliton to be measured, as $\Delta\theta_P^{\mathrm{COL}}$ is proportional to N_s. The significant feature of this interaction is that neither the photon number nor the velocity of either soliton is changed during the collision. In contrast, all other photon-number measurement techniques used in practice modify the photon number. Thus, soliton collisions allow a back-action–evading or quantum nondemolition measurement of the soliton photon number.

4.3 Quantum Nondemolition Measurements

For both the photon-number and the momentum eigenstates of an optical soliton, it is possible to perform two or more back-action–evading measurements that yield identical outcomes and do not change the quantum-mechanical state of the soliton. These are known as quantum nondemolition (QND) measurements. Several optical QND measurements have been proposed theoretically, and partial QND measurements have been demonstrated experimentally by several groups. However, two successive measurements on the same quantum state have yet to be achieved.

The unique characteristics of quantum solitons promise to make successive QND measurements possible. Except for solitons, all optical pulses experience broadening due to group-velocity dispersion in a dielectric medium. Thus, the photon number in any given time interval (the intensity of the pulse) is not a well-defined quantity. Much the same happens for continuous-wave optical signals, unless they are strictly monochromatic. However, quantum solitons can propagate with a well-defined photon-number state, so that two sequential measurements on the same quantum state can easily be carried out. As subsequent measurements can take place in a single optical fiber, so losses can nearly be eliminated.

A partial soliton QND measurement of photon number was recently demonstrated experimentally. Three jitter-free optical pulses—a signal, a probe, and an identical reference—were extracted from single color-center-laser pulses spectrally broadened to a 10-nm bandwidth by self-phase modulation in an optical fiber. These were launched into a 400-m, negative group-velocity dispersion, single-mode, polarization-preserving fiber, yielding a signal soliton at 1460.7 nm and identical probe and reference solitons at 1456.0 nm, all with ~1.0-nm bandwidths and 2.2-ps pulse widths. Timing was adjusted so that the signal and probe collided halfway along the fiber. The reference soliton, offset 30 ps from the probe, propagated without colliding. The three closely spaced solitons moved more quickly through the fiber than it could change as a result of thermal noise processes. This eliminated most of the detrimental effects of guided acoustic-wave Brillouin-scattering noise, which usually plagues quantum optical measurements in optical fibers.

The solitons, after colliding and leaving the fiber, were separated with a diffraction grating. The signal soliton, directed into a photodetector, gave a current proportional to its photon number. The probe and reference solitons, interfering in a soliton-collision interferometer as shown in Fig. 14, gave a current corresponding to the phase of the probe relative to that of the reference.

The results were as predicted by Eqs. (45) and (46): The phase shift of the probe was proportional to the photon number of the signal soliton. For example, when the signal soliton was switched on and off, the probe soliton's phase was modulated by 1.2 radians (70°). In the quantum regime, the fluctuations of the photon number of the signal were observed to be correlated with the phase fluctuations of the probe. Furthermore, the signal soliton's photon-number fluctuations were unchanged by the collision and shot-noise limited, showing that no excess noise was introduced back into the photon number of the signal.

The results of the experiment are shown in Fig. 15. Noise correlations were found by adding and then subtracting the two noise signals—differing results indicated a correlation. In the experiment, a delay line caused the signal-soliton shot-noise fluctuations to alternate in sign depending on the frequency. When the two noise signals were summed, correlations caused a modulation of the noise spectrum. Such a modulation, observed with a radio-frequency spectrum analyzer, is seen in the two sets of experimental data shown in Fig. 15(a). Figure 15(b) shows the modulation more clearly, after the data sets are subtracted to eliminate background variations. The results of the check for excess noise in the signal soliton, carried out immediately after the correlation measurements, are shown in Fig. 15(c). Above 12 MHz, the average difference between the noise of the signal solitons and a quantum-limited calibration signal was less than 0.1 dB, indicating no excess noise due to either the collision or external factors.

The experiment showed that soliton-collision phase measurements satisfy the criterion for a QND measurement. The QND readout (the phase shift of the probe soliton) and the QND observable (the photon number

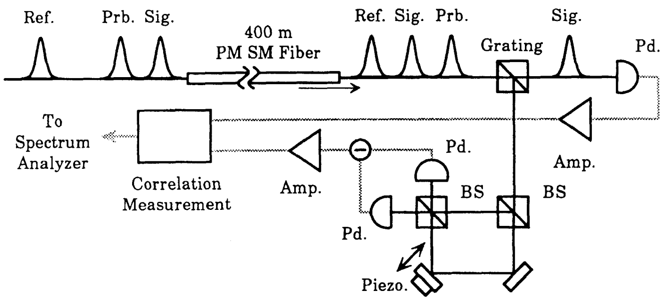

FIG. 14. A schematic diagram of the quantum nondemolition (QND) measurement. A signal soliton (Sig) at 1460.7 nm and identical probe (Prb) and reference (Ref) solitons at 1455 nm propagate in a 400-m polarization-maintaining (PM), single-mode (SM) fiber having anomalous group-velocity dispersion. The signal and probe solitons collide in the fiber, causing the phase of the probe soliton to shift in response to the photon number of the signal soliton. After leaving the fiber, the solitons are separated by a dispersing grating. A photodiode (PD) records the photon-number fluctuations of the signal soliton and an interferometer (with one arm slightly longer than the other so that the probe and reference pulses overlap) measures the phase-shift fluctuations of the probe soliton. Correlation measurements with a radio-frequency spectrum analyzer show the fluctuations to be correlated, indicating a partial QND measurement.

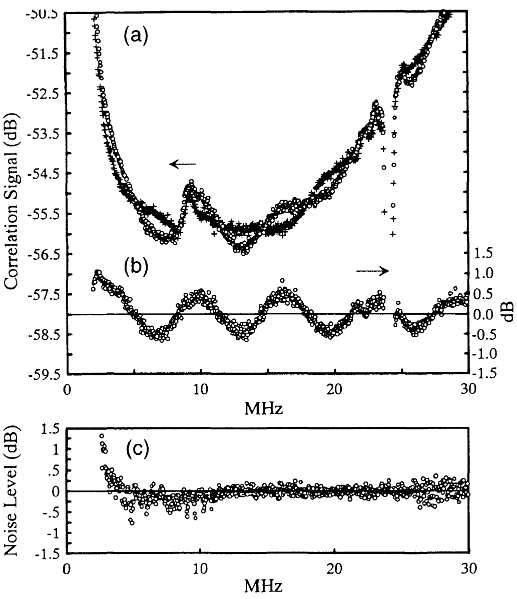

FIG. 15. Experimental results verifying the QND nature of the soliton-collision measurement. The correlation between the shot noise of the signal soliton and the phase noise of the probe soliton is indicated by the modulation of the two radio-frequency spectrum-analyzer traces in (a). Subtracting the two for clarity gives (b). The lack of excess noise due to the measurement is shown in (c), where the data points are the difference of the photon-number fluctuations of the signal soliton and a quantum-limited calibration signal. Above 12 MHz, they cluster about the standard quantum limit (solid line). Taken together, these results show the photon number of the signal soliton and the phase of the probe soliton to be quantum correlated.

of the signal soliton) were correlated; the measurement was back-action evading (no noise was introduced into the signal soliton's photon number), and the QND observable was not changed either by measurement, by propagation, or by external noise. Thus, for a soliton initially in a coherent state, a measurement as described here puts the soliton in a near photon-number state—a partial QND measurement causes photon-number squeezing. An identical second measurement on the same signal soliton, if correlated with the first measurement, could verify that both measurements gave the same result. In principle, this would be a full QND measurement that would leave the quantum-mechanical state of the soliton unaltered. It would be a classical-type measurement in that it would determine the soliton's photon number without changing it.

4.4 Future

Because solitons interact in a particlelike manner, preserving their identity when perturbed, they are also likely to be important for viable optical switching devices or logic gates. Nonsoliton implementations often suffer from pulse distortions that cause incomplete switching. From this perspective, a soliton-collision QND experiment is similar to an optical switching device—information coded on the signal soliton by means of its presence or by its photon number is transferred to the probe soliton. To a good approximation, this realizes a reversible quantum logic gate (Bennett, 1987, and references therein), a device of considerable theoretical interest. Quantum effects in the propagation and collisions of solitons may ultimately determine the limits to performance of optical switching devices. Such limits are only now beginning to be defined.

It is interesting to consider other physical systems that have optical solitons with stronger nonlinearities. Self-induced transparency in resonant two-level systems produces a slightly different type of optical soliton, mathematically described by a Maxwell–Bloch equation (McCall and Hahn, 1969). The leading edge of the pulse excites ground-state atoms to excited states, and then the trailing edge of the pulse stimulates transitions back to the ground state. In this way, the optical pulses propagate without being attenuated or distorted in the medium. As self-induced transparency solitons exist in resonant two-level systems, large nonlinearities are expected, even for solitons with low intensities. Resonant two-level systems also are expected to support spatial solitons with quantum properties similar to those described here, but with larger nonlinearities. Quantum solitons of a different variety—topological solitons—are predicted in a number of model quantum field theories used in solid-state and particle physics (Coleman, 1985). It is possible that our methods could be used to investigate directly these solitons, whose quantum properties are as yet untested by experiment.

5. OUTLOOK

Squeezing, cavity QED, and QND measurement are a nice demonstration of fundamental concepts of quantum mechanics such as Heisenberg's uncertainty relation, vacuum fluctuation, and von Neumann's projection postulate. There are also emerging subjects such as quantum cryptography and quantum computing (parallelism). Theoretical and experimental studies on various quantum optics have contributed greatly to the foundation of quantum mechanics. The field has now started to link with mesoscopic (nanostructure) physics and communication/computer technologies.

However, as Rolf Landauer has criticized repeatedly (Landauer, 1995), any information-processing scheme based on quantum coherence or superposition state is not realistic as a practical technology because it requires a perfect preparation of the system and zero dissipation. There is not such a perfect system in a real world. The computer and communication systems of today are classical ones, even though the principle of constituent devices such as a laser or a transistor has a quantum-mechanical origin. They do not utilize the quantum-mechanical nature of a linear superposition state.

The future evolution of quantum optics with nanostructure devices and atomic-scale devices is expected to give us an answer to the question "Is a real quantum effect useful for practical applications?"

GLOSSARY

Cavity Quantum Electrodynamics: Control of spontaneous emission by modifying a vacuum-field fluctuation by a cavity wall.

Heisenberg Uncertainty Principle: The statement that the quantum-mechanical uncertainties of a pair of conjugate observables such as the position and momentum of a free particle must satisfy a minimum product.

Optical Soliton: A solitary optical pulse that propagates without pulse spreading or breakup. An optical soliton in a fiber is produced by the balance between Kerr nonlinearity and negative group-velocity dispersion.

Quantum Nondemolition Measurement: A quantum measurement without the back-action noise on a measured observable. The measurement error of a measured observable and the back-action noise on the conjugate observable satisfy the Heisenberg uncertainty product.

Squeezed State: A minimum-uncertainty state of light with reduced quantum noise of one observable and enhanced quantum noise of the conjugate observable.

Vacuum Fluctuation: The ground state of an electromagnetic wave has a quantum-mechanical zero-point fluctuation that originates from the Heisenberg uncertainty principle.

INTRODUCTION

Quantum optoelectronics describes a new-generation technology that integrates quantum electronics and optics. In general, optoelectronics also encompasses their boundary fields and applications, as shown in Tables 1 and 2. These related disciplines include, among others, optical-fiber communication, optical-signal processing, space optical communication, optical spectroscopy, applied optical measurements, medical applications, optical power applications, and laser irradiation. All these technologies have rapidly developed and are now widely used in many areas such as home electronic equipment, office automation, and industrial electronics. This article summarizes the historical development, as well as the present status, of optoelectronic devices such as laser diodes, light-emitting diodes, photodetectors, optical modulators, and optical amplifiers. Finally, the latest developments in photonics and optoelectronic integrated circuits and their applications are examined.

1. GENERAL BACKGROUND

1.1 Historical Aspects

In the first days of optoelectronics, electroluminescent materials were used coupled with photoconductors. These materials were later transformed into coupled light-emitting diodes or laser diodes with photodiodes and called photocouplers. The discovery of lasers in the early 1960s laid the foundation for the establishment of optoelectronics (see Laser Physics). Indeed, the development of coherent optics and quantum electronics paved the way for numerous new technologies such as optical communication (*q.v.*), optical recording and memories (see Optical Storage), laser fusion (see Fusion Technologies), and medical applications (see Medical

USE OF LASERS), which make heavy use of different optoelectronic devices (see LASER TECHNOLOGY).

Since the early 1970s, optical communication systems were widely developed using single-mode fibers, laser diodes, avalanche or *p-i-n* photodiodes, and well-designed LSI optoelectronic circuits. Recently, large-capacity optical communication systems have been realized by newly developed erbium-doped optical amplifiers and photonic integrated circuits (see FIBER OPTICS; AMPLIFIERS, OPTICAL). Global communication networks are being constructed using these systems.

1.2 Optoelectronic Devices

1.2.1 Light Sources In late 1962, the first semiconductor injection lasers were reported, almost simultaneously, by four groups, headed by Hall (1962), Nathan (1962), Quist (1962), and Holonyak (1962). While earlier work had considered the possibility of light amplification in semiconductors (Watanabe and Nishizawa, 1957; Boyle and Thomas, 1960), achieving high-efficiency electroluminescence from GaAs *p-n* junctions was the event that prompted accelerated efforts to demonstrate a semiconductor laser. Pulsed radiation of 9.84 μm was obtained from a liquid-nitrogen–cooled forward-biased GaAs *p-n* junction. That same year, Pankove *et al.* (1962) demonstrated the GaAs light-emitting diode (LED). The realization of a continuous-wave (cw) laser at room temperature was later achieved by Panish *et al.* (1970), using double heterojunctions. This structure was independently first proposed by Kroemer (1963) and by Alferov and Kazarinov (1963). These light sources represented real breakthroughs in the practical use of optoelectronics, because all the devices have very small size (about 200 μm) and high efficiency and are best suited for integrated circuits. In 1971, Kogelnik and Shank (1971) proposed the distributed-feedback (DFB) laser and demonstrated the first experimental results for dye lasers. The concept was later implemented for semiconductor lasers by Nakamura *et al.* (1973). Thus, control of the oscillation frequency became possible. In 1978, Holonyak *et al.* (1980) fabricated the first quantum-well (QW) laser, which introduced quantum size effects into heterostructures and revealed excellent properties such as low threshold current, high power capability, and low noise. Tsang *et al.* (1979) achieved further reduction of the threshold current by combining quantum wells with graded-index (GRIN) distribution. The graded-index waveguide itself was previously demonstrated using organic film (Nishizawa and Otsuka, 1972), glass, and semiconductor layers (Nishizawa, 1973).

Recently, other important light sources have been developed from novel optoelectronic-device structures. Vertical-cavity surface-emitting (SE) lasers with submicron diameters have produced the lowest threshold current, the highest quantum efficiency, and the highest modulation speed (Jewell *et al.*, 1990). Furthermore, by the employment of extremely short–cavity-length and high-reflectivity distributed–Bragg-reflector (DBR) mirrors, some lasing characteristics exhibit unique features, like extremely low threshold current, single longitudinal mode, and a circular spot profile of output light (Kuchibhotla *et al.*, 1991). In addition, the ultrasmall SE lasers provide high-density two-dimensional laser arrays, which are essential for parallel optical-signal processing, optical interconnections, and optical computing. In fact, the control of spontaneous emission by microcavities is becoming of great interest for realizing the ultimate performance of SE lasers (see OPTICS, QUANTUM). Improved characteristics have also been achieved by compressively strained quantum-well (QW) lasers (Thijs *et al.*, 1991). Lasers employing tensile-strained QW show a high and a narrow gain spectrum. Such optoelectronic devices are currently of considerable interest because of their dramatically improved performance as compared with bulk and lattice-matched QW devices.

1.2.2 Photodetectors The development of efficient light detectors, like the *p-i-n* photodiode and the avalanche photodiode (APD), has prompted their wide use in optical communication. In this application, detectors receive the transmitted optical pulses and convert them into electronic pulses, with as little loss as possible. The performance requirements are high sensitivity, low noise, wide bandwidth, high reliability, and low cost. Another common application of photodetectors is the monitoring of laser transmitters. For optical communication and signal-processing systems, there is usually a need for high-speed detectors. For several other applications, high gain is necessary. Consequently, bandwidth and gain are fundamental trade-offs, and so the final application determines which type of photodetector is the most suitable. Photodetection is sometimes associated with demodulation, when a high-frequency optical signal is converted into a time-varying electrical signal for further processing and rectification. Photodetectors are used to detect optical signals over a wide range of the optical spectrum (see SIGNAL PROCESSING, OPTICAL).

Recently, coherent optical detection is rapidly gaining importance in long-distance optical communication systems. In this receiving technique, also referred to as *heterodyne detection,* a weak signal is mixed with a strong local-oscillator (LO) wave at a close enough frequency, resulting in an effective signal gain through coherent phase interference. The gain is proportional to the LO amplitude. Heterodyning allows the detection of very weak optical signals, which would not be normally converted into electrical signals through conventional direct-detection techniques.

1.2.3 Optical Fibers Depending on the application, light is transmitted through various media. In free-space communication the medium is air or vacuum. In guided-wave systems, light is transmitted by optical fibers or by dielectric waveguides, usually made of compound semiconductors. The choice of dielectric materials depends largely on the application. A typical fiber is an optical guide with an inner, high-index core and an outer, low-index cladding. The fiber properties are, to a large extent, determined by the core and cladding diameters and refractive indices. Optical fibers have their lowest loss at 1.55 μm. However, with rare-earth doping, the lowest dispersion and optical amplification have been observed at 1.3 μm. For long-distance fiber communication, the materials of choice are InP-based lattice-matched materials, or GaAs- and InP-based mismatched materials. For short-distance fiber transmission, GaAs/AlGaAs is used, since fiber losses at 0.8 μm remain within acceptable limits. Fibers are now being developed for longer wavelengths. Similarly, as semiconductor sources are developed for emission in the visible part of the spectrum, using III-V and II-VI compounds, appropriate guiding materials will also be developed (see FIBER OPTICS).

Recently, erbium-doped fiber amplifiers (EDFA) have been demonstrating their promise for advanced optical communication by allowing the transmission of soliton pulses over extremely long distances without optoelectronic repeaters (Nakazawa *et al.,* 1993).

1.2.4 Optical Modulators In the early days, one of the most promising devices for modulating a laser beam was based on the nonlinear electro-optic effect, discovered by Kerr in 1875. This effect produces a convenient and widely used way of controlling the intensity of propagating optical beams. This type of modulation is used in the *Q* switching of lasers for generating powerful optical pulses, mode locking, and optical beam deflection as well as modulation. The LD and the LED have been successfully used for optical communication since the early 1970s, because these devices can easily achieve direct modulation of the generated light corresponding to speech and video signals (see OPTICAL COMMUNICATIONS). However, direct modulation using the LD has two serious problems. One is that the modulation speed is restricted to less than 10 GHz, because of the relaxation oscillation based on the lifetime of carriers and photons. The other is that chirping produces spectral broadening of the modulated optical signal, restricting the modulation speed. Future optical transmission and processing systems will soon demand higher-speed modulation. Recently, a new type of optical modulators has been developed using multiple-quantum well (MQW), waveguide, and traveling-wave electrodes. These devices exhibit modulation speeds in excess of 20 GHz and efficient and low drive power.

1.2.5 Optical Logic and Bistable Devices For the ideal optical-signal processing required in optical computing, it is important to achieve control of an optical beam with another optical beam. Lasher (1963) and Fowler (1963) first demonstrated mutually quenched injection lasers as bistable devices. The optical logic devices, based on the competing phenomenon between modes in the LD, were built a year later by Nishizawa *et al.* (1965). The response to the change was measured at 98 GHz, which means that the time constant is very close to 10^{-12} s. These devices can be used as logic and memory devices.

More recently, Miller *et al.* (1985) produced a self–electro-optic effect device (SEED), a structure composed of MQW *p-i-n* diodes, which has a low threshold of transition light power and relatively high response. This device exhibits photonic switching, bistability, and optically induced oscillations due to the negative resistance in the photocurrent.

2. LIGHT SOURCES: LASER DIODES AND LIGHT-EMITTING DIODES

By and large, the most important optoelectronic device is the semiconductor laser or laser diode (LD). The LD, in principle, is an optical waveguide terminated by optical mirrors or reflecting faces that form a resonating cavity. The degree of confinement of the optical modes in the optical waveguide, which is usually made of dielectric or semiconductor materials, depends on the index of refraction of the surrounding media or cladding. The LD is small in size, efficient, and feasible to integrate. It has other excellent properties like high-speed switching and quenching, direct modulation of the output light, and light amplification.

The wavelength generated by the laser diode or the light-emitting diode (LED) can be varied from 0.3 to 30 μm by changing the combinations of semiconductor materials. The physical principles of the LD or LED are explained in Fig. 1, which shows the energy bands at the boundary between an *n*-type and a *p*-type region. There is a transition region, only a few angstroms thick, where population inversion exists and electrons in the conduction band can fall down and occupy holes in the valence band, emitting photons

of electromagnetic radiation. The material is in contact with a power supply that makes the electrons in the *p*-type region move toward the junction. Large numbers of electrons cross the junction when the current is flowing toward the *p*-type region, recombining with holes there. This type of laser is known as a junction diode laser, because electrons are injected into the junction region. An example of this device structure is shown in Fig. 2. Laser action takes place in the thin junction region and the emission is made into a bidirectional beam, as a result of the electromagnetic resonance by the highly flat polished end faces, which act as mirrors. The emitted light beam, multiply reflected at both end mirrors, can be changed into a polarized coherent light beam by quantum mechanically induced stimulated emission, which generates the same phase light corresponding to the phase of the standing light wave in the junction region (see Lasers, Semiconductor).

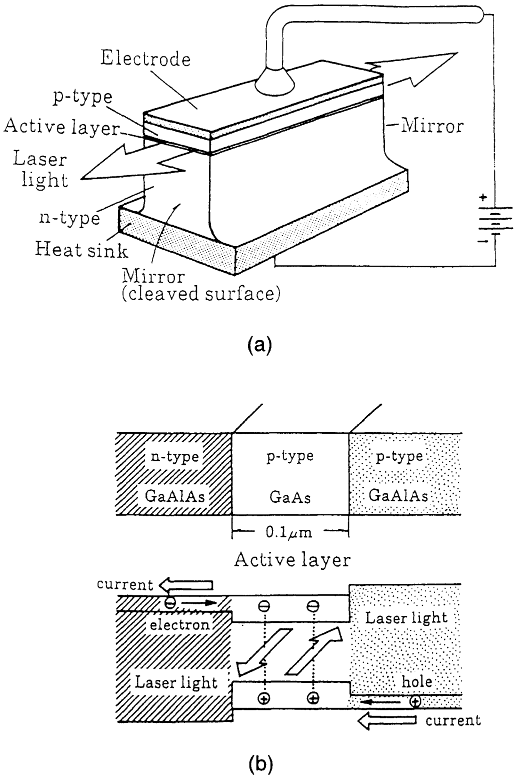

FIG. 2. Construction and operation of a laser diode: (a) system structure and (b) band diagram and carrier mechanism.

The LED is similar to the LD, but it is a structure without the stringent requirement of optical gain and optical resonator and, as a result, it has no stimulated emission. In the early days, the level of spontaneous emission from LED devices was very small. It is only recently, with the development of wider-band-gap II–VI semiconductors, that visible light emission from a biased *p-n* junction has been demonstrated. Some obvious advantages of the LED as a light source are simpler fabrication, lower cost, and simpler drive circuitry. The LED has found wide applications such as indicator lamps, display elements, and sensors (see Light-Emitting Diodes).

3. LINEAR OPTICAL DEVICES

3.1 Optical Amplifiers

The principle of the optical amplifier was already well known in the 1960s (Nishizawa, 1977). When two LDs are closely separated and one of them acts as an amplifier of the light output of the other, then the polarization direction of the incident light is maintained after amplification even if the amplifier's preferable polarization direction is different. Later, both traveling-wave–type and Fabry–Pérot–type amplifiers have been demonstrated and widely studied in the 1980s (see Amplifiers, Optical).

The LD amplifiers (LDA) are built with the same fabrication process as the LD. The traveling-wave–type LDA has nearly perfect antireflection coating on both end faces. When the input optical signal propagates in one direction along the waveguide in the LDA, the input power is gradually amplified without oscillation by injection of dc current. The typical gain for this device is 20–30 dB. The saturation output power is 8–10 dBm but the polarization dependency of the gain is relatively large. The gain × bandwidth product is in excess of 1 THz. To obtain a low noise figure, the beat noise between the optical signal and the spontaneously emitted light needs to be suppressed by using an optical narrow-band-pass filter.

For the resonant-type LDA, the optical frequency of the input light is restricted to coincide with the optical resonant frequency determined by an LD Fabry–Pérot resonator.

This LDA is similar to the LD in basic principles. The typical gain for this device is 15–20 dB. The saturation output power is −10 to −5 dBm. However, the gain × bandwidth product is as narrow as 5 GHz. The noise figure is determined by the beat noise between the optical signal and the spontaneously emitted light.

The fiber amplifier being recently developed is the revival of the concept of a glass laser and it is named for the initials of Er^{3+}-doped fiber amplifier (EDFA). The construction of the EDFA and the corresponding energy-band diagram are shown in Fig. 3. The EDFA operates at a wavelength of 1.55 μm and is composed of dielectric multiple-layer filters and an Er^{3+}-doped fiber that is pumped by an InGaAsP LD on a wavelength of 1.48 or 0.98 μm. This infrared radiation is absorbed by the Er^{3+} atoms, pumping them to a high energy level. When the excited electrons of the erbium atoms occupy a high energy level, if an optical-signal electromagnetic wave comes into the fiber, stimulated emission occurs. As a result, the power of the signal increases gradually along the fiber; that is, the optical signal is amplified. The EDFA has excellent characteristics, as follows. The typical gain is in excess of 30 dB; the gain × bandwidth product is more than 10 THz, and the noise figure less than 4 dB. Furthermore, the past few years have seen stunning developments in nonlinear optical communication with soliton propagation making full use of the advanced EDFA technology now available (Desurvire, 1994).

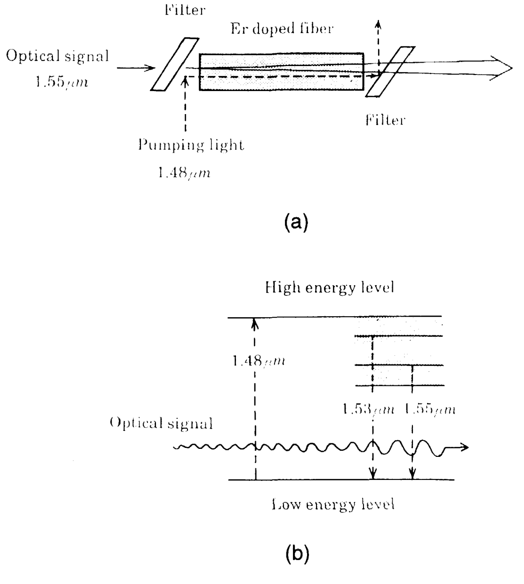

FIG. 3. (a) Basic properties of an optical amplifier and (b) band diagram of an erbium-doped fiber amplifier (EDFA).

Optical solitons were first observed in 1980 by Mollenauer *et al.* (1980). Because pulses as short as a few picoseconds can be transmitted in the soliton regime without broadening, it is evident that fiber-optic communication can potentially operate at ultrahigh bit rates such as 100 Gbit/s. Indeed, under the effect of periodic amplification, solitons can undergo significant power changes without losing their integrity. This property explains the success of EDFA-based experiments, in which the optical gain is confined to lumped fiber sections, such as the one recently reported by a Japanese team (Nakazawa *et al.*, 1993) where a 1000-km straight-line soliton transmission was achieved with four multiplexed channels modulated at a total of 40 Gbit/s.

3.2 Optical Modulators

There are many types of optical modulation, including intensity modulation, phase modulation, frequency modulation, and polarization rotating modulation. Analog or digital signals modulate the light beam. Many physical effects can be used for optical modulation and switching, such as linear (Pockels) and nonlinear (Kerr) electro-optic, magneto-optic, acousto-optic, and electroabsorption, including the quantum-confined Stark effect (QCSE). Even the Zeeman and the pressure effects can be used. These effects, phenomena, functions, and materials are summarized in Table 3. Among them, the most promising high-speed modulators are devices that make use of the Pockels effect or the QCSE.

3.2.1 Optical Waveguides An optical waveguide is composed of a core region of dielectric material through which light is propagated, surrounded by dielectric regions or air having a smaller dielectric constant, as shown in Fig. 4. This structure has been widely used for optical devices, because of the reflection-loss reduction in bulk devices, the compatibility with fibers, and the efficient modulation.

Table 3. Summary of physical effects and materials for optical modulators and optical switches.

Effect	Phenomenon	Function	Material
Electro-optic (Pockels)	Refractive-index change	Modulation: phase, amplitude, frequency, polarization Changes: reflection pass, mode	$LiNbO_3$ $LiTaO_3$ GaAs InP InGaAsP

Quantum-confined Stark	Exciton absorption, refractive-index change	Modulation: amplitude, phase	GaAs InP InGaAsP

There are two types of waveguides: planar waveguides, which guide light in the vertical direction but provide no lateral confinement [Fig. 4(a)], and channel waveguides, which provide three-dimensional confinement [Figs. 4(b) and 4(c)]. For example, channel waveguides in $LiNbO_3$ and GaAs are mainly used for high-efficiency devices. An optical wave propagating will be contained in the core if this has a higher refractive index than the surrounding region. It is analogous to the silica optical fiber (see OPTICAL COMMUNICATIONS). There are two types of profile for the refractive-index distribution in the waveguides. One is a step-index profile made by epitaxial growth and sputtering. The other is a graded-index profile made by diffusion, ion exchange, and ion implantation. In the step-index waveguide, light propagates in the core region by periodic repetition of internal total reflection (ITR), as long as the incidence angle to the substrate is greater than the ITR critical angle ϕ, according to Snell's law:

$$\sin\phi = n_s/n, \quad n > n_s. \tag{1}$$

In the graded-index waveguide, the light is continuously refracted on account of the decreasing refractive index so that light propagates describing a circular arc.

In titanium-strip diffused $LiNbO_3$ devices, the core region has a refractive index higher than the surrounding region by 0.1 to 1%. The waveguide can be fabricated so that the fundamental or lowest-order mode propagates. In practice a titanium pattern is formed by using photolithographic techniques and Ti deposition on the $LiNbO_3$ substrate. Then the crystal is heated in a furnace to diffuse Ti into $LiNBO_3$ at 1000°C for 7 hours. Thus, three-dimensional waveguides are fabricated. Typical waveguide dimensions are 3–8 μm wide and 2–6 μm deep. With epitaxial layers, the necessary index difference can be achieved either by lattice-matched growth of an epitaxial layer with different composition than the substrate or

3.2.2 Electro-optic Modulators An important consequence of dielectric properties is that for a linearly polarized plane wave propagating in the *z* direction, its polarization vector is defined by the direction of the electric field. Furthermore, the phase velocity of the propagating beam depends on the direction of polarization of the electric field. This phenomenon is known as birefringence and it is only observed in anisotropic media. If a linearly polarized wave is launched in the *z* direction, with equal electric field components in the *x* and *y* directions, it can be shown that the propagation constants in the *x* and *y* directions are different as a result of birefringence. This is the basis of electro-optic modulation, and the phenomenon can be used to build efficient field-induced modulators with appropriate crystals.

The linear (Pockels) electro-optic effect provides a change in refractive index proportional to an applied electric field. The way in which this index change produces intensity modulation depends on the device configuration. The optic axis is defined as the direction in a crystal in which, when light is propagated in the same direction, the refractive index is independent of the polarization direction of light. For simplicity, the device is usually fabricated such that the incidence face is parallel to the optic axis. The polarized light upon entering the crystal can be divided into two components: the ordinary component, whose electric field is parallel to the optic axis (and which corresponds to the refractive index n_o) and the extraordinary component, perpendicular to the optic axis (and corresponding to the refractive index n_e). The propagation velocities of these two components within the crystal are different. In general, as they emerge from the crystal, the two components are out of phase. Thus, the output light is elliptically polarized, as shown in Fig. 5. In this figure, the expression for the induced phase shift is

$$\Delta\phi = \frac{2\pi}{\lambda_0} l\Delta n = \frac{\pi n_o^3 \gamma}{\lambda_0 d} V. \tag{2}$$

The electro-optical effect is described by a tensor relation. The linear change in the coefficients of the index ellipsoid due to applied fields (E_j) along the principal crystal axes is

$$(\Delta n)_i = -\frac{n^2}{2} \sum \gamma_{ij} E_j, \tag{3}$$

where $i = 1$–6 and γ_{ij} is a 6×3 electro-optic tensor. This relation can be contracted

FIG. 5. A bulk-type optical phase modulator using the linear electro-optic (Pockels) effect.

with the electro-optic tensor to write the six values of Δn as the elements of a symmetric 3×3 matrix. Typical values for the electro-optic coefficients of such materials are shown in Table 4.

A typical system arrangement of an electro-optic amplitude modulator using $LiNbO_3$ is shown in Fig. 6. It consists of an electro-optic crystal placed between two crossed polarizers, which in turn are at a 45° angle. The output light from the crystal is elliptically polarized and its amplitude changes correspond to the applied voltage. The intensity of the output light can be described by

$$I = I_0 \sin^2(\pi V/2V_\pi), \tag{4}$$

where V_π is the so-called half-wave voltage. As its name implies, it is the voltage necessary to produce a retardation ($\Delta\phi$) of half a wavelength between the ordinary and extraordinary rays. From Eq. (2), we obtain that

$$V_\pi = \frac{\lambda_0 d}{(n_e^3\gamma_{33} - n_o^3\gamma_{13})l}. \tag{5}$$

If $d = 1$ mm and $l = 2$ cm, the value of V_π is about 150 V at a 633-nm wavelength.

There are numerous types of electro-optic modulator systems. These include, among others, bulk-type amplitude modulators, waveguide-type phase or intensity modulators, Mach–Zehnder interferometers, and directional-coupler–type modulators, as illustrated by Fig. 7. Typical values of the electro-optic constants for different materials are summarized in Table 4. A detailed description of such optoelectronic devices is given in a separate article (see MODULATORS AND DEMODULATORS, OPTICAL).

3.2.3 Electroabsorption Modulators

There are mainly three types of modulators based on electroabsorption phenomena, involving the Franz–Keldysh effect, exciton absorption, and free-carrier absorption.

When a reverse-bias voltage is applied to a *p-n* junction or Schottky junction, the optical absorption edge of semiconductors such as AlGaAs and InGaAs shifts to longer wavelengths, as shown in Fig. 8. Thus, the presence of a strong electric field results in the absorption of photons with energies less than the band gap of the semiconductor. This phenomenon is called the Franz–Keldysh effect, and an intensity modulator can be built making use of the difference in the absorption coefficients near the absorption edge, corresponding to the applied voltage. With the light wavelength chosen slightly smaller than the band gap, the light is fully transmitted at zero bias while it is attenuated with the application of a field. To illustrate such a system, the typical characteristics of an InGaAsP/InP substrate waveguide modulator are indicated, as follows: The modulation voltage is 12 V, the bandwidth is 8 GHz, and the insertion loss is 6 dB at a 1.58-μm wavelength.

A reverse-bias *p-i-n* diode with a multiple quantum-well (MQW) structure shows a large electroabsorption based on the quantum-confined stark effect (QCSE), as illustrated by Fig. 9. This effect is caused by

Table 4. Electro-optic constants and refractive index for different materials.

FIG. 6. A $LiNbO_3$ optical amplitude modulator: (a) system configuration and (b) operation principle.

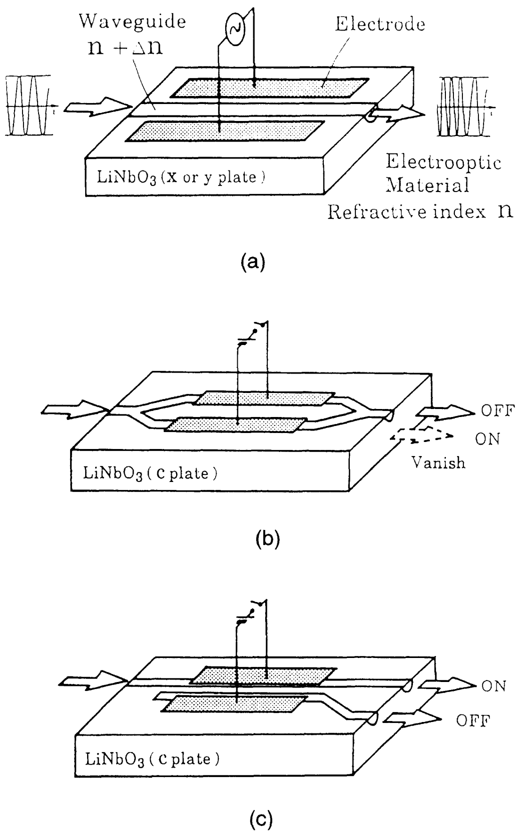

FIG. 7. Various examples of waveguide-type modulators: (a) phase modulator, (b) Mach–Zehnder amplitude modulator, and (c) directional coupler modulator.

Coulomb-coupled electron–hole pair or exciton absorption in the MQW structure, which enables the fabrication of an efficient amplitude modulator. The MQW layer, which is part of a superlattice heterostructure as shown in Fig. 9(b), consists of two periodically laminated materials with each layer usually less than 200 Å. In this two-dimensional structure, the exciton binding energy is about three times that in a three-dimensional or bulk structure. That happens because electrons and holes are confined to a region defined by the quantum-well width, so that the overlap of their wave functions is increased. This results in an increase of the oscillator strength of the interband transitions between the discrete-energy electron and hole bound states, which are produced by the size quantization. Consequently, strong resonances corresponding to the heavy-hole and light-hole transitions are seen near the band edge of the quantum-well material even at room temperature. Thus, a large exciton absorption exists at room temperature and the excitonic absorption edge shifts to longer wavelength (the so-called Burstein shift) corresponding to the reverse-bias applied voltage. The absorption-edge spectrum is abrupt compared with that of the Franz–Keldysh effect and its response speed is as high as 40 GHz. As a result, high-speed amplitude modulation (greater than 22 GHz) with low drive voltage (less than −4 V) and insertion loss less than 18 dB at a 1.54-μm wavelength have been reported for an InGaAlAs/InAlAs MQW waveguide modulator.

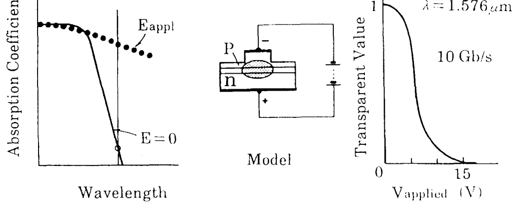

FIG. 8. System configuration and basic characteristics of an electroabsorption modulator based on the Franz–Keldysh effect.

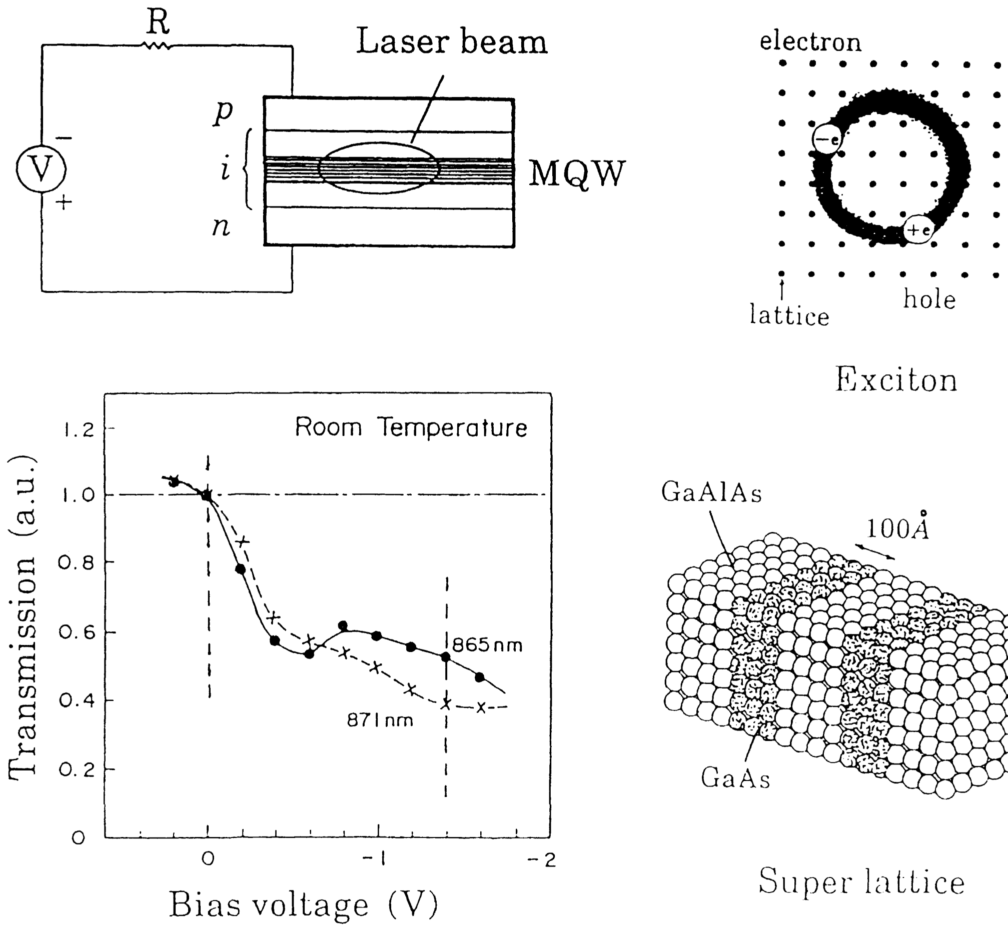
Another mechanism used for electroabsorption modulation is free-carrier absorption. This phenomenon involves the absorption of a photon by the interaction of a free carrier within an energy band, which is raised to a higher energy level as a result. The transition of the carrier to a higher energy level within the same valley must conserve momentum. This momentum change is provided by optical or acoustic phonons or by impurity scattering. Free-carrier absorption is usually present in the long-wavelength region of the spectrum as a monotonic increase in the absorption of the form

$$\lambda^p, \quad \text{where } p = 1.5\text{–}3.5. \tag{6}$$

The value of p depends on the nature of the scattering mechanism for momentum conservation, and the absorption coefficient is proportional to the free-carrier concentration N, as follows:

$$\alpha = \frac{Nq^2\lambda^2}{4\pi m^* n_r c^3 \epsilon_0}\left\langle\frac{1}{\tau}\right\rangle, \tag{7}$$



(a) (b)

FIG. 9. Configuration and characteristics of an electroabsorption modulator based on the QCSE: (a) MQW modulator system and basic transmission characteristics with wavelength as a parameter and (b) exciton (electron–hole pair) and heterostructure superlattice.

where n is the semiconductor refractive index and $\langle 1/\tau \rangle$ is the average value of the inverse of the relaxation time of the scattering mechanism.

3.2.4 Other Types of Modulators

There are many other types of modulators based on a variety of physical phenomena, such as the band-filling effect, the acousto-optic effect, the magneto-optic effect (see MAGNETO-OPTICAL DEVICES), and the thermal-optic effect (see THERMOELECTRIC DEVICES). Two of them are briefly described here.

As shown in Fig. 10, total-reflection-polarization intensity modulators have been fabricated making use of the band-filling effect. In this case, a large negative refractive-index change near the band-gap energy is induced by carrier injection. This refractive-index change is independent of the polarization direction. Typical characteristics of such a system are as follows: The switching injection is 90 mA, the switching speed is less than 1 GHz, the insertion loss is 20 dB, and the extinction ratio is about 10 dB at a 1.55-μm wavelength.

The basic principle of an acousto-optic modulator is illustrated by Fig. 11. An acoustic surface wave generated by an interdigital transducer propagates along a two-dimensional optical waveguide, inducing a distortion that acts as a grating; the pitch is equal

to an acoustic wavelength. An incident optical wave interacts at the grating and is reflected at certain angles that coincide with the Bragg angle between an acoustic wave vector and an optical wave vector. The spectrum of the outgoing light is changed from f_{opt} to $f_{\mathrm{opt}} \pm Nf_{\mathrm{acoust}}$, with N being an integer, so that frequency modulation can also be achieved.

3.3 Optical Detectors

When low levels of light are to be detected, it is desirable to use a photodetector with large sensitivity. For such applications, a large optical gain can be obtained with an avalanche photodiode (APD), as illustrated by Fig. 12. The APD system consists of an optical absorption region, an avalanche region, and a collector, with a reverse-bias voltage applied to the junction. The photons, incident through the window, are absorbed, generating electrons and holes. The photogenerated carriers are accelerated in the junction's depletion region, and if they acquire enough energy from the field, an ionizing collision with the binding electrons of the lattice atoms in the avalanche region can occur. Since each collision generates another electron–hole pair, the impact-ionization process continues, leading to carrier multiplication and gain. As a result, a large avalanche photocurrent is obtained. In other words, the APD has a current-magnification function corresponding to the reverse-bias voltage applied. Therefore, the APD exhibits very high sensitivity. However, its response can only be as fast as 10 GHz, since it is restricted by the carrier transit time across the avalanche region and the time constant containing the electric capacitance and the loading resistance (see DETECTORS, SEMICONDUCTOR).

The best performance of an APD is obtained when the ratio of the impact-ionization coefficients for electrons and holes is ei-

ther 0 or infinity. Unfortunately, in most compound semiconductors, this ratio is close to 1. In this case, both types of carriers continuously recycle through the depletion region, leading to long response and, consequently, small bandwidths. This is a fundamental limitation of the APD. In the last few years, however, clever ways to enhance or reduce this ratio in artificial structures have been explored (Bhattacharya, 1990). In fact, impact ionization in multilayered heterojunction structures was first proposed a decade earlier by Chin *et al.* (1980). Nowadays, superlattice or MQW APDs can be fabricated in such a way that only one type of carrier is confined in a deep quantum well (QW) and, therefore, its ionization rate is reduced (Kagawa *et al.,* 1993). The overall effect is the corresponding enhancement or reduction of the impact-ionization coefficient ratio. These tailored devices, in addition to low-noise performance and gain, can also provide tunability of the spectral response (see SPECTROMETERS, OPTICAL). In such structures, the absorption and avalanche region of the photodiode is made of multiple quantum wells of varying dimension and barrier sizes.

In the case of a *p-i-n* photodiode, the photons incident through the *p*-region window also generate electron–hole pairs. Each electron and hole flow in opposite directions, inducing a photocurrent. To obtain a high-speed response, a reverse-bias voltage is applied to the junction, but its value does not exceed the avalanche voltage. Thus, the photocurrent is very small because there is no current-magnification function. Although the *p-i-n* photodiode has no internal optical gain, by careful choice of material parameters and device design it can achieve very large bandwidths, with high-speed response of up to 60 GHz and very low noise.

4. NONLINEAR OPTICAL DEVICES

The response to small disturbances in most physical systems is linear. For instance, if the intensity of a standard laser beam is doubled, the intensities of the reflected and transmitted beams are also doubled. However, if the intensity is not increased two or three times but several orders of magnitude, it is possible to observe many interesting nonlinear effects, such as the generation of harmonics, two-photon processes, nonlinear mixing, or the Raman effect.

4.1 Second-Harmonic Generation

A most interesting physical phenomenon is second-harmonic generation (SHG). This kind of nonlinear response to the light waves occurs because the dielectric constant of materials is not really constant. In fact, any strong laser beam will be distorted when traveling through an optical material. This distortion is the result of the addition of one or more harmonics to the original laser beam. If the strength of the dipoles is defined by **P** and the applied optical field by **E**, then it may be shown that

$$\mathbf{P} = \chi \cdot \mathbf{E} + \chi_2 \cdot \mathbf{E}^2 + \chi_3 \cdot \mathbf{E}^3 + \cdots \text{etc.,} \tag{8}$$

where χ is the polarizability. From this equation, it follows that if **E** takes the form of $\mathbf{E} = \mathbf{E}_0 \sin(\omega t)$, then

$$\mathbf{P} = \chi_1 \cdot \mathbf{E}_0 \sin(\omega t) + \tfrac{1}{2}\chi_2 \cdot \mathbf{E}_0^2[1 - \cos(2\omega t)] + \cdots \text{etc.} \tag{9}$$

Equation (9) contains a term in 2ω, which corresponds to an optical wave having double the frequency of the incident wave. $\chi_2\mathbf{E}^2$ will not approach $\chi_1\mathbf{E}$ unless **E** has a value of at least 10^5 V/cm (equal to an optical power density of about 10^7 W/cm^2). Not all solids exhibit frequency doubling. Only if the material has no center of symmetry can frequency doubling be observed because χ_2 is not zero. The first researchers who observed frequency doubling focused the 6943-Å photon output from a ruby laser onto a quartz crystal and obtained blue emission at a wavelength of 3422 Å. To realize high-efficiency SHG devices, it is important that the phase (or velocity) matching between the original and the harmonic beam is satisfied. This can be achieved using appropriate optical materials, such as $LiNbO_3$, $KNbO_3$, and $KTiPO_4$ (KTP) crystals in resonant or in waveguide structure.

Figure 13 shows recently developed bulk SHG devices. For instance, a resonator composed of YAG and KTP crystals and a pair of mirrors can be excited by a LD at an 809-nm wavelength [Fig. 13(a)]. This configuration

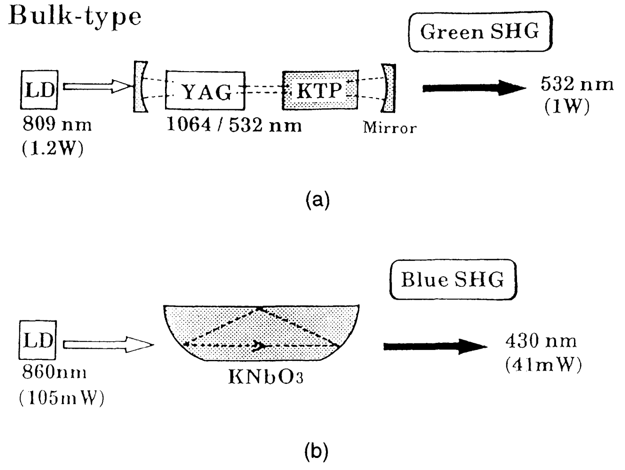

FIG. 13. Bulk-type SHG devices: (a) YAG-KTP and (b) $KNbO_3$.

allows the generation of a 532-nm green SHG beam. Likewise, a ring resonator fabricated from a $KNbO_3$ crystal, which has large nonlinear optic coefficients, allows the generation of a 428-nm blue SHG beam with 41-nW output power when an 856-nm beam from a LD with 105-mW output power is focused onto the crystal [Fig. 13(b)]. This device is highly efficient but demands both severe temperature control (within 0.3°C) and original laser wavelength control (within 0.06 nm).

The waveguide SHG devices are able to confine the original wave into waveguides so that the optical power increases about four orders of magnitude with respect to bulk SHG devices. The efficiency of waveguide SHG devices increases because it is proportional to the power density. Figure 14(a) shows a SHG device composed of a proton-exchanged $LiNbO_3$ waveguide. In this device, the phase-matching condition is automatically satisfied by use of Cherenkov radiation, involving the proton-exchanged waveguide, so that efficiency is about 1% and the direction of the output SHG beam is about 16° under the waveguide surface. In this device, a 410-nm SHG beam with 1 mW is obtained when the 820-nm original LD beam with 100 mW is focused onto the waveguide via an objective lens. The pattern of the output SHG beam has a crescent shape; therefore, a nonspherical lens is needed to convert it into a circular shape.

Recently, more efficient waveguide SHG devices have been developed by using a $LiNbO_3$ film, as shown in Fig. 14(b). To obtain the phase matching, the $LiNbO_3$ film was fabricated on a $LiTaO_3$ substrate, controlling the film thickness and orientation very precisely. The direction of the output SHG beam coincides with the original input beam. In this highly efficient device, 2.2 mW of SHG blue light is generated when only 40 mW of infrared light is focused onto the waveguides. Furthermore, to realize more efficient and practical compact devices, the quasi–phase-matching (QPM) technique can be used, which consists of the coherent domain inversion of crystals such as $LiTaO_3$, as shown in Fig. 14(c). One such recent blue-emitting SHG device is shown in Plate 1.

4.2 Raman Lasers

Another interesting nonlinear phenomenon is the Raman effect. When light of a single wavelength passes through a transparent substance, some of it is scattered. It has long been known that the scattered light contains not only the frequency of the original beam, but also other frequencies, with the frequency differences corresponding to the energy levels of the scattered molecules. These laser Raman lines are not only much more intense than the conventional Raman lines; they are also coherent, so that the laser Raman effect makes it possible to generate coherent light at new frequencies (see RAMAN SCATTERING; RAMAN SPECTROSCOPY INSTRUMENTATION). Recently developed semiconductor Raman lasers (SRL) built as a buried heterostructure with GaP Raman-active layer

and AlGaAs cladding layers could be of importance for heterodyne demodulation in wide-band optical communications, where light modulated with a frequency band exceeding 1 Thz should be detected.

5. OPTICAL LOGIC, OPTICAL BISTABLE, AND OPTICAL MEMORY DEVICES

Research in *optical computing* is already a few decades old. However, despite much progress, versatile optical computers that can replace or even compete with electronic computers remain elusive. Successful demonstrations of optical logic, utilizing the nonlinear effects in MQW structures, have been made. However, these attempts usually run into great difficulties due to the enormous amount of switching energy required and the sophisticated heat-dissipation schemes that subsequently become necessary for arrays of such single wafers. There is a real need for low-power photonic switching devices, which can be effectively used for computing and logic applications (see OPTICAL COMPUTING).

5.1 Optical Logic Devices

Optical logic devices based on the competing phenomenon between modes in the LD are shown in Fig. 15. Two diodes are fabricated in the same crystal. If an applied current is injected into surface D_1, the y direction starts lasing. However, if currents are injected simultaneously to D_1 and D_2, only the x direction is lasing because both D_2 planes are rough surfaces. That is, when the x direction is lasing, the y direction lasing is quenched as a consequence of mode competition. As a result, the optical output in the y direction, as shown in Fig. 15(b), corresponds to the injection currents ID_1 and ID_2. The response to the injection, which depends on the cavity length and the gain of the composed LD, was measured at 98 Ghz.

5.2 Optical Bistable Devices

Optical bistability allows two possible output states for the same input, as shown in Fig. 16. When the input intensity increases from zero, the output intensity gradually increases (A). The output rapidly increases (from A to B) when the input power is just over the threshold value A. It holds a constant value (C) when the input increases over

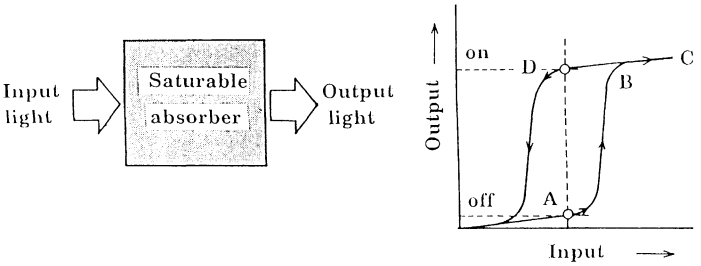

FIG. 16. Input–output characteristic of optical bistability.

the threshold. The output intensity slowly decreases with a decrease in the input power, and it rapidly decreases (from D to 0) when the input reaches another threshold value D, which is smaller than the value B. Thus, the input-versus-output characteristic has hysteresis, as shown in Fig. 16. Optical memory and logic operations can be obtained by utilizing this optical hysteresis curve. Such an operation principle is shown in Fig. 17. With the bias light intensity set at P_B, two stable states exist, according to the hysteresis curve: one "on" state, triggered by the "on" pulse, and one "off" state, triggered by the "off" pulse. If the hysteresis is free, a differential curve is obtained, which acts as a limiter for the output power corresponding to the various input values. Efficient bistability requires a strong intensity dependence to the absorption or to the index of refraction. It is desirable to obtain a large output difference and a small threshold value. There are two types of bistability; one is intrinsic, and the other is a hybrid type. The intrinsic device is fully optical; its intensity dependence arises from a direct interaction of light with matter. The hybrid device is partially optical, mixed with the electrical signal from a detector monitoring the transmitted intensity, usually applied to an intracavity phase shifter.

A reverse-bias *p-i-n* diode in a MQW structure shows a strong nonlinear effect based on the QCSE, previously described in Sec. 3.2.3. Indeed, at appropriate wavelengths, a strong negative–differential-resistance region is observed in the photocurrent-versus-bias voltage relationship of a *p-i*(MQW)-*n* structure. This arises because the photocurrent results from the change in absorption coefficient of the MQW due to the QCSE. It occurs where the heavy-hole and the light-hole peaks cross the photon energy of the input light. As long as the electron and hole densities in the quantum wells are less than 10^{11} cm^{-2}, the absorption process is essentially linear. This nonlinearity has been successfully exploited to tailor device response and demonstrate the operation of simple, optically controlled switching and logic devices. The most important of these devices is the self–electro-optic device (SEED), first demonstrated by Miller *et al.* (1985). The SEED exhibits photonic switching, bistability, and optically induced oscillations due to the negative differential resistance in the photocurrent. Recently, a symmetric self–electro-optic device (S-SEED) has been proposed, as shown in Fig. 18. Two SEED structures are electrically connected in series and inversely biased (-15 V). When input light of a constant value (2 mW) is fed into the SEED-1 and a weak control light pulse (of the order of 10 μW) is fed into the SEED-2, the output of SEED-1 shows dynamic bistability, as shown in Fig. 18(b). If the control light pulse is fed into the SEED-2, the SEED-1 shows the pulse output and has time-sequential power gain.

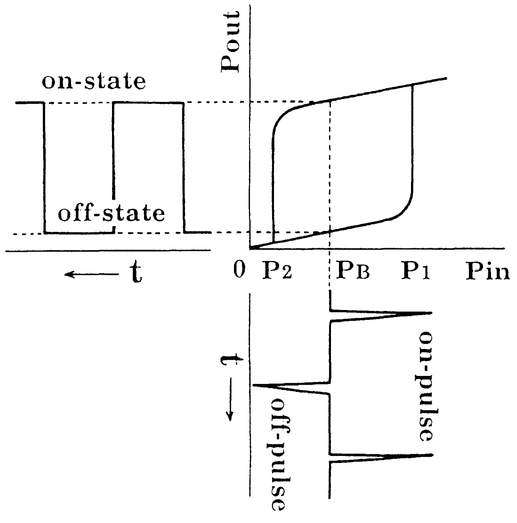

FIG. 17. Basic properties of optical memory and logic devices utilizing the optical hysteresis curve.

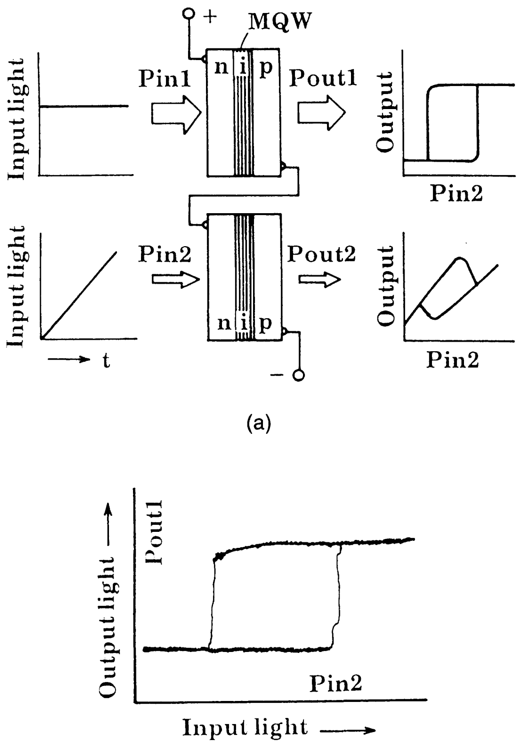
5.3 Optical Memory Devices

In general, optical memory can be achieved by utilizing the hysteresis curves discussed in Sec. 5.2 (see Figs. 16–18). In other words, all bistable devices can be used as optical memory devices.

Recently, a laser containing an absorption and current injection control region has been developed, as shown in Fig. 19. This device can perform as a saturable absorber. The injection-current–versus–optical characteristic has hysteresis. When the input light and the control injection-current values are small, there is no output light. However, when the input light increases beyond a threshold



(a)

(b)

FIG. 18. (a) Structure and characteristics of a symmetric SEED (for MQW with 105-Å GaAs and 80-Å AlGaAs layers) and (b) oscilloscope trace of P_{out1} bistable characteristics.

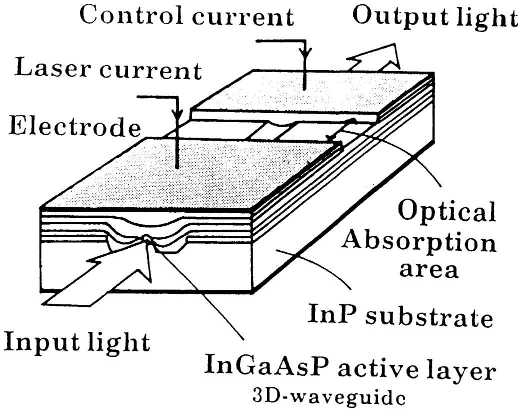


FIG. 19. Structure of an optical memory device based on a bistable LD.

value, there is a strong output light (about a hundredfold increase). Under this condition, even if the input light is eliminated, the output light continues ("on" state). That is, a memory operation can be realized. The "on" state can be switched to the "off" state by stopping the control injection current. This device acts as an optical logic and as a switching device and its response time is less than 1 ns.

Photonic devices hold the promise of massive parallelism and large connectivity. Furthermore, optical interconnections show a great potential for being programmable. Indeed, light beams could be directed from individual sources to individual detectors on the basis of a specific command, depending on the task, using two-dimensional switch arrays (see OPTICAL INTERCONNECTIONS). Thus, smart optoelectronics systems will bring an enormous degree of flexibility to future optical computing architectures.

6. PHOTONICS AND OPTOELECTRONIC INTEGRATED CIRCUITS

Following the invention of the transistor, in a few decades, electron devices dramatically evolved from electron tubes to ultra-large-scale integrated circuits, containing millions of monolithic microcomponents. Similarly, the rapid evolution of optical devices, ranging from discrete components to photonic integrated circuits, is clearly taking place. Indeed, the level of integration of optoelectronic components has increased steadily over the years, as a result of the continuous progress in semiconductor fabrication technologies. However, in contrast to the situation in electronic integrated circuits, where silicon technology completely dominates the field, a great number of different materials are used in the fabrication of optoelectronic integrated circuits (OEIC). While III-V compound semiconductors allow the integration of all active and passive components, $LiNbO_3$ is still the preferred substrate for many applications making use of the electro-optic effect. For purely passive devices, glass and silicon are commonly used. Compared with these inorganic materials, organic polymers are relative newcomers in the field. Nevertheless, the rapid advances in molecular engineering have lately allowed chemists to produce new polymer materials with tailored optoelectronic properties, optimized for applications such as waveguiding, electro-optic effects, or harmonic generation (Van Tomme, 1991).

There are two forms of optoelectronic integration, namely, hybrid and monolithic. In hybrid integration, discrete devices on separate functional blocks or chips are connected using electrical or fiber interconnections. These systems usually use a dielectric substrate, such as glass or $LiNbO_3$, which is externally coupled to light sources and detectors [see Fig. 20(a)]. The main advantage of such hybrid integration is the ability to use high-performance discrete devices available as components. The disadvantages are the lack of compactness and the enhanced parasitics in the interconnections. In monolithic integration, all optoelectronic components such as lasers, waveguide circuits, modulators, and detectors are fully integrated on a III-V compound semiconductor substrate, such as GaAs or InP [see Fig. 20(b)]. These systems, usually referred to as photonic integrated circuits (PIC), have the obvious advantages brought by size reduction, reduced parasitics, and the consequent gains in higher circuit speed and wider bandwidth. However, unlike a Si-based electronic IC in which almost all components are made with the same materials and the same processing steps, the heterostructures and the processing steps of a PIC can be significantly different. This makes the fabrication of high-performance monolithic OEICs or PICs a serious challenge.

As an alternative, some quasi-monolithic systems combine aspects of both types of integration. In these intermediate systems, for example, the light source is made of a compound semiconductor and the photodiodes are integrated on a Si substrate [see Fig. 20(c)].

Recent advances in group IV semiconductors (Si, Ge, C, and Sn) are also paving the way for a variety of new Si-based photonic and electronic devices, mostly SiGe–Si heterostructures. Device-quality SiGe–Si material has been produced by low-temperature CVD (Meyerson, 1992) and MBE techniques (Houghton *et al.,* 1991). Band-gap–engineered SiGe quantum-well and superlattice devices have opened a new realm of optoelectronic device structures that go well beyond conventional Si device systems. These structures have demonstrated new optoelectronic phenomena that are absent or weak in bulk Si.

In the future, the extension of these techniques will allow the growth of crystal alloys like SiGeC and SiGeCSn. A complete PIC can be monolithically fabricated from SiGe, SiGeC, and SiC materials, with every waveguide component connected seamlessly to its neighbors. Good progress has already been made in Si-based 1.3–1.6-μm waveguides and 1.3-μm guided photodetectors. However, efficient Si-based laser diodes, optical amplifiers, efficient LEDs, 1.55-μm photodetectors, 1.3–1.55-μm electro-optic modulators, and optical switches are the challenges that remain ahead.

During the last decade, a number of key developments have laid the foundations for the rapid advancement of photonics technology. Most important among them is the routine fabrication of DFB- and DBR-MQW laser structures, allowing high-*Q* on-chip resonators without cleaving. Another key development has been the progress achieved in high-quality computer-controlled vapor and beam crystal-growth systems for InP-based materials. The excellent large-area unifor-

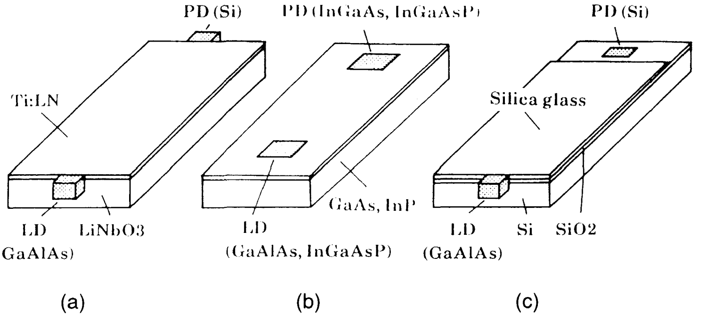

FIG. 20. Three examples of optoelectronic integrated circuits: (a) hybrid, (b) monolithic, and (c) quasi-monolithic.

mity and reproducibility achieved by these systems are crucial to any serious integration effort. In particular, the reproducible growth of highly complex vertical layer structures by use of a large number of ultrathin etch-stop layers has granted new levels of design freedom in the engineering of integrated waveguide devices. Application of these techniques, in some cases without extra growth steps, has resulted in versatile photonics technologies.

A monolithic OEIC or PIC should be constructed with single-mode waveguides in the passive structures. The structure size of its active components is of the order of one wavelength. Lasers, being nonlinear devices, are often fabricated without strictly fundamental-mode waveguides. In addition to the difficulties involved in making the buried heterostructure waveguides strictly single mode, the waveguides typical of most lasers can also be quite problematic for passive couplers or active switches because of their sensitive characteristics. An illustrative optoelectronics problem is the requirement for current blocking in lasers and current or field access to the active sections in the photonic integrated circuit, while retaining Fe-doped InP cladding for the low-loss waveguide interconnections. Nevertheless, many successful examples, such as optical transmitters and receivers constructed with lasers, photodiodes, modulators, switches, filters, integrated-optical rf spectrum analyzer, optical drive, and sensor devices, have been developed.

Figure 21 shows a quasi-monolithic OEIC consisting of a compact-disk reading head. It is constructed by integrating a focusing grating coupler (FGC), a twin-grating focusing beam splitter (TGS), and a photodiode array in a film waveguide on a Si substrate. The guided wave diverging from the laser is focused by the FGC into a point on the disk. The wave reflected by the disk is collected and coupled back into the waveguide. The TGS then divides the reflected wave into two halves, deflecting and simultaneously focusing them into two detecting points. Thus, the disk signal is read out. Whereas optical disk-drive heads are currently built with bulk micro-optics, implementation by fully integrated optics using a waveguide would lead to significant cost-effective improvements, such as better reproducibility, reduction of size and weight, and enhancement of application flexibility (see OPTICAL STORAGE).

Figure 22 shows a monolithic OEIC or PIC consisting of a transmitter of wavelength-divided multiplex. This device is constructed with three different lasers composed of DBR and injection-current control

regions, waveguides, and an optical amplifier. Three light waves with slightly different wavelengths around 1.55 μm emerge, and a stable high-frequency modulation (greater than 1 Gb/s) can be obtained for each laser. Such light sources, as well as similarly integrated photodetectors, will be of great importance in the development of future large-capacity optical transmission systems. Recent progress in compound-semiconductor–based electronic devices has allowed integration of complete electronic circuits with various optical devices on the same chip. Integrated receivers with highly sensitive characteristics, comparable to those of a discrete device circuit, are now being developed. Figure 23 shows the E/O (transmitter) and O/E (receiver) modules of such a system, recently built using an OEIC with high-frequency, wide-band preamplifier electronic circuits, operating at the high speed of 10 Gb/s.

Present-day optical communications systems are almost universally point-to-point in nature, where an optical fiber carries a unidirectional signal from the transmitter to the receiver. While such simple systems could benefit from some level of photonic integration, the true benefit of PIC systems is expected to become evident as optical-system architectures grow in sophistication and complexity. Indeed, their potential for high performance, compact size, high reliability, and low manufacturing cost, with much larger-scale integration and higher operating speeds, will transform them into crucial players of applications such as multichannel coherent or heterodyne (electrically demultiplexed) and incoherent (optically demultiplexed) wavelength-division multiplexed transmission, networking, and switching. In fact, this is even true in simple bidirectional links (Koch *et al.*, 1990) for broadband integrated-services digital networks (B-ISDN) and fiber-to-the-home (FTTH) architectures, which are currently being widely investigated in view of the exploding market demand for these services.

7. SUMMARY

The present article has attempted to review the development, as well as the present status, of the principal quantum optoelectronic devices, discussing their basic structure, their operation principles, and their main applications. We have emphasized the impact of new semiconductor-fabrication technologies, which have allowed us to build high-performance ultracompact optoelectronic devices with increasing levels of integration. It is expected that the powerful driving force of highly demanded market applications, most notably optical communications and computing, will accelerate the existing trends toward ever smarter and more affordable quantum optoelectronic systems.

GLOSSARY

Avalanche Photodiode (APD): Photodetector with high sensitivity due to large gains caused by impact or avalanche ionization of photogenerated carriers.

Cladding: Surrounding low-dielectric media covering the dielectric waveguide materials, which confines the lightwave propagation to the latter material.

Distributed-Feedback (DFB) or Distributed–Bragg-reflector (DBR) Laser: Semiconductor laser with high mode purity obtained by using a corrugated structure or grating that produces a periodic variation of the refractive index within the optical cavity.

Electroabsorption Effect: Absorption of photons with energies smaller than the band gap, with the application of an electric field.

Electroluminescence: The process of radiative recombination of electron–hole pairs, following carrier injection with a *p-n* junction or similar device.

Electro-optic Effect: Induced birefringence, a change in the refractive index of noncentrosymmetric crystals with electric field inversion.

Erbium-Doped Fiber Amplifier (EDFA): Optical fiber doped in its core with erbium atoms (less than 0.1%) and pumped (at 1.48 or 0.98 μm) with a LD coupled into the amplifier with a wavelength multiplexer. This infrared radiation is absorbed by the Er^{3+} atoms causing stimulated emission, which is used to amplify light signals near their lasing wavelength (1.55 μm).

Franz–Keldysh Effect: The change in semiconductor absorption that results in the absorption of photons with energies less than its band gap.

Heterodyning: Coherent phase-interference receiving technique, which allows the detection of very weak optical signals.

Laser Diode (LD): The semiconductor laser, a coherent light source that operates by stimulated emission due to population inversion.

Laser-Diode Amplifier (LDA): Two closely separated LDs, where one of them acts as an amplifier of the light output of the other.

Light-Emitting Diode (LED): A semiconductor light source that operates by spontaneous emission due to electroluminescence.

Multiple Quantum Well (MQW): Superlattice structure formed by multiple QW.

Optical Fiber: Silica-based waveguide, consisting of a high–refractive-index glass core, surrounded by a lower–refractive-index cladding; widely used in optical communications for light signal transmission.

Optical Modulator: Device for changing the intensity, phase, polarization, or frequency of a transmitting light in response to an electrical signal.

Optical Waveguide: Core region of high–refractive-index dielectric material through which light is propagated, surrounded by lower–refractive-index dielectric region or cladding.

Optoelectronic Integrated Circuits (OEIC): Systems that involve the integration of electronic and optical devices and optical interconnections.

Photoconductor: A material that exhibits an increase in electrical conductivity of a specific region with photoexcitation.

Photodetector: An optoelectronic device that absorbs optical energy and converts it to electrical energy, which gives rise to a photocurrent.

Photoluminescence: A process of radiative recombination of electron–hole pairs created by the injection of photons.

***p-i-n* Diode:** A junction photodiode in which an undoped intrinsic region is inserted between the *p* and *n* regions; it has a controlled depletion-layer width, which can be somewhat tailored to meet the requirements of photoresponse and bandwidth.

Quantum-Confined Stark Effect (QCSE): A shift of the semiconductor absorption spectrum to lower energies due to excitonic heavy-hole and light-hole resonances.

Quantum Well (QW): Synthetic structure composed of an ultrathin layer (comparable to the mean free path of carriers) of a narrow–band-gap semiconductor sandwiched between two wide–band-gap semiconductor layers, where carrier energy levels are quantized in the direction perpendicular to the layers.

Self–Electro-optic Effect Device (SEED): A structure composed of MQW *p-i-n* diodes, which exhibits photonic switching, bistability, and optically induced oscillations due to the negative resistance in the photocurrent due to the QCSE.

Stark Effect: A change in atomic energy due to electron energy-level splitting in the presence of an external electric field.

INTRODUCTION

Quartz is the most common crystalline form of silicon dioxide. It is the most abundant substance in the earth's crust and exists in a variety of coarsely crystalline and microcrystalline forms. Three-quarters of the earth's crust is made up of the tectosilicates, quartz and the related minerals.

Quartz is a hard, somewhat brittle substance. It is thermodynamically and chemically very stable. It is an insulator and is piezoelectric. Its unique set of properties has made it the second most widely used electronic material. Quartz is clear, transparent from the infrared to the ultraviolet, birefringent, and optically active. This has led to many optical applications.

Most coarsely crystalline (single crystal) quartz used today is cultured, sometimes referred to as "synthetic." Hydrothermal techniques are used to produce quartz crystals. This method is one of high-temperature, aqueous solution growth. By varying such parameters as the temperature gradient, the crystallization temperature, and the solution composition, growth rate and other properties can be controlled in the finished crystal.

While an extremely pure substance, quartz can exhibit a variety of defects. These defects include point (atomic) defects, inclusions, and structural defects, such as dislocations and twins. These defects can influence the use of this material in electronic and optical applications.

1. DESCRIPTION OF MATERIAL

1.1 Chemical and Crystallographic Structure

Quartz is the principal naturally occurring form of crystalline silicon dioxide, SiO_2. The silicon is tetrahedrally bound to four oxygen atoms. Each oxygen atom is bonded to two Si atoms, and this linkage of the SiO_4 tetrahedra at their corners forms a three-dimensional network. The bonding is about 60% covalent and 40% ionic. One Si–O bond is 1.598 Å in length, the other is 1.616 Å. The bond energy is about 468 kJ mol^{-1}.

There are at least nine different ways that a SiO_2 framework can be constructed. These geometrical arrangements correspond to the nine known polymorphs of SiO_2. The naturally occurring polymorphs fall into three

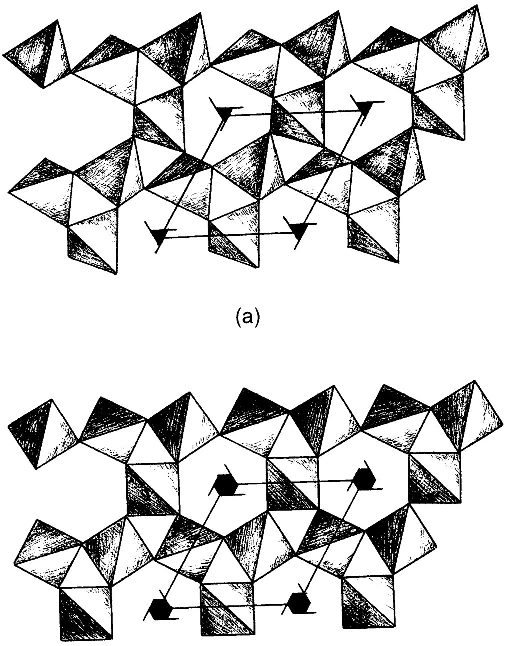
structural categories: *low quartz,* with the lowest symmetry and most compact structure; *low tridymite,* with higher symmetry and a more open structure; and *low cristobalite,* with the highest symmetry and the most expanded structure (Klein and Hurlbut, 1977). The reconstructive transformations that convert one polymorph to another require bond breaking and thus are slow and require high energy. This allows the phases to exist metastably over a wide temperature range. Impurities or alkali-metal oxides can lower this activation energy. Tridymite is sometimes classified as a solid solution of quartz and alkali-metal oxide.

Quartz, tridymite, and cristobalite each have a low and high form [low (α) quartz and high (β) quartz are shown in Fig. 1]. These transformations are displacive, involving only minor atomic rearrangements. They occur quickly, reversibly, and at a well-defined temperature. Displacive transformations involve a much smaller symmetry change than the reconstructive transformations, with the low-temperature form showing the lower symmetry. Elevated pressures raise the transition temperatures.



(a)

(b)

FIG. 1. The structure of the (a) low (α) quartz and (b) high (β) quartz. The unit cell, the threefold axes of low quartz, and the sixfold axes of high quartz are shown.

The common form of quartz is the α-quartz form. It exhibits trigonal symmetry (space group $P3_221$ or $P3_121$). By convention, the Z or c axis is parallel to the threefold axis and the X or a axis is parallel to one of the three twofold axes. In a set of rectangular axes, Y is at right angles to X and Z. The unit cell has 3 SiO_2 molecules. The most complete review of the lattice constants reports $a = 4.9127$ Å, $c = 5.4046$ Å for natural quartz and $a = 4.9134$ Å, $c = 5.4054$ Å for synthetic quartz (Brice, 1980). These values can vary with impurities.

At 573 °C and 1 atm pressure, α-quartz transforms to the β form, which is either $P6_222$ or $P6_422$. Upon cooling through the transition, Dauphiné twinning (see Sec. 3.3) usually occurs.

The SiO_4 tetrahedra in quartz are arranged helically on the threefold axes in both forms of quartz. This helical structure makes quartz enantiomorphic; in other words, crystals exhibit handedness, and thus are optically active. A left-handed helix results in a right-handed crystal. An observer looking along the Z axis at a plane-polarized light source through such a right-handed crystal sees the plane of polarization rotated clockwise.

Quartz occurs naturally in a variety of mineralogical forms. The naturally occurring varieties are divided into coarsely crystalline and cryptocrystalline or microcrystalline (fibrous and granular) varieties. Table 1 lists some of these varieties and their properties.

Quartz is one of the purest natural minerals. The most common impurities are Al, Fe, Ge, H, Li, Mg, and Na, with Ag, Ca, Cl, Cr, Cu, K, and Ti also reported. Total impurity concentrations are typically parts per thousand in milky grades, and in clear, colorless grades are often under 100 ppm.

1.2 Physical Properties

1.2.1 Mechanical and Thermal Quartz is a hard, somewhat brittle material. The density at room temperature is reported as 2.648 22 g cm^{-3}. The hardness on Mohr's scale is 7. The penetration hardness is 30.8

Table 1. The naturally occurring varieties of quartz, divided into coarsely crystalline and cryptocrystalline or microcrystalline (fibrous and granular) varieties, with some of their properties.

	Coarsely Crystalline
Rock crystal	Colorless quartz, commonly distinct crystals
Amethyst	Various shades of purple, color from Fe impurity and irradiation
Citrine	Various shades of yellow, Fe impurity
Rose quartz	Translucent to nearly transparent, pale pink to rose, Ti impurity
Smoky quartz	Brown to black, color from Al impurity and irradiation
Rutilated	Colorless quartz containing needles of rutile (TiO_2)
Tigereye	Yellow to brown with parallel fibers of an asbestos mineral, chatoyant
Milky quartz	Colorless, translucent, milkiness from minute fluid inclusions
	Cryptocrystalline
Chalcedony	General term for varieties composed of tiny fibrous crystals in a partly amorphous matrix
Agate	Layered chalcedony, often forming circular bands
Flint and chert	Granular variety, flint forming nodules, chert forming bedded deposits
Jasper	General term for a variety of translucent, impure chalcedony containing many inclusions

($\times$ 10^3 kg cm^{-2}) parallel to the Z axis and 22.9 perpendicular to Z. Quartz does not generally cleave along cystallographical directions. Fractures are conchoidal; that is, they form in random directions, like in glass. Quartz is much stronger in compression than in tension, and the strength varies with direction. The compression strength is 24 500 kg cm^{-2} parallel to Z and 22 400 perpendicular. Tensile strength is 1120 kg cm^{-2} parallel to Z and 850 perpendicular. The linear thermal expansion coefficient is very low; at 0 °C it is 7.10 $\times$ 10^{-6}/°C parallel to Z and 13.24 perpendicular to Z. It increases approximately linearly with temperature between -100 and 300 °C.

The third-order elastic coefficients are given in table 2, in units of GN m^{-2}. The temperature coefficients of the elastic constants range from -3300 $\times$ 10^6/°C (for c_{12}) to $+164$ $\times$ 10^6/°C (for c_{66}).

Table 2. The third-order elastic coefficients for quartz, in units of GN m^{-2}.

c_{111}	-210
c_{112}	-345
c_{113}	$+12$
c_{114}	-163
c_{123}	-294
c_{124}	-15
c_{133}	-312
c_{134}	$+2$
c_{144}	-134
c_{155}	-200
c_{222}	-332
c_{333}	-815
c_{344}	-110
c_{444}	276

Quartz is thermodynamically very stable. Its melting point is 1670 °C, with a boiling point of about 2230 °C. The vapor pressure at 1732 °C has been reported as 10 mm. The free energy of formation is 805 kJ mol^{-1} ($Si + O_2 \rightarrow SiO_2$). The heat capacity of 0 °C is 696.2 J/g. The molar specific heat has been described by the equation

$$C_p = 47.0118 + 3.4358 \times 10^{-2}\, T(\mathrm{K}) - 1.131 \times 10^6\, T^{-2}\, (\mathrm{J\ mole^{-1}\ K^{-1}}),$$

where T is the absolute temperature.

Quartz is a fair thermal insulator; at 20 °C the conductivity is 0.12 J/cm s °C parallel to the Z axis and 0.067 perpendicular to the Z.

The Curie temperature, that is the temperature of the α–β transition, is 573.3 °C (on heating), with a very small hysteresis and a latent heat of transformation of 10.5 J/g.

1.2.2 Chemical The chemical stability of quartz is also very high. Quartz is completely insoluble in water or organic solvents at room temperature and only 0.1–0.3 wt% in supercritical water. Quartz is attacked by hydrofluoric acid and solutions of fluoride salts, particularly at elevated temperature. The solubility is also greatly increased in supercritical water by the addition of mineralizing agents, such as alkali-metal salts, particularly the hydroxides and carbonates.

1.2.3 Electrical Quartz is the most widely used piezoelectric material. Broad use in the electronics industry is based on the unique combination of features quartz possesses. Among these are piezoelectricity, the existence of device orientations (cuts) with a variety of properties such as zero or high temperature coefficients, low mechanical losses (high *Q*), and ease of processing. Quartz's piezoelectricity arises from the crystallographic structure, which lacks a center of symmetry. The effect couples electrical current and voltage to elastic displacement and stress in the crystal. This coupling is described by coupling constants, which are dependent upon direction and temperature. Quartz has eight independent piezoelectric constants. The existence of the twofold symmetry axis in the *X* direction means that there is no piezoelectric effect along any axis perpendicular to *X*. The piezoelectric constants at 25 °C for right-handed quartz are given in Table 3. These constants are dependent upon temperature and pressure. The signs would be reversed for the left-handed form.

The dielectric constants for α-quartz are $\epsilon_{11}^T = \epsilon_{22}^T = 39.97$, $\epsilon_{33}^T = 41.03$, $\epsilon_{11}^S - \epsilon_{11}^T = -0.76$, and $\epsilon_{33}^S - \epsilon_{11}^T = 0$, all in units of 10^{-12} F/m. In this notation, the first number is the direction along which the voltage is applied, the second is the direction of measurement, with 1 the *x* axis, 2 the *y*, and 3 the *z*. The dielectric constants are dependent upon both temperature and field strength.

Quartz is an electrical insulator with resistivities ranging from 10^{14} Ω-cm at room temperature to 10^5 Ω-cm at 300 °C.

1.2.4 Optical Quartz's clarity, chemical and mechanical durability, and optical activity make it a widely used optical material. Clear α-quartz shows no absorption from the UV cutoff at around 160 nm to around 3 μm in the infrared. The index of refraction varies from about 1.48 at 3500 nm to 1.76 at 160 nm. It shows a slight dependence upon temperature, decreasing about 7 × 10^{-6}/°C. Quartz is birefringent, with the birefringence varying from 8.98 at 0.71 μm to 21.38 at 0.15 μm. The birefringence also shows a small decrease with increasing temperature. The rotatory power of quartz goes from 201.9 °/mm at 2265 Å to 11.589 at 7948 Å. The rotation is clockwise in right-handed quartz. The rotation power increases 1.4 × 10^{-4}/°C. The *Z* axis is the optically active axis.

Table 3. The piezoelectric constants at 25 °C for right-handed quartz.

Strain	Stress
$d_{11} = -2.31 \times 10^{-12}\ \mathrm{C\ N^{-1}}$	$e_{11} = -0.171\ \mathrm{C\ m^{-2}}$
$d_{14} = -0.727 \times 10^{-12}\ \mathrm{C\ N^{-1}}$	$e_{14} = -0.0406\ \mathrm{C\ m^{-2}}$
$g_{11} = -0.0578\ \mathrm{m^2\ C^{-1}}$	$h_{11} = -4.36\ \mathrm{N\ C^{-1}}$
$g_{14} = -0.0182\ \mathrm{m^2\ C^{-1}}$	$h_{14} = 1.04 \times 10^9\ \mathrm{N\ C^{-1}}$

2. GROWTH OF CRYSTALS

2.1 Natural Occurrence and Quality

Quartz is an abundant mineral, found particularly in igneous and metamorphic formations. Because it can be transported in water at high temperatures, quartz is also found as a secondary mineral in sedimentary rocks. Clear, colorless, single crystals (rock crystal) are widely distributed, with notable deposits in Brazil (generally recognized as the best for large, single crystals), the Alps, the Ural Mountains, and in the United States in Arkansas and New York. Important amethyst deposits have been found in Brazil, Zambia, and the Urals.

2.2 Cultured

2.2.1 History The first reported growth of quartz crystals by Schafhäult in 1845 and by de Sénarmont in 1851 produced microscopic crystals. G. Spezia, from 1898 to 1908, published reports on the growth of macroscopic crystals. He used solutions of sodium silicate, natural crystals as seeds and supply, and a silver-lined vessel. By heating the supply end of his vessel to 320–350 °C, and the other end to 165–180 °C, he obtained about 15 mm of new growth over a 200-day period. Unlike modern practice, the hotter part of vessel was at the top.

In the period before and during World War II, Richard Nacken led an extensive German effort to grow quartz crystals, especially once the supply of natural crystals from Brazil was blocked. They used an isothermal growth process that relied on the higher solubility of the vitreous silica supply to supersaturate the solution.

Following the war, researchers working with the U.S. Army Signal Corps studied the German work and developed it into a commercially viable process. C. B. Sawyer, D. R. Hale, Hans Jaffe, and others at Brush Development, and then Sawyer Research Products, Inc., developed the low-pressure sodium carbonate process (next section). R. Laudise, N. C. Lias, and others at Bell Laboratories and Western Electric developed the high-pressure sodium hydroxide process (next section). Today, these processes are used worldwide.

2.2.2 Hydrothermal Growth With a melting point of 1670 °C and high chemical resistance, quartz crystals would be very difficult to form by either melt or flux techniques. Since cooling through the Curie point at 573 °C usually produces twins, any technique for production of single crystals must be done below the Curie temperature. The process used is a solution-growth technique called hydrothermal growth. This technique is very similar to the processes by which natural quartz crystals are formed.

Hydrothermal growth is conducted in steel pressure vessels called autoclaves (Fig. 2). A supply of nutrient material, usually natural clear or milky quartz, is placed in the bottom half of the autoclave. In the top half, seed crystals, cut from either cultured (synthetic) or natural crystals are hung. The baffle, a metal plate with one or more holes cut in it to provide a constant and controlled opening (usually expressed as a percentage of the total cross section), is placed between the upper and lower halves. An aqueous solution, usually an alkali-metal hydroxide or carbonate solution, is added to the autoclave so that the solution occupies a set percentage of the total free volume of the vessel. The alkali-metal compounds acts as a mineralizer, increasing the solubility of the quartz in the solution, through the formation of soluble silicate complexes.

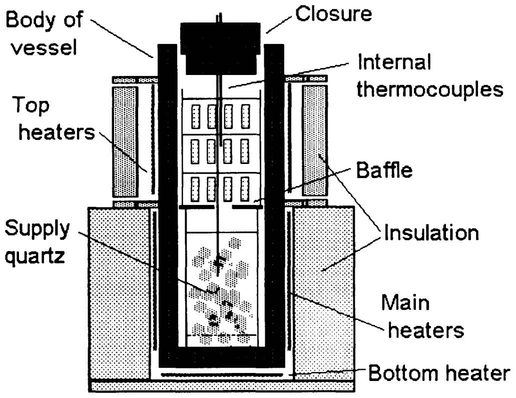


FIG. 2. Schematic drawing of an autoclave showing the various components (not to scale).

After sealing of the vessel, the autoclave is heated to operating conditions with the use of external resistance heaters. Typical operating conditions are generally between 300 and 400 °C. The internal pressure developed is controlled by the temperature and the amount of solution added to the autoclave. The critical point for pure water is well established at 374 °C. The critical points for solutions used in quartz growth have not been established but are probably altered by the addition of the mineralizer.

At operating conditions, the temperature is controlled such that a temperature difference is established between the internal temperature in the lower half of the autoclave, called the dissolving chamber, and the upper half, called the growing chamber. A temperature gradient in a closed cylinder of fluid in a gravitational field establishes a natural convection pattern called a closed thermosyphon. In the warmer dissolving chamber, quartz dissolves in the solution. The warm, less dense fluid rises. In the growing chamber, the cooler temperature leads to supersaturation of the solution for quartz and the quartz precipitates on the seed crystals. The cool, dense fluid sinks into the dissolving chamber and the cycle continues.

The temperature difference between the growing and the dissolving chambers is the chief process control of the growth rate. The temperature difference controls not only the supersaturation in the growth chamber, but together with the baffle, controls the rate of fluid and heat transfer between the two chambers. Growing temperature also has a strong effect, with growth rate increasing with increasing temperature. Other factors that influence the growth rate are pressure, mineralizer type and concentration, other chemical additives (particularly lithium), and seed orientation.

The mineralizer is a compound added to the solution to increase the solubility of the compound of interest, in this case, quartz. Typically, alkali-metal salts, particularly sodium hydroxide or sodium carbonate, are used. In natural systems, sodium chloride is believed to be the most common mineralizer. The mineralizer increases the solubility by complexing with the solute to form more soluble species. While the exact form of the dissolved species is unknown, it is believed that soluble silicates of forms such as $Si_3O_7{}^{2-}$ and $SiO_3{}^{2-}$ are formed in the presence of hydroxides and carbonates, respectively. Lithium is added at low concentration (typically 0.01 to 0.1 moles/L) to improve the relationship between proton uptake and growth rate (see Sec. 3.1.1). The mechanism of this improvement is not completely understood. Under these conditions, complex alkali-metal–iron silicates form on the steel surfaces of the autoclave. These silicates act as a passivation layer, preventing further corrosion. They are also the compounds that form inclusions (see Sec. 3.2).

Two similar processes are the most widely used in the cultured quartz industry. They are known as the low-pressure and high-pressure processes. The low-pressure process typically uses a (0.6 to 0.8)*M* sodium carbonate solution, a growing-chamber temperature of 345 °C, a temperature difference of 10 °C, and a pressure of 700–1000 bars. Typical growth rates are 0.4 mm/day in the *Z* direction. The chief advantage is the lower capital expense of autoclaves that operate at this pressure.

The high-pressure process typically uses 1.0*M* sodium hydroxide solution, a growing temperature of 360 °C, a temperature difference of 25 °C, and a pressure of 1000–1500 bars. While the capital costs for such equipment are greater, growth rates of up to 1.0 mm/day (*Z*) can be achieved at these conditions.

The anisotropic structure of quartz results in large differences in growth rate in different crystallographic directions. Growth rate in the *Z* direction can be up to three times the growth rate in the *X* direction. The orientation of the seeds used can affect not only the growth rate of the crystals but the uptake of impurities.

2.2.3 Post-Growth Processing Although most quartz is used without further treatment, sweeping is sometimes used for post-growth processing. Sweeping is a high-temperature, solid-state electrolysis of the quartz crystal. It is used to remove or replace interstitial ions in the quartz lattice.

Sweeping is conducted for one of two reasons. The first is to increase the radiation hardness of quartz. When quartz is irradiated, alkali-metal ions from defects such as $Na_{(\text{interstitial})}$–$Al_{(\text{substitutional})}$ are displaced from these defects, with the formation of Al–hole or Al–OH centers. This can cause immediate and/or permanent changes in the crystal's electrical properties. Sweeping substitutes the alkali-metal ions for protons (when swept in air) or holes (when swept in vacuum). This minimizes permanent changes in the crystal when irradiated.

The second use of sweeping is for the reduction of etch channels (see below). Though the mechanism is not completely understood, it is believed that etch channels are formed when impurity-decorated dislocations dissolve faster than the surrounding crystal, in an appropriate etchant. Sweeping reduces the formation of etch channels either by removing the impurity ions from the dislocations or by depositing an insoluble species into the dislocation.

The sweeping process involves applying an electrode material to the *Z* surface of the quartz bar. Typical electrode materials are plated metals such as gold, metal foils, or carbon films. An electric field on the order of 1 kV/cm is applied. The bar is heated to just below the Curie temperature, so as to increase the conductivity of the crystal without creating twins. Current densities on the order of μA/cm² are generated. Sweeping generally takes from days to weeks to complete.

3. COMMON DEFECTS IN QUARTZ

3.1 Point Defects

Point defects are atomic-size defects. They usually involve the replacement of one atom in the structure by a foreign atom (substitutional), or the insertion of an extra atom into the structure (interstitial). They may also involve other atomic or subatomic species such as holes and electrons (see POINT AND

EXTENDED DEFECTS IN SOLIDS). Given the openness of the quartz structure and the stability of the Si–O bond, interstitial defects are much more common in quartz. By far the most common interstitial atom is hydrogen, in the form of OH^- groups. These defects have significant effects upon the electronic properties (see below). Li, Na, K, Al, Fe, and holes are commonly found interstitially; Al, Fe, Ge, and Ti are found substitutionally, and a variety of other cations have been reported. Often a substitutional defect, such as Al^{3+} or Fe^{3+} substituted for a Si^{4+}, is paired with an interstitial species, such as H^+ or Li^+, for charge compensation. Anionic defects are much less commonly reported in quartz, with Cl particularly found in natural samples and F occasionally found in synthetic.

Quartz exhibits an anisotropic uptake of impurities; in other words, different regions of quartz have relatively higher or lower concentrations. The highest concentrations are found in the $+X$ region, followed by the $-X$ region, and then the Z regions (see Fig. 3). Concentrations in the $+X$ region can be from 3 to 10 times higher than in the Z.

The structure of the impurities sites also seems to be anisotropic in quartz. While synthetic amethyst and citrine are both formed from Fe^{3+}-containing solutions, amethyst is formed in the rhombohedral growth (particularly from seeds cut parallel to the rhombohedral faces), and citrine is formed in the Z growth (particularly from seeds parallel to the Z face).

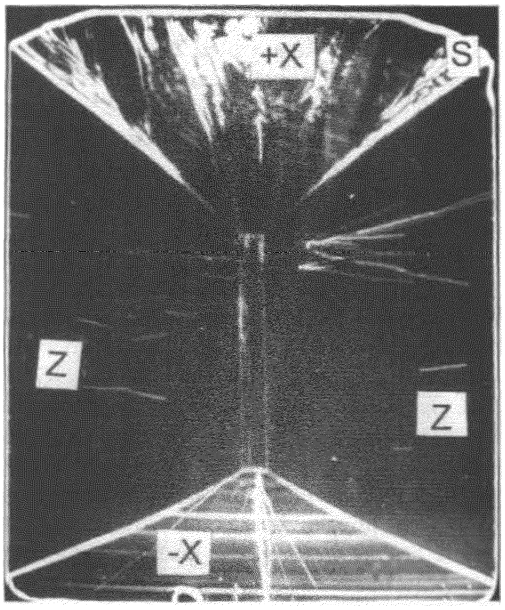

FIG. 3. X-ray topograph of a cultured quartz slice showing the growth zones.

3.1.1 Hydroxide Defects As mentioned above, protons are the most common defect in quartz. The infrared absorption at various frequencies between 3400 and 3600 cm^{-1} gives a reliable measure of the hydrogen concentration. Dodd and Fraser (1965) and Sawyer (1972) established a correlation between the extinction coefficient α and the electrical quality factor Q. This extinction coefficient is determined by the formula

$$\alpha = (1/t)\log[T_{\text{base}}/T]$$

where t is the sample thickness in centimeters, T_{base} is the percentage transmittance at a baseline wave number (nominally 3800 cm^{-1}), and T is the percentage transmittance at the wave number of interest (usually 3410, 3500, or 3585 cm^{-1}). An infrared quality factor can be determined from this.

Hydrogen concentration has also been found to be proportional to growth rate. By measuring α across the major growth direction of the crystal, the variation in the growth rate over the course of the growth cycle can be determined.

3.2 Inclusions

Inclusions are trapped solid particles or fluid bubbles, with a diameter typically between 25 and 150 μm. They are found in both natural and cultured quartz.

Fluid bubbles are fairly common in natural quartz, particularly in the milky grades. They are less common in cultured quartz, occurring mostly at the seed veil, the interface between the seed and the bulk crystal. Since bubbles are tiny samples of the solution from which the quartz formed, they have been analyzed to learn more about this solution.

Solid inclusions are common in both natural and cultured quartz. In natural quartz, the inclusions may be trapped by the growing crystal, may be formed simultaneously with the crystal, or may form after the growth of the host. Rutile is probably the most common solid inclusion in natural quartz. A wide variety of other minerals have been found, including various asbestos minerals, mica, tourmaline, hornblende, hematite, and gold.

In cultured quartz, solid inclusions are generally one of a variety of alkali-metal–iron silicates. Given the growth conditions of quartz in steel vessels, this is not surprising. Acmite, $NaFeSi_2O_6$, has traditionally been the archetypical inclusion species. However, the iron silicates {$Na_5FeSi_4O_{12}$, $Li_6Na_6Fe_2Si_{18}O_{45}$, emeleusite ($Li_2Na_4Fe_2Si_{12}O_{30}$), and riebeckite [$Na_2(Fe^{2+},Fe^{3+})_5Si_8O_{22}(OH)_2$]}, as well as lithium silicate, magnetite, and hematite, have all been identified. It appears that these inclusions are typically formed elsewhere in the autoclave, are circulated by the fluid, and are trapped by the growing crystal. Large solid inclusions can cause other defects, such as bubbles and dislocations, by disrupting the crystal structure.

Inclusion densities are estimated by immersing the crystal in an index-matching fluid and illuminating the crystal with a high-intensity light. The inclusions will appear as tiny illuminated points of light.

A more accurate method is to examine the bar microscopically. Sites in the bar are chosen and observed at moderate magnification (usually ×30). By scanning along the direction of observation, the number of inclusions in a set volume can be counted. Using a reticule with a scale, the counts can be made for a given size range of inclusions. Typically, inclusion densities are reported for inclusions 25–75, 75–100, and >100 μm in size.

3.3 Structural Defects

As in any crystalline material, various structural defects are found. Dislocations are found in single crystals of natural and cultured quartz, though they are generally more common in the latter. Screw, edge, and mixed dislocations (see POINT AND EXTENDED DEFECTS IN SOLIDS) have all been found.

Dislocations have three sources in cultured quartz. The first is continuations of dislocations in the seed. The second source is defects on the seed veil, either on the surface of the seed itself (usually damage from the cutting of the seeds) or deposited inclusions. The third source is inclusions in the bulk of the crystal.

When a quartz wafer is etched—for example, in a fluoride solution—etch pits form on the surface of the wafer and etch channels form into the bulk. Both are caused by dislocations. The increased strain energy around the dislocation causes an increase in etch rate around them. While every dislocation forms an etch pit, only about $\frac{1}{3}$ of the dislocations form etch channels. It is believed that impurity decoration of dislocations that form etch channels accounts for the difference.

A related phenomenon is that of filaments. These are line defects, generally parallel to the major growth direction, that are visible to the naked eye under intense illumination. They appear to be related to dislocations and may be dislocations decorated with fluid or other impurities.

As in other crystalline material, twins can form. There are basically two types of twins in quartz, electrical twins and optical twins. Electrical twins (also called Dauphiné twins) are regions that exhibit an X-axis orientation opposite to that of the bulk crystal. They are usually irregularly shaped. They can be caused by heating above the Curie temperature, by high pressure, or by a very intense electric field.

Optical twins (also called Brazil twins) are regions with the opposite handedness to that the bulk crystal. The boundaries of these twins are usually straight. Both types of twins can be revealed by the etching of the crystal, and then observation of the surface with an incident light source.

Cultured quartz crystals exhibit distinct growth zones or sectors around the seed. The zones, $-X$, $+X$, and Z, are named for the seed faces off which they form. In some crystals, a boundary region, called the S region, forms between the $+X$ and the Z regions (Fig. 3). The growth zones can be clearly seen in a slice taken perpendicular to the Y axis (X-Z plane) by either optical or x-ray topography, or by gamma-irradiating the sample and examining the optical darkening. The boundary between the growth zones consists of a small lattice distortion, on the order of 0.01%, and probably a tilting of the lattice on the order of 10^{-6} radians.

4. APPLICATIONS

4.1 Electronic

The Curies were the first to describe the piezoelectric effect, and determined the existence of it in quartz. During World War I, quartz plates were first used in early sonar. The first reported use of quartz as an oscillator was in the 1920s. Throughout the 1920s and 1930s, quartz-crystal units were used for radio broadcasting. The mass production of such units was brought about by the communication needs of World War II. Radio broadcasting, other commercial communications, and military applications were the only significant uses of quartz-crystal components until color television in the early 1960s.

Thereafter came the citizens' band radio, watches, and clocks, followed by digital electronics. Now, quartz is firmly established as the material of choice in frequency control. Only silicon for semiconductors is manufactured in larger quantity than single-crystal quartz.

All electronic applications of quartz involve the piezoelectric effect (see PIEZOELECTRIC DEVICES). Through this effect, electrical energy is converted into mechanical energy, and vice versa (the converse piezoelectric effect). The use of the piezoelectric effect occurs in three very different ways: exciting bulk waves, launching surface waves, or establishing static charges. Frequency-control components result from utilizing resonant elements to trap bulk or surface waves. Frequency control refers to oscillators (frequency sources) and filters (frequency selectors) (see PIEZOELECTRIC FILTERS AND RESONATORS). Resonant elements used in oscillators can be considered filter elements, selecting the frequency that will be amplified by the active part of the circuit. In an even broader sense, all resonant devices can be considered as frequency-sensitive phase-shift networks.

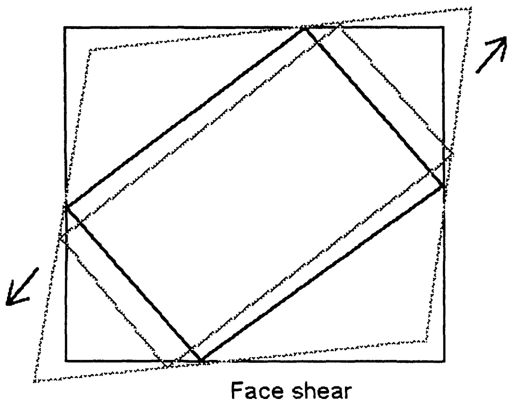
In principle, quartz can be used in a static mode, in which pressure is related to charge. There has been little interest in developing commercial applications based on this property.

The most common applications use the very high stability of quartz components over wide operating conditions to create components with nearly invariant characteristics over large temperature ranges, long time intervals, and so on. However, it is also possible to accentuate the effect of a particular environmental variable, temperature for example, on the resonant element and use it as a high-quality sensor. Such elements have the advantage of a digitized output (frequency), which makes it unnecessary to carry out further analog-to-digital conversion. Frequency measurement is a well-developed technology capable of higher precision than is achieved with measurement of other parameters.

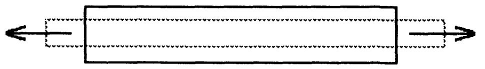
The first quartz resonators used bulk-wave excitation. Resonant quartz devices are passive; they respond to stimuli but are not used as energy sources. The normal scheme is to introduce the resonant element into a broadband stimulus. The response of the element is controlled by the mechanical resonance of the device, with the mechanical excitation resulting from the conversion of the electrical stimulus to mechanical motion. Thin-film, conductive electrodes are deposited on the mechanical resonators to provide coupling between the mechanical and the electrical energy. These electrodes become part of the resonant system and must be considered in resonator design. Electrically, the presence of electrodes results in capacitance which must also be considered. Mechanically, the electrodes result in mass loading and acoustic mismatch between regions of the element with electrodes and those without. This mismatch can result in energy trapping, which is the basis of resonance.

4.1.1 Bulk Wave Bulk-wave devices are designed so that the bulk of the material is in motion during the resonant cycle. Many modes are usually excitable. For example, a cymbal is a mechanical resonator in which many modes are excited when it is excited mechanically. A tuning fork, on the other hand, responds in one mode (440 Hz, for example) very strongly, while minimizing others to the greatest extent possible. Quartz devices are designed to maximize certain vibration modes and to minimize others. The variables in the design primarily relate to device shapes and electrode characteristics. Some quartz resonators are simply rods supported at each end, analogous to a string or xylophone plate; others are shaped like tuning forks. The scale is typically a few to several millimeters.

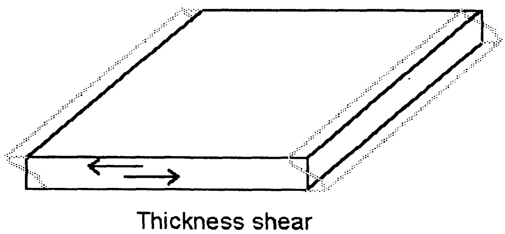
The early bulk-wave devices were plates with strong vibrations in length-extension or face-shear modes. Later the thickness-shear modes became dominant (Fig. 4). The main reason for the increased use of thickness-shear cuts was higher stability. Experimenters had noticed that with plates of one crystallographic orientation resonant frequency increased with temperature, while with others it decreased. The conclusion was that a zero–temperature-coefficient orientation existed. This orientation was determined, and the thickness-shear mode was dominant. The resonant frequency of such a device is determined almost exclusively by the thickness of the plate.



Face shear



Length-extension shear



Thickness shear

FIG. 4. The various of modes of vibration for bulk-wave quartz devices.

Well-known glass fabrication methods were easily adapted to the processing of bulk-wave components, supplemented by thin-film deposition technology. Cutting, lapping, etching, and polishing are the normal procedures used for forming devices, followed by thin-film deposition. The main differences between fabricating glass and crystal quartz shapes are the final thickness control and maximum temperature of quartz. The final thickness tolerance is often the equivalent of a monolayer (such tolerances require chemical milling as the final step). The local temperature at the contact between abrasive and crystal cannot exceed 573 °C, or destructive twinning will result.

The common range of frequencies of bulk-wave devices is 30 kHz to 150 MHz based on mechanical processing. Chemical processing methods recently have been developed to increase the frequency to a few hundred MHz (at 250 MHz, the thickness of a thickness-shear device operating in the fundamental mode is about 7 μm).

The quartz crystal in wrist watches is produced in quantities of over one billion per year. It is a quartz resonant element in the shape of a tuning fork, operating at 32.768 kHz (2^{15} Hz), surrounded by an inert atmosphere in a cylindrical metal package no larger than 3 × 8 mm. The personal computer is another example of our many contacts with quartz components. The speed of the computer relates to the frequency of the internal quartz oscillator, often 10 to 66 MHz.

4.1.2 Surface Acoustic-Wave Devices

Bulk-wave devices face inherent limits to the frequency of operation related to the strict rules that relate shape and frequency. In the thickness-shear devices, for example, an upper frequency limit exists because of limits on how thin the device can be made in a controllable way. As communication technology has migrated up in frequency, related to spectrum limits and semiconductor advances, the need for GHz-range frequency-control devices has begun.

In the case of surface acoustic-wave (SAW) devices, the frequency of the launched wave is controlled by the spacing of interlaced, thin-film conductive fingers.

These fingers are alternately of positive and negative polarity, giving rise to a compression wave with $\frac{1}{4}$ of its wavelength equal to the spacing between adjacent fingers of opposite polarity. Thus, the frequency characteristic of a SAW device is controlled by the pattern of the electrodes, not the shape of the device, nor the substrate dimensions. The resulting wave is referred to as a surface wave because it is normally confined to a volume very near the surface. This is much the same as the waves on a large body of water.

The electrode pattern is established using photolithography techniques well known to the semiconductor industry. Submicron line width and spacing are required for GHz-range devices.

Another method adopted from the semiconductor industry is the concept of processing many devices on one wafer. Bulk-wave devices were typically handled one by one through manufacturing. Using the wafer philosophies and equipment of the semiconductor processors has opened many new possibilities for miniaturization, higher-frequency operation, and cost reduction.

4.2 Optical

Single-crystal quartz is also used in the optical industry, though in smaller quantities than in the electronic industry. Two properties, birefringence and optical activity, are used. Birefringence is the simultaneous existence of two indices of refraction. Optical activity relates to the rotation of the polarization vector as light passes along the optic axis. This property is used in laser optics to achieve $\frac{1}{4}$ and $\frac{1}{2}$-wave rotations in the optical path.

Birefringent elements have found their way into some consumer applications. Most home video cameras use an optical quartz device to control certain interference patterns associated with charge-coupled–device imaging elements. The compact-disc player uses a Wollaston prism in the laser path to detect the phase difference between the reference and the beam reflected from the metallized CD surface.

4.3 Other Applications

Natural quartz has for centuries served man as a gem material. Amethyst is iron-containing quartz, citrine is also iron-containing (though of different valence then amethyst) quartz, and smoky is aluminum-bearing quartz. In addition to clear, the other three important quartz-related gems have been cultured to a very high quality and uniformity. As the best grades of natural stones become less available and as the labor cost of processing small, random stones increases, the interest in cultured varieties has increased.

In addition to the cultured gems mentioned above, other colors not naturally occurring in nature have been created. Blue is the best example. Green quartz, rarely occurring naturally, has been cultured. There is very limited commercial interest in these materials.

INTRODUCTION: QUASICRYSTALS—IMPOSSIBLE CRYSTALS

Until recently, we classified solids as either crystalline, where the basic constituents, atoms or molecules, are ordered in a periodic array, or amorphous, with a disordered arrangement of constituents, as in glasses. The structure of crystals is simply described by a repetition of a single motif, called a unit cell, consisting of one or more atoms. Diffraction patterns of crystals, which are related to structure by a Fourier transform, reflect the crystal symmetries and consist of sharp diffraction peaks, indicating the presence of a long-range order. For the crystalline state, powerful theories have been developed that make use of the symmetry imposed by the periodicity. According to these theories, pentagonal (fivefold) symmetry is impossible in solids.

Discovered in 1982 by Dan Shechtman (1984), icosahedral quasicrystals exhibited an extraordinary fivefold diffraction pattern with sharp diffraction peaks, indicating the presence of a long-range order similar to that found in crystals. Additionally, peaks along a radial, straight line, were not spaced equally distanced as in crystals but were related to each other through an irrational number $\tau = 2 \cos 36°$, suggesting a new kind of ordering. Figure 1 illustrates three different state-of-the-art quasicrystalline compounds, which are quasiperiodic in one, two, and three dimensions and periodic in any remaining dimensions. Diffraction patterns are also shown along the tenfold, fivefold, and twofold directions.

The following illustration will help explain the controversy over order and fivefold symmetry. Imagine covering a planar surface with square-shaped tiles, as shown in Fig. 2(a). In this simple process, tiles are placed periodically next to each other until the plane is covered. Next, imagine covering the plane using pentagonal tiles, as shown in

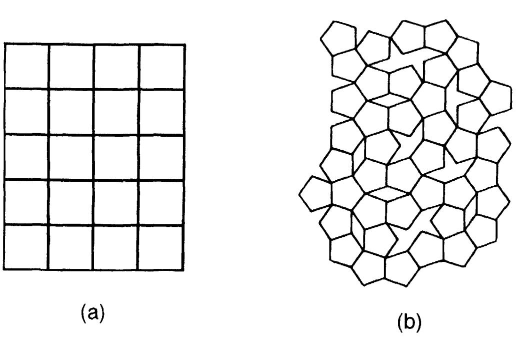
Fig. 2(b). These tiles leave gaps in between when the edges are matched, and the plane cannot be covered completely. Most importantly, the overall structure of the tiling appears disordered, unlike the square-tiled surface. The tiles used in these examples are direct analogs of unit cells used in describing crystalline systems, and qualitatively illustrate why fivefold order is incompatible with the high degree of periodic order found in crystals. Quasicrystals, because of their extraordinary structures, are sometimes referred to as "impossible crystals."

After a decade of intense research on quasicrystals, remarkable progress has been made in understanding this exotic form of matter. The purpose of this article is to present an introduction to quasicrystals.



(a) (b)

FIG. 2. Tiling a planar surface demonstrates that pentagonal tiles appear disordered compared to square tiles.

1. QUASICRYSTALLINE STRUCTURE

In this section, quasiperiodic systems in one, two, and three dimensions are studied, and methods to generate them are described.

1.1 Periodic and Quasiperiodic Structures

The crystalline state of matter consists of periodically spaced atoms or molecules, whose positions are defined by the vector

$$\mathbf{R} = n_1\mathbf{a} + n_2\mathbf{b} + n_3\mathbf{c}.$$

The primitive translation vectors **a**, **b**, and **c** describe the shortest separation between identical units, and the n's are integers. Letting the n's take all possible values, we describe a crystalline lattice. Any crystal, therefore, appears identical when viewed from points spaced by the translation vector **R** and exhibits so-called long-range periodic translational symmetry. Crystals or periodic systems also exhibit a point-group symmetry, which includes rotations and reflections of the lattice by keeping one point fixed. For crystals, rotations of only 360°/n, $n = 1, 2, 3, 4, 6$, are allowed. As demonstrated in Fig. 2, it is impossible to construct a periodic system that exhibits a fivefold point-group symmetry. (For more details, readers are referred to the article CRYSTALLINE STATE.) There is also an orientational long-range order that is common to all crystals and quasicrystals. This restricts the orientations of the unit cells to a special discrete set of directions and is demonstrated by the edges of the square and pentagonal tiles of Fig. 2, which are aligned along the same direction with respect to their neighbors, despite the disordered appearance of the pentagonal tiles.

1.2 Generating Quasiperiodic Structures

In generating quasiperiodic structures, a quasiperiodic but long-ranged translational order can be constructed. Similar to the single unit-cell concept used in crystals, for quasicrystals there exist two or more unit cells, or building blocks. These unit cells are decorated with atoms or molecules. Quasicrystalline structures are then generated by some aperiodic arrangement of these unit cells or building blocks. A one-dimensional construction that belongs to the famous mathematician Fibonacci is as follows. Imagine having two different unit length building blocks, of lengths L (for long) and S (for short). The lengths L and S are related through an irrational number, the so-called golden mean, $\tau = 2 \cos 36° = 1.618..$, by $L/S = \tau$. The Fibonacci sequence is then generated by applying the following iterative substitution. At each stage of iteration, substitute L in place of S and LS in place of L. Successive iterations generated from a starting block L then become

1. *L*
2. *LS*
3. *LSL*
4. *LSLLS*
5. *LSLLSLSL*
6. *LSLLSLSLLSLLS*
7. *LSLLSLSLLSLLSLSLLSLSL*

⋮

n . . .

This sequence has many interesting properties. First, it has a perfect aperiodic order; that is, no part of the sequence repeats itself periodically. In the limit as n approaches infinity, the ratio of the total number of L to S used in the process becomes equal to τ. It is possible to find identical local patterns in different parts of the sequence, independent of the size of these patterns. Another remarkable property is the self-similarity of the sequence upon the substitution, meaning each iteration duplicates the starting finite sequence in addition to new extra terms. This point is illustrated for a chain of atoms ordered quasiperiodically in Fig. 3. The calculated diffraction pattern of such a chain of atoms consist of sharp diffraction peaks spaced quasiperiodically.

A two-dimensional quasiperiodic packing of pentagons was first discovered by the mathematician-physicist Roger Penrose (1974). He was able to pack pentagons in two dimensions with a perfect long-range quasiperiodic order by following certain rules in matching neighboring pentagons. These matching rules were enforced by six different interlocking tiles, resembling the pieces of a jig-saw puzzle (Fig. 4). A beautiful long-range order was revealed by the perfectly aligned small line segments of the pat-

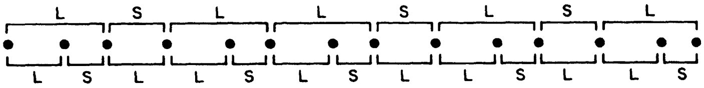


FIG. 3. Sequential spacing of atoms placed on a Fibonacci lattice remain unchanged by the iterative substitution.

tern, forming small sections of infinitely long straight lines. Here it becomes clear that matching rules are a very important part of generating good quasiperiodic order. Such a long-range quasiperiodical order is missing in the disordered pattern of Fig. 2b.

1.2.1 Space filling with Tile Matching

An ideal quasicrystal is constructed by an infinite repetition of two or more unit cells packed in a lattice that has long-range quasiperiodic order. A two-dimensional pentagonal quasicrystal can be constructed using two rhombic tiles, as shown in Fig. 5. These tiles are more convenient versions of the original Penrose tiles. Here, a long-range quasiperiodic order is now enforced through the following local matching rules. In building the two-dimensional quasiperiodic structure from individual tiles, the pointed arrows of the neighboring tiles are matched. Figure 5 also shows a two-dimensional Penrose quasicrystal where all the matching rules are obeyed. In real materials, these matching rules would be equivalent to having different atomic decorations for these two tiles. These structural models were first introduced by Levine and Steinhardt (1984). Independent of the experimental discovery, they generalized the notion of long-range order found in crystals to quasicrystals with quasiperiodic translational order. Using the pair of distinct unit cells or polyhedral tiles mentioned ear-

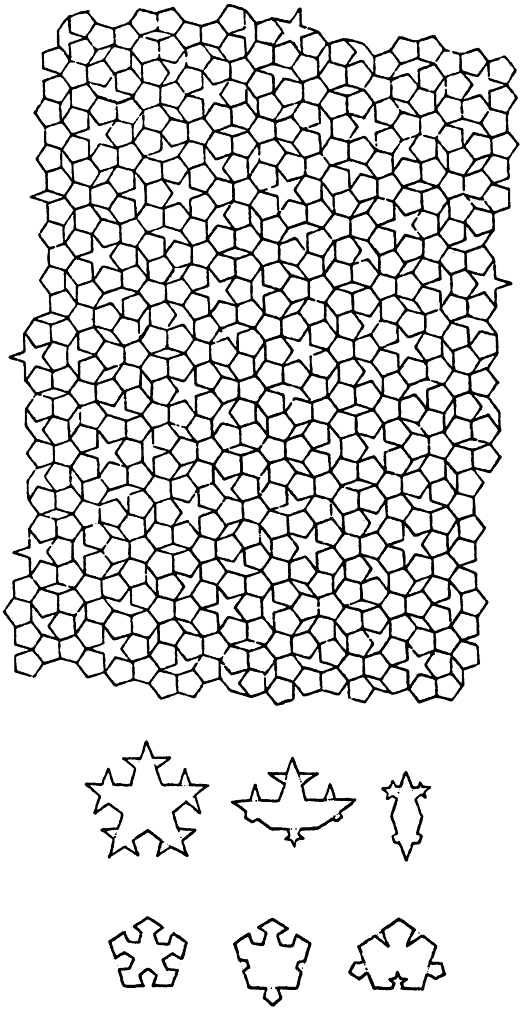

FIG. 4. Pentagons can be packed with a perfect quasiperiodic order, using six different tiles.

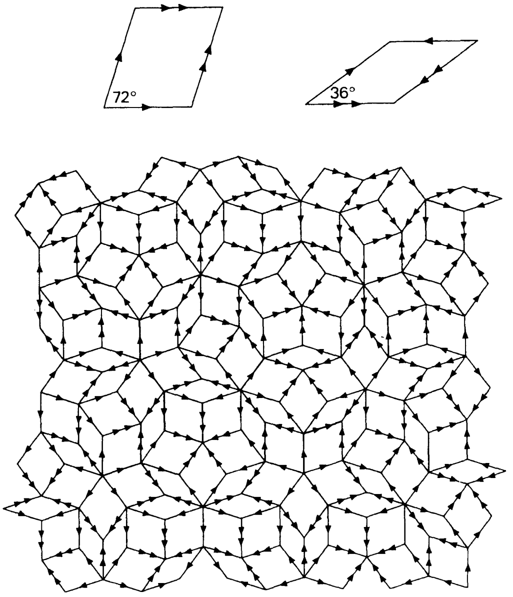

FIG. 5. Rhombic Penrose tiles with matching rules are used to generate a two-dimensional quasicrystalline structure.

lier, they showed that space could be filled quasiperiodically and calculated a diffraction pattern with an icosahedral symmetry and sharp intensities, very similar to the experimental pattern.

Following the local matching rules alone, however, is not sufficient to construct an ideal quasicrystal. Consider building a quasicrystal by adding one tile at a time, using the matching rules. Soon after adding several tiles, there will be a choice to make about which tile to use. With the wrong choice, gaps will appear in the structure that cannot be filled with any tile, as illustrated in Fig. 6. These mistakes can only be corrected by going back a few steps and starting the tiling process all over again. This example demonstrates that, in building a perfect quasicrystal from rhombic tiles, imposing matching rules is a necessary but not a sufficient condition. The self-similarity property of quasicrystals can also be used in generating quasicrystals similar to the one demonstrated for the one-dimensional Fibonacci sequence case. In two dimensions, starting from a fat or a thin rhombus, one can generate an arbitrarily large quasicrystal. This process involves iterative replacements of the fat rhombic tile with three fat and two thin tiles and the thin tile with two fat and two thin tiles, as shown in Fig. 7. These substitutions are also called inflation-deflation rules and were first applied by Penrose in conjunction with the matching rules.

Unlike crystalline structures, quasicrystalline structure patterns are not unique. In other words, in a crystalline system, given many unit cells, these cells can only generate a single pattern, irrespective of how these cells are used, simply because all the cells are identical. In quasicrystals with two unit cells, however, the pattern generated depends on the sequence of tiles that are used in building it. In ideal quasicrystals, this sequence will be only quasiperiodic. Since the pattern generated would be always finite in size, we would always be studying a small section of an infinite quasiperiodic sequence at a time. Two seemingly different patterns may therefore both belong to the same quasicrystal, as these may represent different finite sections of the same sequence. Two patterns with every finite configuration of cells in each occurring in the other are referred to as locally isomorphic, and this is called local

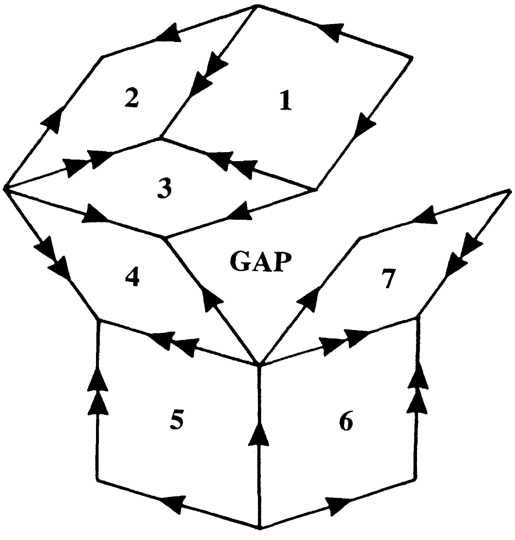

FIG. 6. Matching rules alone are not sufficient to generate perfect quasicrystalline structure.

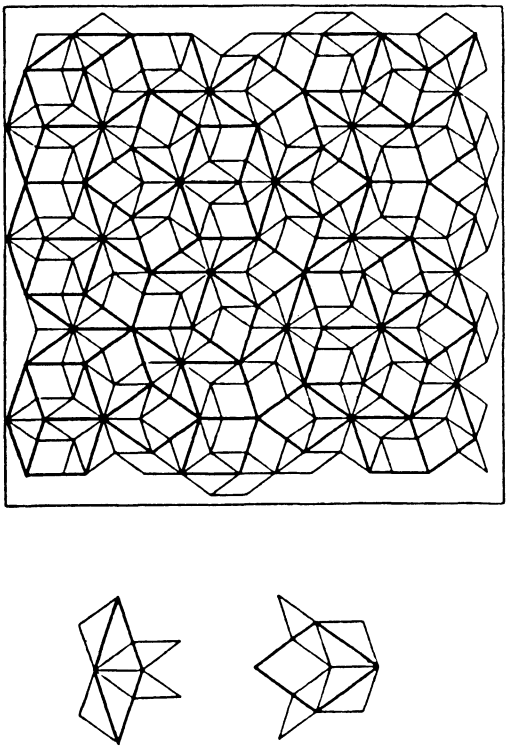

FIG. 7. A Penrose tiling generated by the substitution of each fat and thin tile (*thick lines*) by the set of smaller tiles (thin lines), as shown for individual tiles in the figure.

isomorphism (LI). Figure 8 shows three different tilings, all in different LI classes, generated by using the Penrose tiles. The pentagonal quasicrystal discussed in Fig. 5 is in the so-called Penrose local isomorphism (PLI) class. Here, we limit our discussion only to the PLI class, because of its close connection to real quasicrystals.

1.2.2 Strip-Projection Method Quasicrystals can also be generated from projections of crystalline systems from higher dimensions. Consider a two-dimensional square lattice, and its projection on a one-dimensional straight line that has a slope angle of α, as illustrated in Fig. 9. For an irrational slope, for example $\alpha = 36°$, the line does not intersect any of the lattice sites, and the projection of the lattice sites on this line will form a dense array of points. If we only project the sites that remain within a strip of unit cell dimensions, the projected point separations will then make more physical sense in terms of plausible interatomic distances. Interestingly, for the $\alpha = 36°$ choice, the sequence of projected site spacings now follow the Fibonacci sequence. Note that we generated a quasiperiodic structure in $\mathbf{R}_{\text{par}}$ or physical space by projecting a periodic structure in two-dimensional $\mathbf{R}_{\text{par}}$, $\mathbf{R}_{\text{perp}}$ space. The terms $\mathbf{R}_{\text{par}}$ and $\mathbf{R}_{\text{perp}}$ refer to parallel and perpendicular components, and $\mathbf{R}_{\text{perp}}$ is often referred to as the complementary space. This strip-projection method can be generalized to higher-dimensional quasicrystals. For instance, an icosahedral quasicrystal can be generated from projection of a six-dimensional hypercubic lattice on to the three-dimensional physical space. Just as three vectors **a**, **b**, and **c** are needed to define the vertices of a unit cell of a periodic system in three dimensions, the minimum number of vectors needed to define the vertices of a regular icosahedron is six, as shown in Fig. 10, indicating that the corresponding periodic system is in the six-dimensional space.

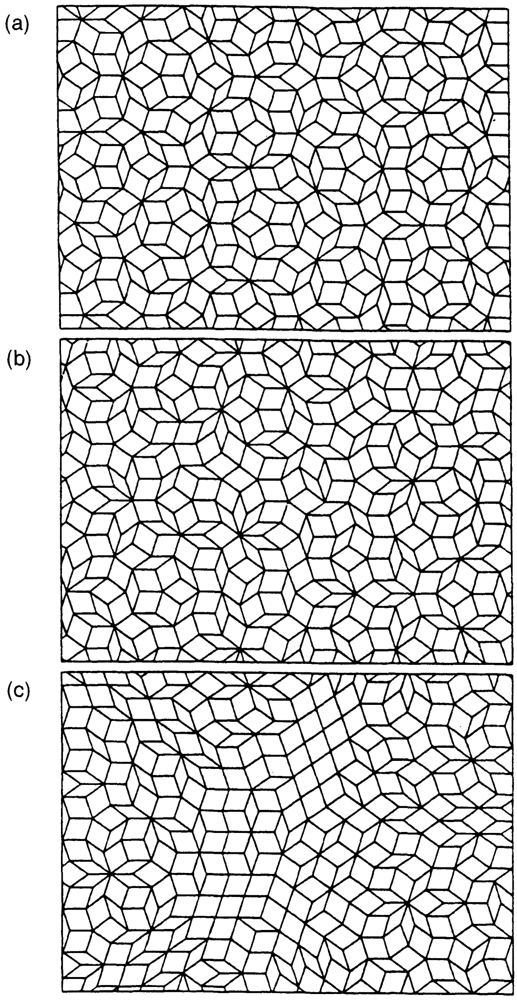

FIG. 8. Three different locally isomorphic quasiperiodic tilings. The patterns are visibly different from each other. Only (a) is generated by using the Fibonacci sequence and is in the Penrose Local Isomorphic class. (Courtesy of J. E. S. Socolar and P. J. Steinhardt.)

1.2.3 Generalized Dual Method This method starts with multiple grids of quasiperiodically spaced parallel lines in two dimensions and surfaces in three dimensions. The intersection points of these grids are

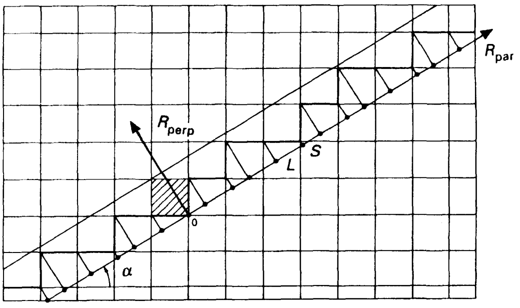

FIG. 9. A one-dimensional Fibonacci quasicrystal obtained by projection-and-cut method from a two-dimensional square lattice.

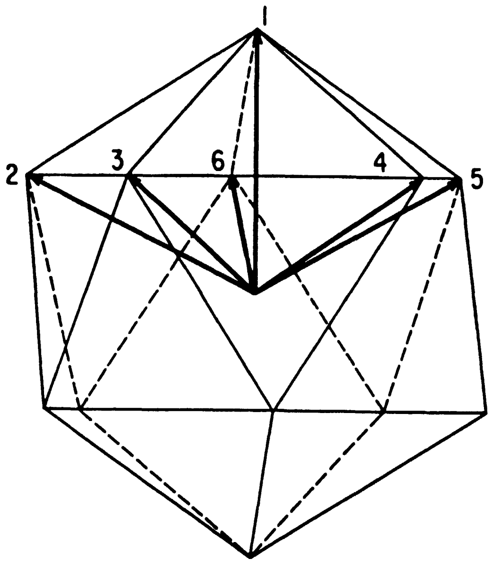

FIG. 10. A regular icosahedron and six unit-cell vectors that define the vertices.

then decorated with tiles. This construction has the following properties: a quasiperiodic translational symmetry, an orientational symmetry, and a minimal separation between atoms for a physical system. For the two-dimensional Penrose lattice, such a construction is referred to as an Ammann quasilattice, and the sequence of spacings between the parallel lines becomes the Fibonacci sequence, as illustrated in Fig. 11. Individual tiles, as shown in the figure, become decorated with sections of straight lines, and lines run continuously across the whole lattice when the tiles are properly matched. Since the model starts from the long-ranged ordered grids, the tilings always have a long-range quasiperiodic order. This method also works for generating three-dimensional quasicrystals. In three dimensions, Penrose tiles take the shape of oblate and prolate rhombohedra, as shown in Fig. 12.

2. QUASICRYSTAL-FORMING COMPOUNDS

Real materials with the exotic structure described above actually exist in nature. Almost all known quasicrystal-forming compounds have a well-known crystalline compound with a similar stoichometry. These crystalline phases usually exhibit an extensive icosahedral local order, and they are referred to as Frank–Kasper phases. Naturally, most of the search for new quasicrystals, therefore, has focussed on alloys that are known Frank–Kasper phase formers.

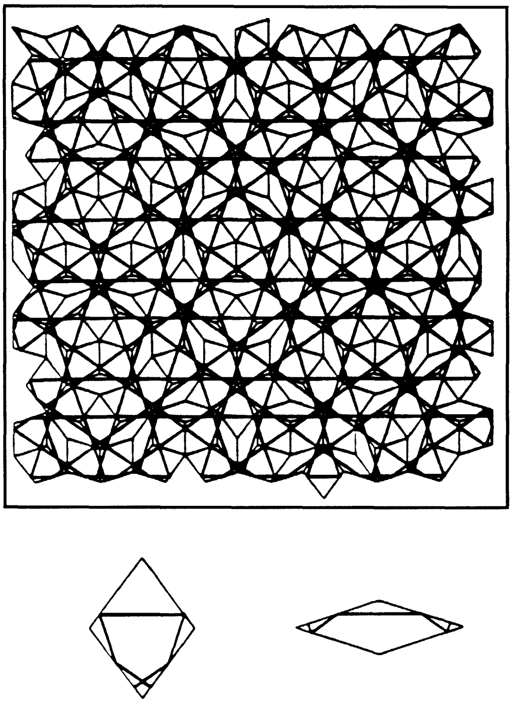

FIG. 11. A Penrose quasicrystal constructed from five sets of quasiperiodically spaced parallel Ammann lines and individual tiles with corresponding decorations.

First discovered in metastable form, quasicrystals had only few-hundred-angstrom-size defect-free regions. After several short years, the number of quasicrystal-forming compounds is now exceeding one hundred. Many new quasicrystalline compounds are discovered with one-, two-, and three-dimensional quasicrystallinity. Several compounds discovered recently by Tsai *et al.* (1989) exhibit a crystalline thermodynamic stability, and a quasicrystalline structural perfection surpassing many crystals.

2.1 Early Metastable Compounds

Quasicrystals were first discovered in aluminum-rich transition-metal (TM) alloys, in the compositional range of 10–14 at.% TM

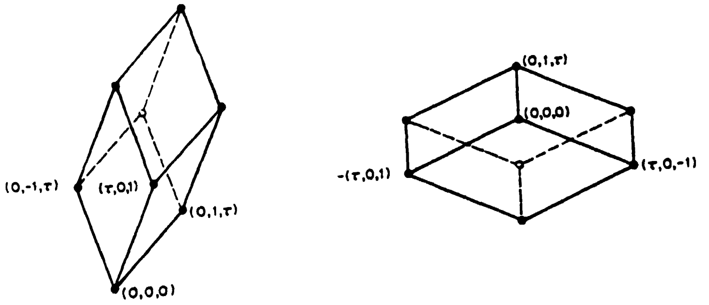

FIG. 12. Prolate and oblate rhombohedra used in three-dimensional Penrose tilings. Vertex coordinates refer to an orthogonal coordinate system.

= Mn, Fe, Cr. These alloys were prepared by rapidly quenching molten metal alloys on a rotating copper cylinder, with typical quench rates of 10^5–10^9 K/s. Ribbonlike samples were several microns thick and a few millimeters wide and contained micron-size icosahedral quasicrystalline grains as well as a few other phases. The addition of a few percent silicon to the alloy greatly improved the stability and structural perfection of the icosahedral-phase grains, which were mostly dendritic in nature. Figure 13 shows a scanning electron microscope (SEM) image of the top surface of a melt-spun ribbon of an $Al_{74}Mn_{20}Si_6$ quasicrystal. Here, individual quasicrystalline grains with sizes a fraction of a micron were resolved, which collectively defined pentagonal features on the surface, characteristic of their quasicrystal symmetry. This is explained by a dendritic growth mechanism, induced by the large undercooling.

These early icosahedral (*i*) phase alloys were all in the *i*-Al-TM class, which included *i*-$Al_{86}Mn_{20}$, *i*-$Al_{79}Cr_{17}Ru_4$, *i*-$Al_{60}Si_{20}(Mn,Cr)_{20}$, *i*-$Al_{65}Ge_{15}(Mn,Cr)_{20}$, and *i*-$Al_{75}Cu_{15}V_{10}$. The structures of these quasicrystals are closely related to the crystalline structure of $Al_9Mn_2Si_2$, and they all form peritectically, i.e., from a liquid-solid reaction. Because of kinetic limitations induced by the undercooling and slow diffusion of the liquid in solid, phase formation never reaches completion, and large compositional inhomogeneities result in a high density of structural defects.

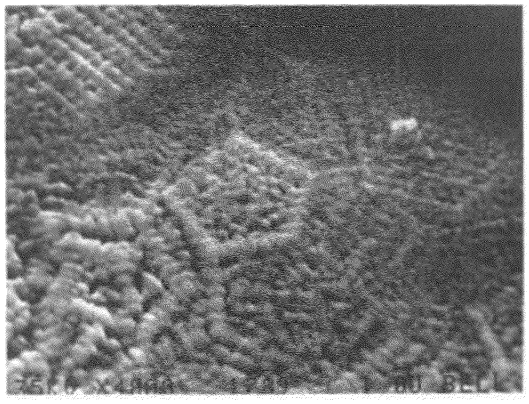

FIG. 13. Surface solidification morphology of a melt-spun $Al_{74}Mn_{20}Si_6$ alloy ribbon.

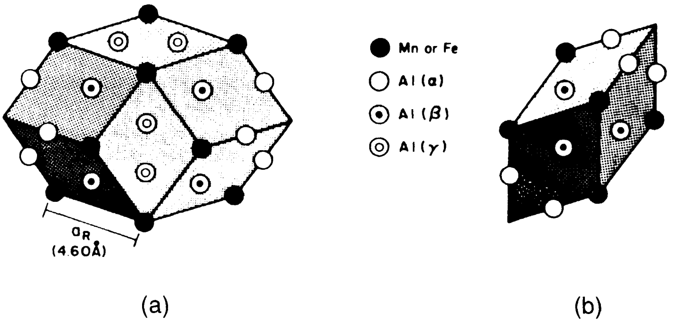
A well-known crystalline α-{AlMnSi} phase has a composition $Al_{72.5}Mn_{17.4}Si_{10.1}$, which is similar to the quasicrystalline $Al_{74}Mn_{20}Si_6$. Using the known local order found in the α phase, and a projection method, three-dimensional Penrose tiles have been constructed to describe α-{Al-(Mn,Fe)-Si} phases. Illustrated in Fig. 14, these tiles are not believed to promote the *i* phase. Instead, two slightly different packings of a 54-atom icosahedral structural unit [also called Mackay icosahedron (MI)] give rise to α or quasicrystalline phases.

2.2 Stable Compounds

2.2.1 Al_5Li_3Cu Quasicrystal This system appeared to be remarkably stable compared to earlier systems and made it possible to apply conventional techniques to grow large single grains. This ternary compound contains *s*, *p*, and *d* elements and defines a new *spd* class. Other *spd* quasicrystals include *i*-$Al_2Mg_3Zn_3$, *i*-Al_6Mg_4Cu, *i*-Al_6Li_3Au, *i*-$Al_{51}Li_{32}Zn_{17}$, *i*-$Al_{50}Mg_{35}Ag_{15}$, and *i*-$Ga_{16}Mg_{32}Zn_{52}$. Structurally, these are closely related to the $Im\bar{3}$, (bcc) Al_5Li_3Cu crystalline phase, which can be described as a body-centered close-packed structure of icosahedral-shaped



(a) (b)

FIG. 14. (a) Rhombic dodecahedron and (b) prolate rhombohedron, used in constructing α-Al(Mn,Fe)Si structures. (Courtesy of V. Elser.)

atomic clusters. Each cluster, referred to as a Samson complex, consists of shells of Al, Cu, and Li atoms distributed on five successive shells, and contains 104 atoms. These shells have the shapes of icosahedron, pentagonal dodecahedron, truncated icosahedron, and a small triacontahedron, as illustrated in Fig. 15. Based on the local order derived from the bcc phase, three-dimensional Penrose tiles have been constructed by atomic decoration of canonical Penrose tiles, as shown in Fig. 16. A reasonable agreement with the experimental diffraction data has been achieved by introducing a partial chemical disorder.

In most quasicrystal-forming systems, the quasicrystalline icosahedral phase I occurs as a noncongruently melting compound close to a congruent crystalline phase in the phase diagram. Quasicrystals then form by a peritectic reaction of the melt with the crystalline phase. For the $Al_{5.1}Li_3Cu$ quasicrystalline phase, this neighboring crystalline phase is the $Al_{4.8}Li_3Cu$ body-centered cubic phase, as shown in Fig. 17. Both compounds span a narrow range in composition and appear to be thermodynamically stable. Using a solute (Al)-rich starting liquid, large single grains are grown directly from the liquid using arbitrarily slow cooling rates. When the liquid is aluminum rich ($x > 6$, in Fig. 17), and cooled below the liquidus line, the only phase that nucleates and grows is the *i* phase. It is essential, however, in this approach to cool very slowly to minimize the coring effect and not to induce constitutional undercooling at the liquid-solid interface that will initiate a dendritic growth. Centimeter-size single quasicrystal grains have been grown using this approach. X-ray diffraction measurements find a large mosaic spread (~1°) in these samples, indicating some structural disorder. In another approach to growing quasicrystals, a stoichiometric composition can be cooled slowly through the liquidus line. This results in nucleation and growth of the cubic phase. By the time the melt is cooled to the *i*-phase boundary, the melt would contain large grains of the cubic phase, and the quasicrystal growth will be hindered by the slow diffusion of the liquid in these solid grains of the cubic phase. This approach yields kinetically limited growth and poor-quality quasicrystals. The liquidus region can also be quickly by-passed by rapid quenching of the liquid before giving the cubic phase a chance to nucleate. In principle, this results in a very small grain size because of the large nucleation density, as demonstrated by small-grain ribbons produced by melt-spinning experiments. In cast-cooled samples, single-grain quasicrystals are

observed in shrink cavities. Figure 18 shows a hundred-micron–size single grain with very well-developed facets. Solidification morphology is a triacontrahedron, with twofold planar facets, which indicates that growth is limited by a small nucleation rate on these planes.

A close structural relationship between the cubic and i phases is also demonstrated morphologically. Figure 19 shows a quasiepitaxial growth of i-phase grains on a crystalline cubic grain. Here, three distinct quasicrystalline i-phase grains nucleate and grow on the {111} vertices of a cubic grain. The threefold axes of the i-phase grains are aligned with the cubic threefold axes, and i-phase twofold planes are aligned with the cubic {111} planes. Interestingly, growth-limiting cubic {100} planes share the same alignment with the growth-limiting quasicrystalline twofold planes, suggesting a quasiepitaxial interface between the two grains.

2.2.2 $Al_{65}Cu_{20}(Fe,Ru,Os)_{15}$ Quasicrystals

Quasicrystals of this remarkable class are very well ordered, with the size of defect-free

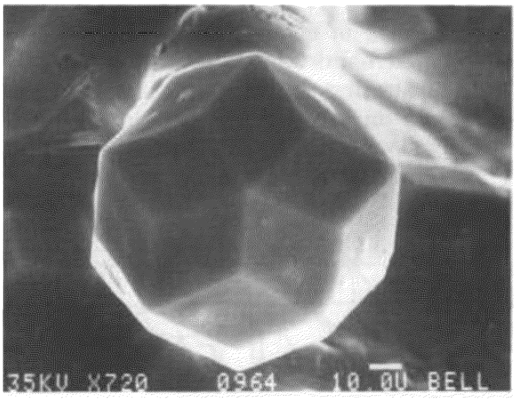

FIG. 18. A single grain of Al-Li-Cu quasicrystal. Naturally formed facets reveal the icosahedral phase symmetry.

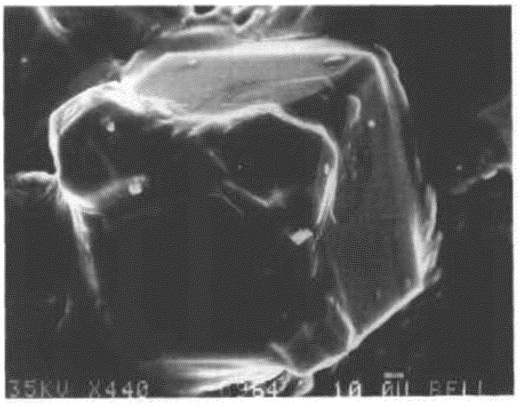

FIG. 19. *i*-phase grains grow quasiepitaxially on the cubic **R**-phase grain.

regions exceeding thousands of angstroms. The ternary phase diagram of this system, however, is very complicated. Attempts to grow large single quasicrystals were not successful because of an unusually large nucleation rate. The largest grains obtained were fractions of a millimeter in size. An additional complication has been the existence of nearby low-temperature crystalline phases, which the quasicrystalline phase sometimes transforms into. Figure 20 shows an electron microscopy image of the grain structure in a cast-cooled $Al_{65}Cu_{20}Fe_{15}$ sample. The grains have pentagonal dodecahedral morphology with very well-developed facets, indicating that the growth is limited by the layer nucleation process on the fivefold surface.

2.2.3 Decagonal Quasicrystals Discovered by Bendersky, decagonal quasicrystals are quasicrystalline in only two dimensions and crystalline in the third dimension. The atomic structure can be viewed as periodically stacked layers of two-dimensional, planar atomic structures with quasicrystalline order. Although the original discovery was made on thermodynamically unstable micron-size grains of Al-Mn alloys, stable forms occur in $Al_{65}Cu_{15}Co_{20}$ and $Al_{70}Ni_{15}Co_{15}$ ternary compounds. In these stable systems, there appears to be a vanishingly small peritectic liquidus region, which makes it possible to grow large grains under equilibrium conditions starting from stoichiometric liquids. Well-isolated single grains with ten naturally formed facets can be observed in cast-cooled samples, as shown in Fig. 21. Several millimeter-size single grains are grown under equilibrium conditions with very slow cooling rates. Single-crystal x-ray diffraction measurements of these grains indicate few-thousand-angstrom–size defect-free regions and confirm the two-dimensional quasiperiodic structure. Figure 22 shows the single-crystal scans made along the quasiperiodic and periodic directions.

The large grain sizes of decagonal quasicrystals also allow the application of conventional surface structure measurement techniques. Scanning tunneling microscopy (STM) measurements with atomic resolution also provide very valuable real-space information about the atomic structure. Figure 23 illustrates an STM image of the quasiperiod-

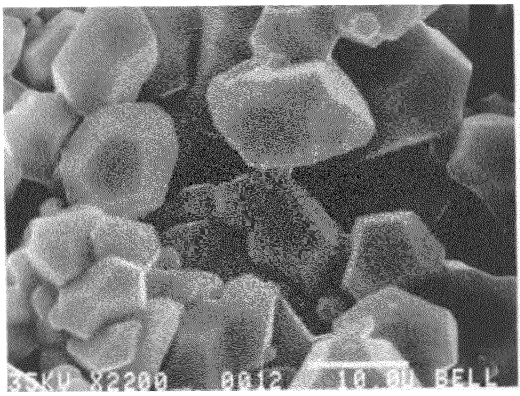

FIG. 20. Pentagonal dodecahedron-shaped single grains of $Al_{65}Cu_{20}Fe_{15}$ quasicrystal.

ic surface layer, in both the top and tilted views. Most of the atoms and periodically spaced terraces along the *c* axis are resolved. The tilted-image view shows that individual atoms lie on straight lines, an indication that the structure is defect free on large length scales. These mass-density lines resemble the Ammann quasilattice mentioned earlier. The fact that lines run uninterrupted across terraces suggest that layers are packed on top of each other along the periodic direction. A structural model with reasonable interatomic distances can be constructed on the basis of this information. Figure 24 shows a local STM image, a Penrose lattice with atomic decoration, and their overlay. The model assumes a pentagonal network mostly made out of aluminum, and a center decoration with mostly transition-metal atoms. A similar local image illustrates two-dimensional Penrose tiling, using fat and thin tiles, as shown in Fig. 25. Individual tiles, shown in the inset, demonstrate the presence of different atomic decorations for these tiles. STM images find quasicrystalline atomic order ranging in scale from a few angstroms to several hundred angstroms.

2.2.4 $Al_{70}Pd_{20}Mn_{10}$ Quasicrystal This stable icosahedral quasicrystal is particularly important because of its vanishingly small peritectic range. A partial phase diagram of this ternary system is shown in Fig. 26. Depending on the composition, this system forms face-centered-icosahedral (FCI), simple icosahedral (SI), or decagonal-like (D) phases. The FCI phase exhibits a strong chemical ordering and a remarkable structural perfection. Figure 27(a) shows a single-grain FCI phase grown over a period of 3 weeks. The only measurable defect in this grain is a small-angle (~2°) grain boundary, as indicated by the dark line on the surface. Structural perfection is also evident in the transmission Laue x-ray pattern taken from this grain shown in Figure 27(b). Dynamical x-ray diffraction, which is extremely sensitive to structural imperfections, has also demonstrated that $Al_{70}Pd_{20}Mn_{10}$ quasicrystals are almost perfect.

2.3 Predicting New Quasicrystals; Quantum Structure Diagrams

Searching for new quasicrystalline compounds is a very difficult process, considering that there are thousands of ternary compounds. Quantum structure diagrams (QSD) have proven to be very useful in predicting new compounds, especially in *spd* systems. These diagrams are constructed from atomic size ratios, electron concentrations, electronegativity differences, and other parameters. Figure 28 shows such a diagram for all the known stable quasicrystals in a plane whose coordinates are compositionally weighted ternary size ($\overline{\Delta R}$) and electronegativity difference ($\overline{\Delta X}$). All stable quasicrystals fall within a square region, indicating that these diagrams can, in fact, distinguish small differences between different ternary compounds.

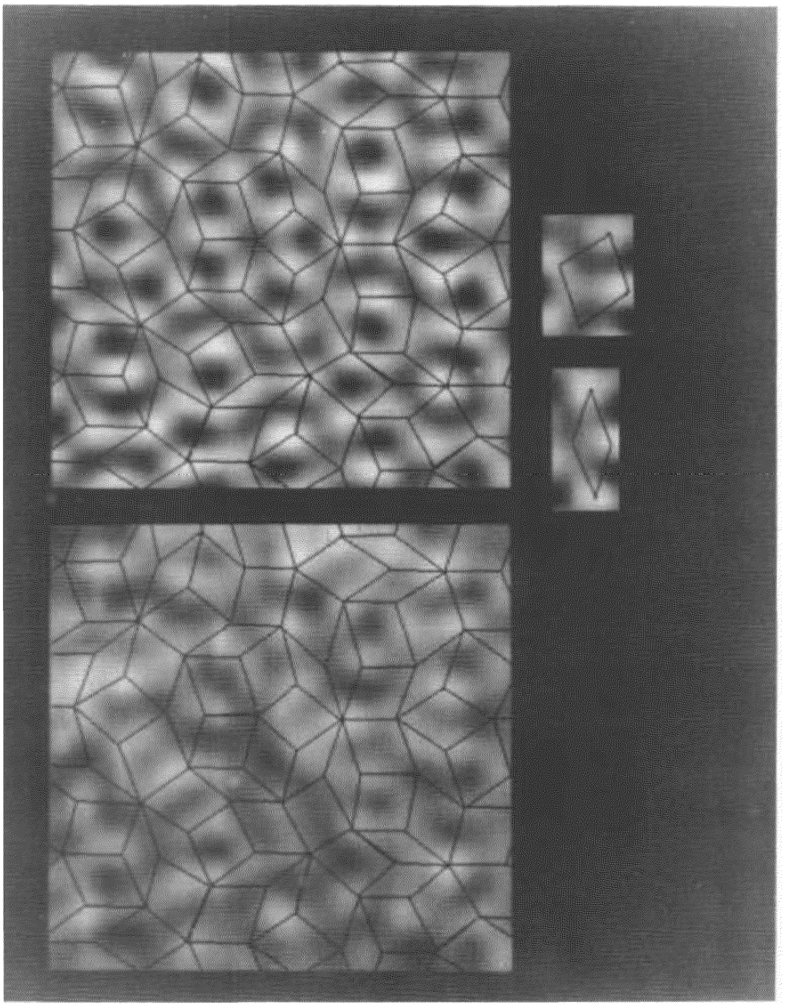

FIG. 25. Two-dimensional Penrose tiles (inset) are used to fit the raw and (upper) enhanced images.

These stable compounds are (1) $Al_{60}Li_{30}Cu_{10}$, (2) $Zn_{43}Mg_{37}Ga_{20}$, (3) $Al_{65}Cu_{20}Fe_{15}$, (4) Al_{65}-$Cu_{20}Ru_{15}$, (5) $Al_{65}Cu_{20}Os_{15}$, (6) $Al_{65}Co_{20}Cu_{15}$, (7) $Al_{70}Co_{15}Ni_{15}$, (8) $Al_{70}Pd_{20}Mn_{10}$, and (9) Al_{70}-$Pd_{20}Re_{15}$. The region enclosed by the dashed line contains *spd* quasicrystal-forming systems alone. For *spd*-type compounds, similar quantum diagrams were able to pick 55 possible ternaries out of some 2600 systems, and four new *spd* quasicrystals, Al_6Li_3Au, $Al_{51}Li_{32}Zn_{17}$, $Al_{50}Mg_{35}Ag_{15}$, and $Ga_{16}Mg_{32}Zn_{52}$, have been discovered with the help of this list.

3. QUASICRYSTALLOGRAPHY

3.1 Icosahedral Quasicrystals

There are a few different conventions in indexing an icosahedral pattern, all making use of six indices. One convenient method is choosing a cubic coordinate system alligned with the three orthogonal twofold axes of the icosahedron, as shown in Fig. 29. In this coordinate system, fivefold vertices of the icosahedron are of the form $(1\ \tau\ 0)$, and in general any of the high-symmetry axes can be

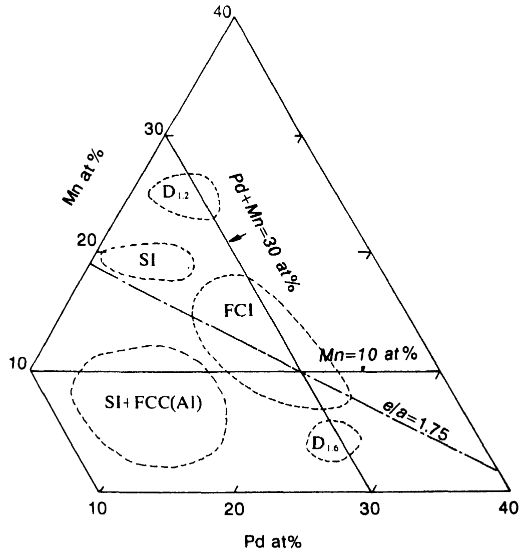

FIG. 26. Al-Pd-Cu phase diagram and regions where different quasicrystals form. (Courtesy of A. P. Tsai.)

expressed with indices of the form

$$(h + h'\tau \; k + k'\tau \; l + l'\tau)$$

or $(h/h', k/k', l/l')$ for short. Here h, h', k, k', l, l' are all integers and $\tau = 2 \cos 36°$. The need of a minimum number of six Miller indices implies the existence of a six-dimensional hypercubic system, whose projection yields three-dimensional quasicrystallinity. The six vectors along the fivefold axes then become

$$\begin{aligned} q_1 &= (1/0\ 0/1\ 0/0), \\ q_2 &= (0/1\ 0/0\ 1/0), \\ q_3 &= (0/0\ 1/0\ 0/1), \\ q_4 &= (\bar{1}/0\ 0/1\ 0/0), \\ q_5 &= (0/1\ 0/0\ \bar{1}/0), \\ q_6 &= (0/0\ \bar{1}/0\ 0/1). \end{aligned}$$

Any lattice site in reciprocal space can now be expressed as

$$Q = n_1 q_1 + n_2 q_2 + n_3 q_3 + n_4 q_4 + n_5 q_5 + n_6 q_6.$$

Here the n's are integers. In terms of three-dimensional cubic coordinates,

$$Q = \{(n_1 - n_4)/(n_2 - n_5), (n_3 - n_6)/(n_1 - n_4), (n_2 - n_5)/(n_3 - n_6)\}.$$

Combining this with the symmetry operations of the icosahedral group, certain restrictions on the indices and extinction rules are derived. Accordingly, three reciprocal lattices possible in six dimensions, primitive (P), face-centered (F), and body-centered (I), have different extinctions in the diffraction pattern. Figure 30 shows the calculated diffraction patterns of P, F, and I lattices along the twofold and fivefold zone axes. In order to make a distinction in identifying a structure, diffraction patterns along more than one zone axis must be examined.

3.2 Decagonal Quasicrystals

Decagonal quasicrystals, or two-dimensional quasicrystalline systems, require a minimum of four unit vectors to define the reciprocal lattice sites of a planar layer. A fifth index is introduced to describe the *c* axis or the periodic direction component. In terms of projection methods, this implies that the structure can be generated by projecting from a five-dimensional tetragonal lattice to three dimensions.

4. QUASICRYSTAL STRUCTURE AND GROWTH MODELS

4.1 Early Models

As mentioned earlier, a defect-free quasicrystal would have very sharp (delta function) diffraction peaks, just as a perfect crystal does, and the presence of defects would broaden these peaks. A remarkable property of quasicrystals is that even a highly defective sample, e.g., the structure in Fig. 2, would still give a quasiperiodic diffraction pattern, but with broadened peaks. This is due to the orientational order that exists even in disordered quasicrystals. An early model based on random packing of icosahedral clusters was therefore quite successful in explaining the defect-broadened diffraction patterns of earlier samples. Another model attempted to explain the forbidden symmetries by multiple twinning of very small crystallites and found reasonable agreement with these broad peaks. Stable quasicrystalline compounds discovered more recently, however, exhibit very sharp diffraction peaks, demonstrating that the observed

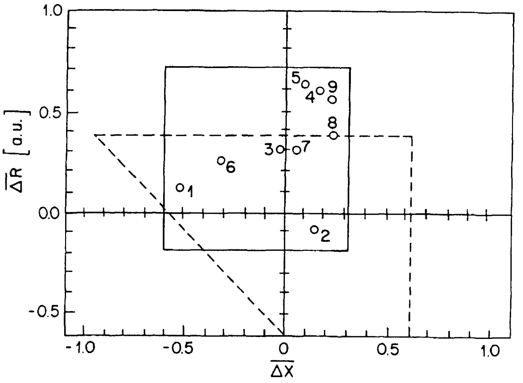

FIG. 28. A typical quantum structure diagram used in predicting new quasicrystals. Square box encloses all known stable compounds. (Courtesy of K. M. Rabe and J. C. Phillips.)

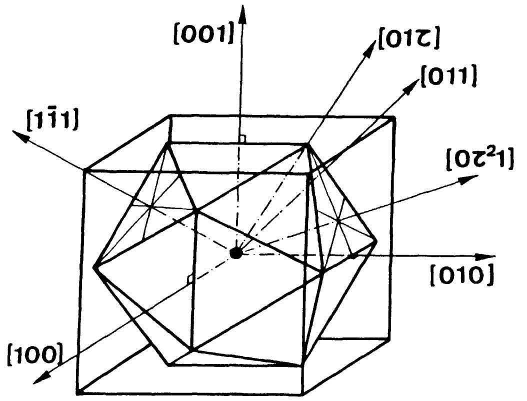

FIG. 29. An icosahedron oriented with cube axes is used in an indexing method.

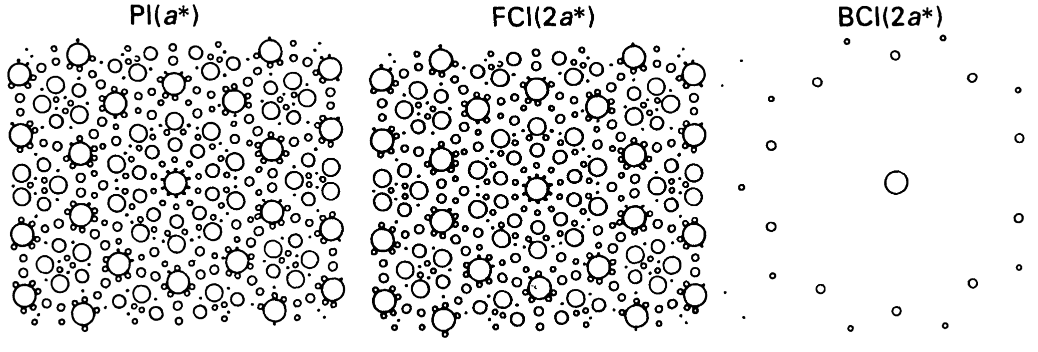
disorder is not an intrinsic property of quasicrystals, and quasicrystallinity is the most reasonable structure.

4.2 Growth of Perfect Quasicrystals

An important problem in quasicrystal growth is the generation of long-range order from short-range interactions. In generating perfect tilings, long-range order was artificially introduced into the system, as in the case of Ammann lines or grid lines. If we assume that Penrose tiles with local matching rules exist in physical systems, with matching rules replaced by some interatomic forces, we face the problem explained in Fig. 7: that a defect-free quasicrystal cannot exist. As more tiles are added to the system, the long-range aperiodic translational order will be significantly reduced, and entropy will determine the degree of order that exists in the system. It is clear that the original matching rules cannot produce perfect quasicrystals.

Remarkably, however, if certain restrictions are imposed on the original matching rules by only allowing eight different types of local patterns of Fig. 31 to occur in the lattice, then the problem encountered in Fig. 7 can be avoided, and a nearly defect-free two-dimensional Penrose lattice can be constructed. This restriction on local patterns is referred to as a vertex-matching rule. This construction suggests that a long-range quasicrystalline order in real systems can be explained by a finite-range, local interaction between the atoms.

Perhaps a more physical model, the "cluster picture," offers a more refined explana-



PI(*a**)

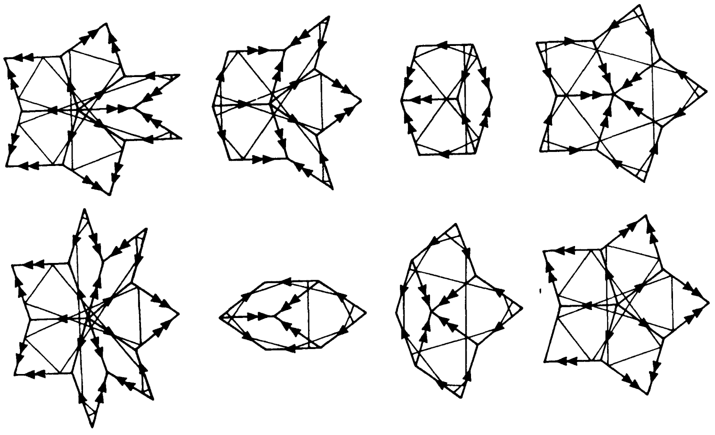

FIG. 31. Vertex-matching rules used in growing perfect quasicrystals. (Courtesy of P. J. Steinhardt.)

tion of the structure and formation of quasicrystals. Starting with a set of one or more small atomic clusters of low energy, an energetically stable quasiperiodic structure is generated by an energy-minimizing calculation that allows partial overlap of these clusters. This model generates energetically stable quasicrystals that are distinct from Penrose tilings.

5. DEFECTS IN QUASICRYSTALS

5.1 Phonons and Phasons

Quasicrystals have defects and elementary excitations that are closely related to their aperiodic translational order and rotational symmetry. These are identified in a density-wave description, where the mass density is expanded in a Fourier series:

$$\rho(\mathbf{r}_n) = \sum_{\mathbf{G}_n} \rho_{\mathrm{G}} \exp[i(\mathbf{G}_n \cdot \mathbf{r}_n)],$$

where $\mathbf{G}_n$ is a reciprocal vector in an n-dimensional space and ρ_{G} is a complex number with amplitude $|\rho_{\mathrm{G}}|$ and a phase ϕ_{G}. Consider displacing atoms of the lattice from their equilibrium positions by $\mathbf{u}$; then the phases are modified by

$$\phi_{\mathrm{G}} = \phi_{\mathrm{G}}^{0} + \mathbf{G}_n \cdot \mathbf{u}_n.$$

For the physical case of interest, i.e., for three-dimensional space, the projection method preserves the amplitudes and phases, and the density wave becomes

$$\rho(\mathbf{r}_{\mathrm{par}}) = \sum_{\mathbf{G}_{\mathrm{par}}} \rho_{\mathrm{G}} \exp[i(\mathbf{G}_{\mathrm{par}} \cdot \mathbf{r}_{\mathrm{par}})],$$

with the physical phases

$$\phi_{\mathrm{par}} = \phi_{\mathrm{G}_n} = \phi_{\mathrm{G}}^{0} + \mathbf{G}_{\mathrm{par}} \cdot \mathbf{u}_{\mathrm{par}} + \mathbf{G}_{\mathrm{perp}} \cdot \mathbf{u}_{\mathrm{perp}}.$$

Here, parallel and perpendicular components refer to the physical-space and complementary-space components, similar to the case described in Fig. 9. The $\mathbf{u}_{\mathrm{par}}$ component is called the phononlike component since it represents a real displacement in physical space. The $\mathbf{u}_{\mathrm{perp}}$ component, referred to as phasonlike modes, represents displacements in the complementary space and has the effect of locally rearranging the tiles. This tile rearrangement will only effect a local region without disturbing the rest of the lattice. In real systems, this will correspond to the local rearrangement of atoms. The $\mathbf{u}_{\mathrm{par}}$ is also referred to as the propagating mode and has an analog in crystals as phonons, whereas $\mathbf{u}_{\mathrm{perp}}$, also referred to as a diffusive mode, is unique to quasicrystals. Figure 32 illustrates phonon and phason strain fields for the two-dimensional Penrose lattice. Phononlike disturbances induce continuous and long-wavelength fluctuations in the pentagrid and will have a Debye–Waller-type effect on the diffraction pattern. Peaks will decrease in intensity and broaden with increasing q in reciprocal space. Phasonlike disturbances, meanwhile, can be detected as discontinuities or jags on the pentagrid, and cause shifts in the Bragg peak positions in proportion to the perpendicular component of the peaks. These types of defects were com-

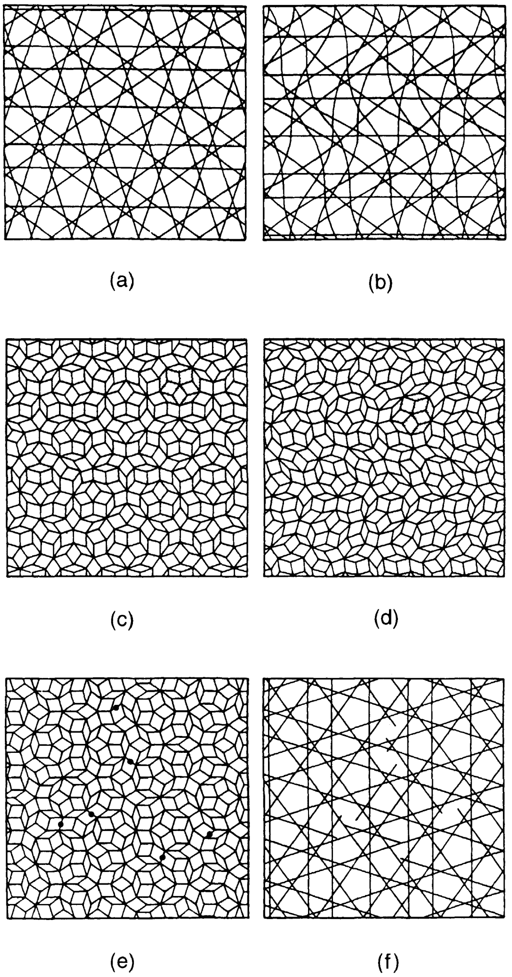

FIG. 32. Pentagrids corresponding to (a) perfect and (b) phonon-strained quasicrystals, and (c), (d) their respective Penrose tilings. Penrose-matching rules are violated (filled circles) in phason-strained tiling in (e), and the corresponding pentagrid displays jags in the pattern. (Courtesy of J. E. S. Socolar and P. J. Steinhardt.)

monly observed in early quasicrystals. $\mathbf{u}_{\text{par}}$ and $\mathbf{u}_{\text{perp}}$ are also referred to as $\mathbf{u}$ and $\mathbf{w}$, respectively.

5.2 Dislocations

Another defect that occurs in quasicrystals is the dislocation. Similar to the case of crystals, dislocations in quasicrystals are characterized by Burgers vectors. The Burgers vector $\mathbf{b}$ of a quasicrystal is, however, an n-dimensional vector (e.g., $n = 6$ for icosahedral quasicrystal). The well-known expression for crystals,

$$\mathbf{G}\cdot\mathbf{b} = 2\pi m,$$

where m is an integer, is modified for quasicrystals as

$$\mathbf{G}_{\text{par}}\cdot\{\mathbf{u}(2\pi) - \mathbf{u}(0)\} + \mathbf{G}_{\text{perp}}\cdot\{\mathbf{w}(2\pi) - \mathbf{w}(0)\} = 2\pi m.$$

Dislocations in quasicrystals have both phonon and phason contributions to the strain field. Figure 33 shows a dislocation on a two-dimensional Penrose lattice and its corresponding pentagrid.

6. PROPERTIES

6.1 Electronic

The charge-transport mechanism in crystals is closely related to the periodicity of the system. Here, the energy band concept and the Bloch theorem are all developed to treat the case of long-range periodic order. The electronic states of a crystal are extended in real space, meaning that charge carriers at the Fermi level ideally can travel freely throughout the system. For a quasicrystal, the potential energy is no longer periodic but has a dense set of Fourier components defined by peaks in reciprocal space. This translates into a dense set of energy gaps at all values of energies. Overall electrical conductivity is expected to be low. Experimentally, measured resistivities increase dramatically with the improved perfection of

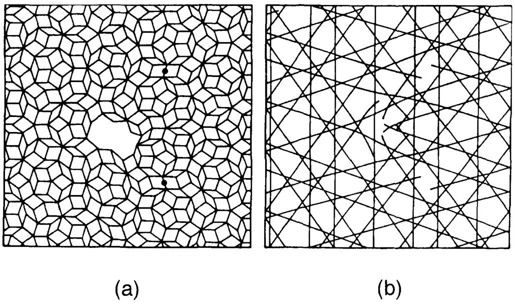

FIG. 33. (a) A dislocation in a Penrose tiling and (b) its corresponding pentagrid.

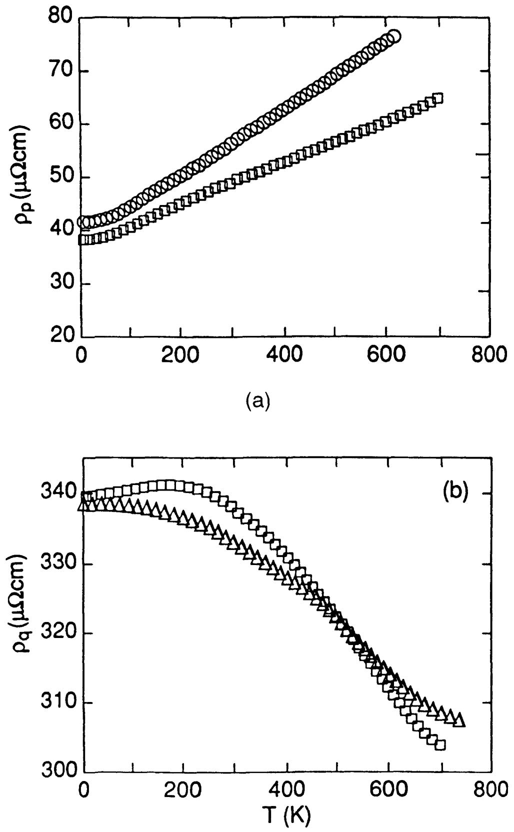
quasicrystals. Good quasicrystals are found to be marginally metallic with resistivities as high as 30 000 $\mu\Omega$ cm. Figure 34 illustrates measured resistivities of $Al_{65}Cu_{15}Co_{20}$ and $Al_{70}Ni_{15}Co_{15}$ single-grain decagonal samples. Since these samples have both periodic and quasiperiodic directions, it is possible to make valuable structure-related comparisons on the same sample. The temperature dependence of the resistivities demonstrates that along the periodic direction, conduction is metallic, whereas along the quasiperiodic direction, it is nonmetallic, and a phonon-assisted mechanism is suggested. The resistivity ratio of periodic to quasiperiodic directions is about a factor of 8.



(a)

(b)

FIG. 34. Temperature dependence of the resistivities (a) along the periodic direction are different in character compared to (b) the quasiperiodic direction, for Al-Cu-Co (circles) and Al-Ni-Co (squares) decagonal quasicrystals. (Courtesy of S. Martin.)

6.2 Magnetic

Magnetism in solids is related to the splitting of the *f* and *d* energy levels under the crystal-field symmetry. Since quasicrystals are more isotropic in symmetry compared to crystals, splitting is expected to be small. Experimentally, icosahedral quasicrystals display magnetic behavior ranging from weak paramagnetism to weak diamagnetism. Good quasicrystals, however, exhibit a weakly diamagnetic behavior. This can be understood by the reduced number of conduction electrons, which give rise to paramagnetism. The observed diamagnetism may then be mainly due to core electrons and the cyclotron motion of the conduction electrons, which may become significant in quasicrystals.

7. SUMMARY

Quasicrystals are an unusual form of condensed matter with a long-range quasiperiodic order and a long-range orientational order. Discovered only a decade ago in an unstable form in Al-Mn alloys, quasicrystals are now being discovered in many different systems, some in stable form and some with structural perfections rivaled only by crystals. Remarkable progress has also been made in understanding the structure, growth, and properties of quasicrystals, but there still remain many important issues unanswered or unexplored. In this article, we introduced some of the basic features of quasicrystals including their quasicrystalline structure modeling, generation and growth models, real quasicrystals, and some properties. For a comprehensive treatment of the subject, readers are referred to the books listed below.

GLOSSARY

Ammann Quasilattice: An ordered quasilattice, with a long-range aperiodic translational order, generated by matching segments of straight lines that decorate the Penrose tiles.

Fibonacci Sequence: A one-dimensional and self-similar aperiodic sequence.

Frank–Kasper Phases: Crystalline phases with an extensive icosahedral local order.

Penrose Lattice: A special kind of quasiperiodic lattice with a perfect long-range orientational and a long-range aperiodic translational order.

Penrose Tiles: A pair of fat and thin rhombic tiles, which are the basic building blocks of a Penrose lattice.

Quasicrystal: A newly discovered form of condensed matter that has a long-range orientational order, an aperiodic translational order, and a noncrystallographic space group.

INTRODUCTION

Radar is an active electromagnetic sensor that operates at a wavelength within the 1-mm to 100-m range to provide detection and measurements of the location, radial velocity, size, and orientation of one or more objects. Objects or targets of interest include aircraft, missiles, satellites, space debris, ground vehicles, weather, planetary surfaces, humans, and animals. Operating nearly independently of the measurement environment, the radar is the source of energy for transmission and the receiver of energy reflected from scatterers, including the objects of interest and associated objects. Radar utilizes either pulsed wave forms or continuous wave (cw) and operates at average powers between a few milliwatts and several megawatts, with sensitivities on the order of picowatts. The radar achieves its maximum probability of detection in the presence of noise by processing the received return signal through a matched filter. In order to achieve high–measurement-accuracy estimates of target location, radial velocity, orientation, or radar cross section, the radar must isolate or resolve the desired object or target from other objects. To accomplish this resolution, the radar utilizes directive antennas to achieve angle resolution, wave-form bandwidth to achieve range resolution, and

observation time to achieve Doppler-shift resolution. Linear interpolations within the resolution cell boundaries provide measurement estimates of the target in position and radial velocity with respect to the resolution cell that are an order of magnitude improvement over the resolution capability, depending on the signal-to-noise ratio. Algorithms that use the measured characteristics of targets can provide highly useful radar imagery, particularly in terms of planetary surface mapping.

The original basic function of radar was to provide target detection, location, and velocity. Radar applications now include land, sea, and air vehicular control; space object and debris tracking; weapon-systems fire control; remote sensing of the Earth and other planets; and security surveillance. Research has also been directed to the phase, amplitude, and polarization measurements involved in target classification and identification. Radar has been highly successful in its roles of detection, metric measurements, and remote sensing, but less successful for object classification and identification.

The function of detection is accomplished by the controlled transmission of electromagnetic (EM) energy and reception of target-reflected energy that exceeds pre-established thresholds. These thresholds may be applied to amplitude, phase, range, angle, Doppler frequency shift, or polarization, or combinations thereof. The thresholds are set to reduce the number of false detections caused by noise, other targets, or background reflectors (clutter). False detections represent wasted expenditure of radar time and energy and overload of operator and data-processing resources. Therefore, false detections may limit the number of targets on which a radar can perform measurements.

Target angular location referenced to the radar is accomplished through the directivity of the antenna. Target radial velocity may be determined by the Doppler shift of the EM wave. Target range may be measured through the time difference between the transmission and reception of a modulated EM signal. Amplitude measurements of the EM signal give a measure of the target radar cross section (RCS). Sequential measurements of amplitude and phase, the latter with respect to the transmitted signal, can provide estimates of target size, orientation, and radial velocity. Polarization measurements, in combination with amplitude and phase measurements, can provide data for target classification and identification.

There is no single figure of merit for radar performance, because radars are used in so many different applications. The hydrometeor clutter that may limit an air-route surveillance radar in its search for aircraft targets is the target of interest for weather radar. The resolution and measurement capabilities of a radar determine its performance in its particular application. The resolution capability indicates the degree to which the radar measurements of the desired target are independent of other targets and clutter. Its metric measurement capability may be defined in terms of range, angle, and Doppler-shift accuracy for functional applications, or in terms of amplitude, phase, and polarization accuracy for phenomenology measurements.

This article begins with a brief history of the development of radar in Sec. 1. The radar equation is introduced in Sec. 2 as the vehicle through which a systematic approach to the theories used in radar can be developed, including resolution, radar cross section, detection, measurement, and electromagnetic interference. Radar system design is considered in Sec. 3, which includes discussions of each of the subsystems and the technology involved. A few of the broader applications of radar are discussed in Sec. 4.

1. HISTORY

In 1886, Hertz sought to verify Maxwell's electromagnetic theories, utilizing hardware components that are functionally identical with the radars of today. With a spark-gap transmitter operating at microwave frequencies, directive antennas, a target reflector, and a spark-gap detector, he experimentally demonstrated that electromagnetic waves would be scattered by metallic and dielectric objects in the propagation path (Hertz, 1900). Tesla recognized in 1889 that electromagnetic waves had the capability to provide location and through their use "may determine the relative position or course of a moving object, such as a vessel at sea, the distance traveled by same, or its speed."

In 1904, Christian Hülsmeyer of Germany, in his English patent No. 13 170, stated, "My invention is based upon the property of electric waves of being reflected back towards their source on meeting a metallic body, and will be readily understood by imagining a transmitting and a receiving station such as indicated placed side by side at the same point and so arranged that waves projected from the transmitter can only actuate the receiver by being reflected from some metallic body, which, at sea, would presumably be another ship" (Hülsmeyer, 1904).

Though Hülsmeyer experimentally demonstrated the concept, the maximum detection range obtained was less than one mile. Since one could see further than that, it was concluded that his system had little practical value. In 1922, however, Marconi took up the subject and stated in similar language to Hülsmeyer, "It seems to me that it should be possible to design apparatus by means of which a ship could radiate or project a divergent beam of these rays in any desired direction, which rays, if coming across a metallic object, such as another steamer or ship, would be reflected back to a receiver screened from the local transmitter on the sending ship, and thereby immediately reveal the presence and bearing of the other ship in fog or thick weather" (Marconi, 1922).

During that and the next decade, France, Germany, Great Britain, Holland, Italy, Japan, Russia, and the United States proceeded independently in the development of systems for radio location. Though the initial effort proceeded at a modest pace, the specter of war led to increased emphasis during the latter part of the 1930s. The direction of these later efforts and those during World War II was toward specific applications, including initial warning of aircraft attacks, vectoring of interceptor aircraft, and gunlaying. Airborne radar systems were developed for interceptor aircraft and for ground mapping. Ground-based radar systems were developed for landing aircraft in inclement weather (Swords, 1986).

It was in 1940 that the code name "radar" as an acronym for "Radio Detection And Ranging" was suggested by officers in the United States Navy and became widely accepted. The intense research, development, and production effort put forth in World War II produced results that otherwise might have taken a number of decades. It established a base of theory, technology, and applications that has stood up remarkably well over the succeeding half-century. Radar use in the defense of Great Britain and its use in naval battles established its importance. Radar landing systems for aircraft enabled the breaking of the Berlin blockade in the early 1950s (Guerlac, 1987).

Military development was the primary driver of radar technology and still is today. Commercial radar has been a key factor in air traffic control and in weather observations and prediction. Radar speed-detection systems have provided a degree of vehicle control on the highways. Radar astronomy was used for generating planetary imagery a number of years before space platforms carrying on-board radar provided mapping capabilities of distant planets and satellites. Maps of the Earth's surface from radars aboard aircraft and orbiting satellites provide daily information of environmental conditions on Earth.

2. PHYSICAL AND TECHNICAL PRINCIPLES OF RADAR

Radar involves a number of technologies based on detection, scattering, measurement, and propagation theories as well as the instrumentation for antennas, transmitters, signal processing, and data processing. The control of the instrumentation is another subject, as is the processing of the reflected signal and the data resulting from the metric and phenomenological measurements with the radar. The *radar equation* is used to discuss radar principles in a systematic manner, and each element of the equation must be addressed to understand radar theory.

2.1 Radar Equation

The basic analytical tool utilized to estimate the detection performance of a particular radar or radar design is the equation

$$\frac{S}{N} = \frac{P_t \tau \eta_t A_t \eta_r A_r \sigma}{4\pi R^4 \lambda^2 k T_s L_t L_r L_p L_{sp} L_o}, \qquad (1)$$

where S = signal power, N = noise power, P_t = peak power of transmitter, τ = transmitted pulse length, η_t = transmitting-aperture illumination efficiency, A_t = transmitting-aperture area (scan-angle dependent in phased-array radars), η_r = receiving-aperture illumination efficiency, A_r = receiving-aperture area (scan-angle dependent in phased-array radars), σ = radar cross section (RCS) of target (the mean or median of a statistical distribution describing target size), R = range of target, λ = wavelength of operation, k = Boltzmann's constant (1.38×10^{-23} J K^{-1}), T_s = system noise temperature (includes Ohmic receiving losses), L_t = Ohmic and non-Ohmic transmission losses between transmitter and antenna face, L_r = non-Ohmic receiving losses between antenna face and receiver including mismatches in impedances, L_p = propagation losses—multipath interference and attenuation (two-way), L_{sp} = signal-processing losses, and L_o = other losses.

The single-pulse signal-to-noise (*S*/*N*) ratio expressed in this equation is the value at the input to the detector. The major component of the noise represented by kT_s is noise internally generated by circuit elements in the receiving channel of the radar. The detrimental effects of all noise components on target detection and tracking are expressed by the inclusion of temperature components [T_a representing the external noise received by the antenna, T_r from the radio frequency (rf) plumbing, and T_e from the receiver] in the equation for system input temperature,

$$T_s = T_a + T_r + L_r T_e = T_a + T_p(L_r - 1) + L_r T_o(F_n - 1), \qquad (2)$$

where T_p is the physical temperature of the rf components, L_r is the loss in the rf components between the receiver and the antenna face, T_o is the reference temperature, 290 K, and F_n is the receiver noise figure.

There are a number of variants for the radar equation that take into account the integration of a number of single pulses that take place before detection and other losses including beam shape, i.e., the target off-center of the radar beam, or the receiving channel filters not being an optimum match to the received signal. Other variants of Eq. (1) can also be used to estimate radar performance in the presence of clutter [signal-to-clutter (*S*/*C*) ratio] and man-made interference, such as jamming [signal-to-jamming (*S*/*J*) ratio], if they rather than noise are the limiting factors (Nathanson, 1991). In general, the limitation of radar performance in clutter is a function of the noise in the radar transmitted signal, the phase stability (pulse to pulse) or coherence of the radar, the propagation path, and the clutter. The limitation in external jamming interference into the antenna main beam, as opposed to antenna sidelobes, is the energy available from the radar transmitter for target illumination.

2.2 Radar Block Diagram

A simple block diagram of a monostatic radar system, which uses a common antenna for transmission and reception, is shown in Fig. 1. Most radars built today follow this basic configuration whether they are simple or complex systems. Bistatic systems or multistatic systems that have separate transmitting and receiving systems are used where isolation between the transmitting and receiving antennas is required to reduce electromagnetic coupling or to perform interferometer measurements. Monostatic or bistatic systems may operate with either pulsed or continuous electromagnetic (EM) waves. The angular location of an object is achieved through the directivity of the antenna, whereas the object's range is determined through the time difference between transmission and reception of a modulated segment of the electromagnetic wave (pulsed or cw). Radial velocity of the object is determined by the Doppler shift of the EM wave or the differentiation of range with respect to time.

The control subsystem directs the antenna toward the desired position and then initiates the generation of a wave form of a single pulse or multiple pulses by an exciter. This wave form modulates the output of the transmitter. The duplexer directs the transmitter output energy to the antenna, isolating the high power from the sensitive circuits of the receiver. After reflection from a target, the EM wave is intercepted by the antenna and passed through the duplexer to the receiver. The duplexer may transfer megawatts of rf energy from the transmitter to the antenna, but it transfers only picowatts from the antenna to the receiver, thus

protecting the receiver from burnout. The receiver provides the initial amplification of the signal return from a scatterer or target, a down-conversion from rf to a lower intermediate frequency (IF) to obtain high amplification, and bandpass filtering to isolate the received signal from rf interference. The front end (input) components of the receiver are a major source of the noise in the system, and much of the design effort goes into minimization of that noise.

The receiver or the signal processor may have a matched filter, i.e., a filter whose transfer characteristic is the Fourier transform of the complex conjugate of the transmitted wave form, to improve the S/N ratio. If there are n pulses in the waveform, then the matched filter performs a coherent integration that improves the S/N ratio over that of a single pulse by the factor n.

The signal processor, as the name implies, operates on the signal to perform one or more functions including integration, thresholding, detection decisions, and estimations of the position and Doppler shift of the target with respect to a reference. The references for estimates are the angular position of the antenna, the initial time of transmission of the signal from the antenna, and the rf carrier phase or frequency. The estimates are summed with the reference values to give absolute values of position and velocity. The functions of moving-target indication (MTI) and pulsed Doppler processing to derive Doppler shift to resolve the target from the clutter and to improve S/N ratio are performed in the receiver or signal processor. The signal processor may be either analog or digital, or a combination of both. Many modern radars perform an early transition from analog to digital format in order to better preserve phase and amplitude information.

After integration by the pulse-compression, MTI, or pulsed-Doppler filters, the IF signal is rectified by a detector to obtain the envelope (which preserves amplitude only), phase detected by a zero-crossing detector (which preserves phase only), or passed through a coherent detector (which preserves phase and amplitude). Earlier radars utilized the output of the detector to go directly in analog form to a cathode-ray tube display for the operator to make a detection decision, and a number of radars still do. But with the advent of the computer, more radars are digitizing earlier in the receiving channel. The output to both the user and the operator may be in an analog or digital format, or a combination. The data processor first converts the signal information about target presence, location, and velocity into a form suitable for display to an operator or for information to a user, such as an air traffic control or a weapon system. If the data are to be used external to the radar, they are often passed along in unfiltered format rather than filtered by further processing in the data processor. The data processor may be used to establish not only current position but also a trajectory on multiple targets (>200) and then to pass that information to the user. The data processor is also used to develop information to control the radar. This would include the data for decisions as to the next set of wave-form transmissions or the next antenna beam position.

2.3 Resolution, Detection, and Estimation

Radar functions can be divided into three successive stages: resolution, detection, and estimation. Resolution means the extent to which the radar can distinguish between closely spaced objects and can perform measurements of one or more radar parameters, i.e., azimuth and elevation angles, range, or frequency (Doppler shift), for each object. Detection is the process of determining whether the signals corresponding to each resolution cell represent the presence of a target. Estimation is the process of determining a specific target metric characteristic, typically its coordinates in range, angle, or Doppler shift, or the phenomenological characteristics of amplitude, phase, or polarization.

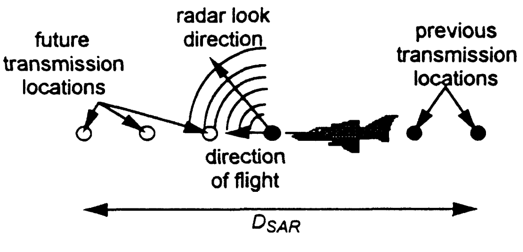
2.3.1 Resolution Radar systems are sometimes characterized by their resolution characteristics. Resolution is the property of radar that enables the separation of the target of interest from other targets and clutter to reduce false alarms in the detection process and to reduce the contamination of estimates in metric or phenomenological measurements. Resolution may be accomplished in terms of the antenna beamwidth for spatial resolution in two orthogonal angles, in terms of signal bandwidth for time resolution in range, and in Doppler shift for radial velocity separation. Polarization resolution occurs naturally in most radars, since most antennas have only a single polarization orientation. Circular polarization and sequential linear orthogonal polarization may be utilized in special cases where phenomenology measurement or target identification is of interest.

The resolution of the system in the two spherical coordinates, such as elevation angle and azimuth angle, is normally determined by the 3-dB beamwidths of the antenna in those planes. The angular resolution determined by the antenna beamwidth is termed the *real aperture* resolution. For an aperture of extent d in the horizontal plane, the corresponding angular resolution δ_θ is approximately λ/d (where λ is the radar wavelength). The corresponding spatial resolution δ_{CR} (often termed *cross-range resolution*) at a range R is

$$\delta_{\mathrm{CR}} \approx \lambda R/d. \tag{3}$$

Similar results are defined for the elevation plane.

For typical radar parameters and scenarios, the cross-range resolution is often much poorer than the range resolution. While acceptable in many applications, this is undesirable in radar imaging or mapping. Finer cross-range resolution can be obtained with the technique of *synthetic aperture radar* (SAR). SAR uses motion of the radar antenna relative to the area being mapped to synthesize an antenna much larger than the real aperture. As shown in Fig. 2, the physical radar antenna of aperture size d is moved from point to point by the platform motion to create a virtual linear array antenna of size D_{SAR}. The physical antenna serves successively as each element of the larger phased array. The received signals at each transmission location are collected and combined coherently in the signal processor to process the data to obtain the same spatial resolution result that would be obtained by using an array antenna whose physical extent matched the total distance traveled, D_{SAR}. The cross-range resolution achieved by a SAR system is inversely proportional to D_{SAR} and is lower bounded by half the physical aperture size (Richards, 1988), i.e.,



radar look direction
future transmission locations
previous transmission locations
direction of flight
D_{SAR}

FIG. 2. Virtual array-antenna generation by platform motion.

$$\delta_{\mathrm{CR,SAR}} \approx d/2. \tag{4}$$

The range resolution δ_R for a simple constant-frequency, constant-amplitude pulse of duration τ is approximately

$$\delta_{\mathrm{R}} \approx c\tau/2, \tag{5}$$

where c is the velocity of propagation. Equation (5) implies that higher resolution requires shorter pulses, but higher resolution can also be obtained by modulating the pulse in a way that increases its bandwidth and using appropriate matched filter signal processing. Phase modulation is used when it is undesirable to reduce transmitted energy by amplitude modulation of the pulse.

Matched filtering of the received phase-modulated pulses is referred to as *pulse compression* processing. The two most common types of phase modulation are *linear frequency modulation* (LFM, or *chirp*) and *biphase coding*. In the former, the instantaneous frequency is swept linearly during the pulse duration; this corresponds to a parabolic variation in phase as a function of time. In the latter, the instantaneous frequency is constant, but the absolute phase is abruptly switched by 180° a number of times within the pulse in a fixed code sequence. If the bandwidth of the modulation function is β, then δ_R will be approximately

$$\delta_{\mathrm{R}} \approx c/2\beta. \tag{6}$$

The corresponding time duration of the modulation function is approximately $1/\beta$, and this can be shorter than the actual transmission pulse length by a factor of 10 to 1000 in many systems. Bandwidths of 100 kHz up to 1 GHz are common and provide

range resolutions of 1.5 km to 0.15 m, respectively.

In nonimaging radars, Doppler-shift filtering may be applied to the received signals to resolve moving targets from stationary clutter or from one another. One form of Doppler filtering is termed *moving-target indication,* or MTI, filtering, and is accomplished by applying high-pass filters to a series of returns from the same spatial resolution cell. The simplest filter is the *two-pulse canceler* shown in Fig. 3 that subtracts successive pulses separated by the interpulse period t_{PRF}. dc signal components due to stationary clutter cancel, while Doppler-shifted components due to moving targets do not.

Pulsed Doppler processing (Fig. 4) passes the signal through a range gate set for a specific range and then sends it in parallel through a bank of bandpass filters each of which is tuned to a different value of Doppler frequency shift. Moving-target signals are passed by the bandpass filter centered nearest their actual Doppler shift. Pulsed Doppler processing is more complex than MTI filtering because it requires multiple filters, but provides more information by resolving multiple moving targets and providing estimates of their radial velocity. Attainable velocity resolution is determined by the observation period on the target (known as the observation time, t_o), which

sets the Doppler frequency resolution at approximately $1/t_o$. The corresponding velocity resolution is $\lambda/2t_o$.

2.3.2 Detection Detection is a term utilized in several ways in the radar literature. One connotation is the initial down-conversion of the radar return at the transmission frequency to a lower frequency (IF) for amplification in the receiver chain. The second is the conversion by a detector from IF to baseband, or video, with no carrier. The second conversion may or may not conserve phase or amplitude information. The third connotation, and the one used here, is that of a test threshold and the decision as to whether a signal from a target is present in the presence of noise, interference, or clutter.

Detection performance is optimized by maximizing the signal-to-noise (S/N) power ratio into the detector that converts from IF to baseband. This occurs when the frequency response $H(\omega)$ of the receiver constitutes a *matched filter* for the transmitted wave-form modulation, $H(\omega) = M^*(\omega)$, where $M^*(\omega)$ is the complex conjugate of the Fourier transform of the transmitted wave-form modulation $m(t)$. When a matched filter is used, the resolution and side-lobe characteristics are determined by the autocorrelation of the wave form and not the wave form itself.

If the matched filter is for a train of pulses, such as a MTI or pulsed Doppler filter, predetector (coherent) integration improves the S/N ratio. Postdetector integration prior to the threshold may also be used to improve the S/N ratio further. The latter integration may be coherent or noncoherent, based on whether both amplitude and phase are preserved by the detector. Coherent integration is generally the more efficient, with the S/N ratio improving by the number of pulses integrated, whereas noncoherent integration improvement is proportional to a factor within the range $n^{0.5}$ to $n^{0.8}$. The pulse repetition frequency (PRF) and target dynamics may also limit the number of pulses that can be integrated effectively.

After translation of the intermediate-frequency (IF) signal to video or baseband, a detection decision is made. The criterion for detection or the test to determine whether a target is present in the presence of noise or clutter can be as simple as determining whether an amplitude or phase threshold is crossed by the signal after it is processed by the detector and integrator. Since there is a probability that a noise signal alone could cross the threshold, the threshold is set high enough to limit the number of noise crossings in a specified interval. If the threshold is set too high, there will be many missed targets. If the threshold is set too low, noise crossings can overload operators or automatic detection systems. There is a considerable body of literature in the radar field on detection theory (Nathanson, 1991).

An amplitude threshold for a single pulse repetition interval can be selected to maintain a fixed probability of false alarm P_{fa} from thermal noise, i.e.,

$$P_{\text{fa}} = \exp(-V_T^2/2\varphi_0), \tag{7}$$

where V_T is the threshold setting, and φ_0 is the mean square value of the noise voltage into the detector in the receiver (Skolnik, 1980). Typical values of P_{fa} range from 10^{-8} to 10^{-2}, depending on the system type and interference statistics. The threshold is a function of the interference power and statistics, and these are rarely known *a priori* with sufficient accuracy. For this reason, the threshold used to test a given resolution cell may be estimated from the signal power values in adjoining cells under the assumption that they represent interference only. This idea is illustrated in Fig. 5. A measured value of received power is associated with each range resolution cell. The power values measured in a few range cells to either side of the test cell (representing echoes received from ranges nearer and farther than the test cell) are averaged to estimate the mean interference level. A threshold is then set based on this estimated interference level, the assumed probability density function (pdf) of the interference power, and the desired P_{fa}. If the power in the test cell exceeds the threshold, a target is declared. Though this constant false alarm rate (CFAR) threshold scheme is used in some radar systems, there are other thresholding techniques.

The probability of detection P_d for a detection threshold of V_T is

$$P_d = \int_{V_T}^{\infty} P_s(R_j)\,dR_j, \tag{8}$$

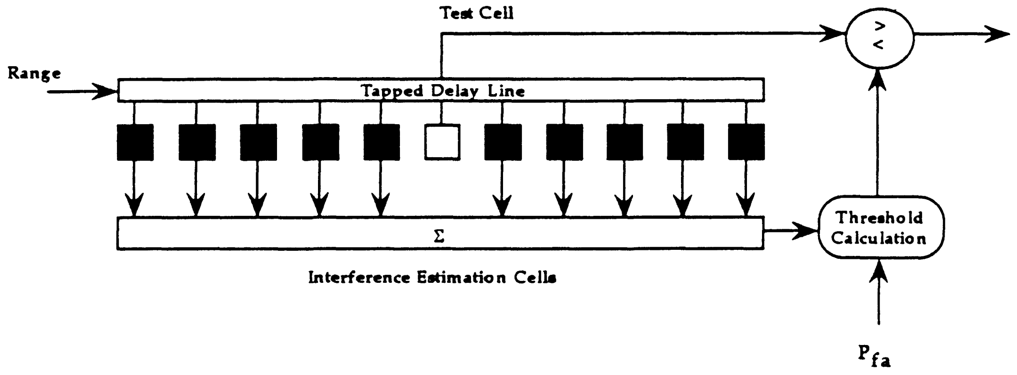

FIG. 5. Threshold for constant false-alarm rate (CFAR).

where $P_s(R_j)$ is the joint probability density function of signal and noise. The trade-off between the false alarm probability of Eq. (7) and detection probability of Eq. (8) is accomplished through the threshold setting.

2.3.3 Estimation Once a target is detected, the data in the resolution cell may be interpolated to obtain better estimates of the target position or radial velocity within the resolution cell. If a target peak is observed in resolution cell n, then a quadratic curve is fitted through the data in cells $n - 1$, n, and $n + 1$. The fractional cell location and amplitude of the peak of the quadratic can be found in terms of the three data samples, yielding an estimate of range or Doppler shift with a precision of a fraction of the resolution cell size. Though the angle can be estimated by use of such a technique, a monopulse antenna is often used to obtain high-precision angular coordinate measurements.

Monopulse is a radar technique in which the angular location of a source or target is obtained by comparison of signals received in two or more simultaneous beams that are identical but are pointed at slightly different directions and have a common volume containing the target. The simultaneity of the beams enables a single-pulse, i.e., monopulse, estimate of angle as an alternative to beam switching or conical scanning that require two or more pulses. The difference (Δ) signal is generated by taking the difference of the signals received in the two beams, and the sum (Σ) signal is generated by adding the signals received in the two beams. The plane defining the contour for equal amplitudes between the two beams is the boresight direction, or axis, where the difference signal approaches zero and the sum signal is maximized. The magnitude and phase of the ratio Δ/Σ off axis is an indicator of the angular position of the target with respect to the boresight axis. The normalization of the difference signal by the sum signal makes the estimate independent of target fluctuations in size. The detector of the signal is often a dot or cross product, with the magnitude V_e of the voltage out being

$$V_e = \mathrm{Re}(\mathbf{\Delta} \cdot \mathbf{\Sigma}/|\Sigma|^2). \qquad (9)$$

Four overlapping beams arranged in a quadrant can provide the range and the two orthogonal angle estimates simultaneously, with one transmitted pulse. Doppler shift and target size may also be obtained. The primary objective of monopulse is to minimize angle error due to target-signal amplitude fluctuations between successive pulses, which occurs when time-sequential or conical scanning beams were used.

The standard deviation σ_e of the estimated target position in a range, angle, or Doppler shift depends on the resolution δ in the same coordinate and the S/N ratio, and is given by

$$\sigma_e \approx k \frac{\delta}{\sqrt{S/N}}, \qquad (10)$$

where the proportionality constant k is typically in the range of 0.5 to 2.0. For a typical $S/N = 100$ (or 20 dB) for a detected target, the measurement error is approximately one-fifth to one-twentieth of a resolution cell.

2.4 Radar Cross Section

2.4.1 Targets The radar cross section (RCS) parameter σ in Eq. (1) is a transfer function that quantitatively relates the transmitted power incident on the target to that backscattered by the target into the radar antenna. Radar cross section is a characteristic of the target alone (at a particular radar frequency and polarization) at a particular target aspect.

The fact that radar cross section is a characteristic of a target and not its environment implies that the target is in the *far field* of the radar antenna and that the electromagnetic wave fronts incident on the target are, for all practical purposes, planar. This fact is implicit in the theoretical definition of radar cross section,

$$\sigma = \lim_{R\to\infty} 4\pi R^2 \, |E_r^2/E_i^2|, \tag{11}$$

where E_r = electric field magnitude at the radar receiver, E_i = electric field magnitude incident at the target.

The components of the received electric field vector $\mathbf{E}_r$ may be related to the components of the transmitted electric field vector $\mathbf{E}_t$ by the equation

$$\begin{bmatrix} E_h^r \\ E_v^r \end{bmatrix} = \begin{bmatrix} a_{hh} & a_{vh} \\ a_{hv} & a_{vv} \end{bmatrix} \begin{bmatrix} E_h^t \\ E_v^t \end{bmatrix}, \tag{12}$$

where the first subscript of the components of the polarization matrix denotes the transmitted polarization, and the second subscript denotes the received polarization. The symbols h and v are used, for example, for horizontal and vertical polarization in this equation. The matrix

$$\begin{bmatrix} a_{hh} & a_{vh} \\ a_{hv} & a_{vv} \end{bmatrix}$$

is called the full polarization scattering matrix and contains all of the information reflected from a target for a particular radar frequency, target orientation, and polarization vector basis set. The parameters a_{xy} are complex valued and can be related to the appropriate RCS parameters by the expression

$$a_{xy} = \sqrt{\sigma_{xy}} \exp(j\varphi_{xy}). \tag{13}$$

The polarization, i.e., the locus of the tip of the electric field vector over time, of the radar signal, as an electromagnetic wave, may be linear, circular, or in its most general form, elliptical. In the radar literature, circular polarization is defined as either right-hand or left-hand circular looking *in the direction* of energy propagation. The physics convention looks *into* the direction of energy propagation. Many radars, however, use linear polarization for transmission and reception, with circular polarization and sequential linear polarization being used for phenomenology measurements.

There are three very distinct regions for the general wavelength dependence of the RCS of an object, of which the perfectly conducting sphere may be considered representative. At low frequencies, where the radar wavelength is much greater than the sphere's circumference (the Rayleigh region, where $2\pi a/\lambda \ll 1$), the sphere's RCS varies proportionately to $(ka)^4$, where k is the wave number. Likewise, where the radar wavelength is much smaller than the sphere's circumference (the optical region, where $2\pi a/\lambda \gg 10$), the sphere's RCS is essentially wavelength independent and asymptotically approaches a value of πa^2, its geometric cross section. In between these two frequency regions (the Mie region, where $1 \ll 2\pi a/\lambda \ll 10$), the sphere's RCS oscillates about its geometric cross-section value, as a function of frequency. This oscillatory character is the result of the constructive or destructive interference of the specular radar reflection from the "front" of the sphere with the radar wave that "creeps" around the shadowed side of the sphere.

In reality, the radar cross section of an object must be described statistically, because it varies with target aspect angle. The composite radar cross section is the coherent summation of the cross sections of all the scattering centers of the target. Relative motion among the scatterers that results in differential displacement of a factor of a wavelength along the radar line of sight can result in significant radar cross-section variation. The classic statistical models that are used to define target radar cross sections have been based on

1. the reflectivity characteristics of the scattering centers on the target that is assumed to be completely illuminated by the radar, and
2. the temporal decorrelation characteristics.

Swerling (1960) defined four target models, which have since been referred to as Swerling Cases 1–4. Case 1 assumes a Rayleigh distribution function for target backscatter voltage and a slow temporal dependency, i.e., significant backscatter changes only on a scan-to-scan basis. The target radar cross section for Case 1 will be characterized by the probability density function $p(\sigma)$ defined as

$$p(\sigma) = (1/\bar{\sigma})e^{-\sigma/\bar{\sigma}}, \tag{14}$$

where $\bar{\sigma}$ is the average radar cross section. Case 2 assumes the same distribution function but a rapid signal decorrelation, i.e., significant backscatter changes on a pulse-to-pulse basis. Case 3 assumes the probability density function

$$p(\sigma) = (4\sigma/\bar{\sigma}^2)e^{-2\sigma/\bar{\sigma}} \tag{15}$$

and a slow temporal dependency. Case 4 assumes the latter distribution function but a rapid signal decorrelation. Occasionally, one also refers to a Swerling 0 target model, for the case of the nonfluctuating, target backscatter signal.

The probability density function of Eq. (14) corresponds to a target having numerous, small, statistically independent scattering centers. Many aircraft and large targets present this type of probability density function for radar cross-section characteristics. The probability density function of Eq. (15) corresponds to a target having one dominant scatterer and many smaller, independent scatterers. Small, streamlined aircraft can have distribution functions of this nature at the lower radar frequencies. The Swerling target cases corresponding to rapid signal decorrelation can be produced by radar systems that change transmitted frequency on a pulse-to-pulse basis. The four Swerling models are special cases of the chi-square distribution. The Rice and the log normal are also two density functions often used to describe the radar cross section of targets. These probability density functions must be combined with the probability density function of the type of detector used in order to determine the probability of detection.

2.4.2 Clutter Land- and sea-surface backscatter is characterized by σ^0, the radar reflectivity per unit area illuminated by the radar, or

$$\sigma^0 = \sigma/A, \tag{16}$$

where σ is the radar cross section of the illuminated area, and A is the illuminated area of the sea surface or ground. The illuminated area A should be reduced by a beam-shape factor of 1.33, due to a Gaussian rather than a rectangular beam shape. By convention, σ^0 is shown in superscript form and is usually specified as *sigma zero* or *sigma naught.* The parameter σ^0 is a complex function of

1. the radar's frequency and polarization;
2. the surface's roughness, tilt variation, and content; and
3. the geometry between the radar line of sight and the local surface normal.

For example, ground reflectivity depends on the soil makeup, water content, roughness, tilt variation, snow cover, and foliage cover, among other factors. Sea reflectivity will depend on the average wave height, wind speed and direction, and wave direction.

The shape of the instantaneously illuminated area on the surface can be a function of the incidence angle to the surface, the radar pulse length, and the radar antenna elevation and azimuthal beamwidths. The illuminated area is either elliptical or rectangular, depending on whether or not the vertical projection of the pulse length onto the surface is greater than the footprint range extent of the elevation beamwidth on the surface. At a high incidence angle that might be characteristic of an air-to-ground geometry, the reflecting surface area is an ellipse, for pulse-length projections that are larger than the footprint range extent. At a lower incidence angle that might be characteristic of a ground-to-ground geometry, where the pulse-length projection is usually less than the footprint range extent, the reflecting surface is essentially rectangular, with a width determined by the azimuthal extent of the antenna beamwidth and a length determined by the vertical projection of the pulse length.

Volumetric backscatter, such as from rain, is conventionally quantified by the parameter η that represents the radar cross section per unit volume of the scattering material. The volume of the resolution cell is defined by antenna patterns in azimuth and in elevation and by the range resolution $c\tau/2$. If the radar antenna has a pencil beam pattern, the azimuth and elevation beamwidths, defined by the 3-dB points of the beam pattern, will determine the extent of the resolution cell in the vertical and horizontal dimensions. If the azimuth and elevation beamwidths are given by θ_{az} and θ_{el}, respectively, the resolution cell cylinder will have diameters of just $R\theta_{az}$ and $R\theta_{el}$, respectively, where R is the range to the resolution cell. The range extent of the resolution cell will be simply $c\tau/2$, and the volume V of the cylinder is

$$V = [R^2\theta_{el}\theta_{az}][c\tau/2]. \tag{17}$$

The value of the normalized backscatter parameter η is then just σ/V, where σ is the actual *measured* radar cross section of the clutter within the resolution volume. The illuminated volume should be reduced by a beam-shape factor of 1.77, due to a Gaussian rather than a rectangular beam shape.

2.5 Propagation Theory

2.5.1 Attenuation In the radar equation, the propagation loss is composed of two factors: the absorption attenuation of energy (transformation to heat) and the reradiation (scattering) of energy over the entire 4π-sr volume (forward scattering and backscattering). The sum of the two effects represents the total loss of signal energy and is termed *signal extinction.* The signal extinction is taken from the optical and infrared research community and is equivalent to the radar engineering term *signal attenuation,* which does not differentiate by signal loss process.

The nomenclature of the radar engineering community will be used here, where the appropriate terminology is signal attenuation, and the conventional attenuation symbol is α (measured in dB/km). The component of the loss L_p in Eq. (1) due to both absorption and scattering processes is designated L_{att} and is quantified by the one-way signal attenuation α', expressed in nepers per meter (Np/m), assumed to be constant over the entire range extent. When the attenuation is not uniform over the entire range extent, the total, two-way attenuation loss L_{att} is found by integration over the range extent of the lossy medium:

$$L_{att} = \exp\left[-2\int_{\text{near}}^{\text{far}} \alpha'(R)dR\right]. \tag{18}$$

The propagation loss is conventionally depicted in logarithmic form, and the median loss of $10\log L_{att}$, in decibel (dB) units, is expressed as

$$\begin{aligned} 10\log L_{att} &= 10|\log e^{-2R\alpha'}| \\ &= 4.343|2R\alpha'| = 2R\alpha/1000, \end{aligned} \tag{19}$$

where the attenuation factor α has units of decibels per kilometer.

The most often encountered source of propagation loss is rain. Rain attenuation coefficient data have been empirically modeled in both the microwave and the millimeter wave regions as a two-parameter monomial

$$\alpha = AR^B, \tag{20}$$

where α is in dB/km, R is the rainfall rate in mm/h, and A and B are taken from Table 1.

2.5.2 Multipath Interference When the radar antenna beam is pointed toward a target at a low incidence angle to the surface, the radar signal may follow four different two-way paths, as shown in Fig. 6. The energy may follow a direct-direct, direct-indirect, indirect-direct, or indirect-indirect path between the radar antenna, the target, and the radar antenna again. The constructive or destructive interference among these signals at the receiving radar antenna gives rise to a lobing effect in received target backscatter signal, shown in Fig. 7. This form of the pattern is developed when the reflection coefficient is unity and the elevation beamwidth of the antenna has equal gains along the direct and indirect paths.

For a target altitude h_t much greater than

Table 1. Predicted rainfall attenuation coefficients as a function of rainfall rate (Adapted from Currie, Dyer, and Hayes, 1975).

	α(dB/km) = AR^B			
	10 GHz	35 GHz	70 GHz	95 GHz
R (mm/h)	$A = 0.009$ $B = 1.16$	$A = 0.273$ $B = 0.985$	$A = 0.634$ $B = 0.868$	$A = 1.6$ $B = 0.64$
5	0.05	1.33	2.56	4.48
10	0.13	2.64	4.68	5.98
15	0.21	3.93	6.65	9.05
20	0.30	5.22	8.54	10.88
25	0.39	6.50	10.36	12.55

radar altitude h_a, the first interference lobe will occur at an elevation angle of approximately $\lambda/4h_a$ radians. This loss L_m component of L_p is given by

$$L_m = \frac{1}{16}\csc^4\left(\frac{2\pi h_a h_t}{\lambda R}\right). \tag{21}$$

2.5.3 Refraction Index-of-refraction nonhomogenieties within the propagation medium may significantly affect the path of an electromagnetic wave. The radar beam may bend such that an incorrect (high) elevation angle and an incorrect (long) range to the target are indicated. The primary physical source for this effect is the exponential variation of the refractive index n of the atmosphere with altitude. It is convenient for radar applications to define the refractivity N as

$$N = (n - 1)10^6. \tag{22}$$

The refractivity as a function of radius r from Earth center is

$$N = N_s \exp\left(-\frac{\Delta N}{N_s}(r - r_s)\right), \tag{23}$$

where N_s is the refractivity at the Earth's surface (radius $r = r_s$).

The limiting angle $\Delta\Theta$ through which the radar beam is bent, at elevation angles $\Theta > \pi/12$ and for targets well beyond the atmosphere, may be approximated by

$$\Delta\Theta = N_s \cot\Theta \times 10^{-6}. \tag{24}$$

The corresponding limiting range error may be approximated by

$$\Delta R = 0.007\, N_s \csc\Theta. \tag{25}$$

This refractive effect will result in incorrect tracking of an airborne target, both in elevation angle Θ and in range R (Barton, 1988).

Superrefraction will occur when there exists a rapid decrease in refractive index with altitude, such as might be caused by a temperature inversion or a high humidity gradient. The radar beam becomes trapped in this *duct* in a manner not unlike an electromagnetic wave confined within a waveguide structure.

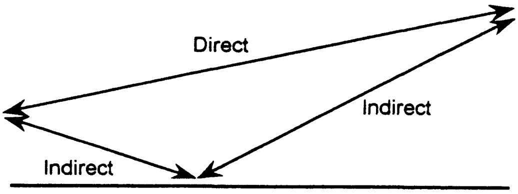

FIG. 6. Direct-direct, direct-indirect, indirect-direct, and indirect-indirect signal paths.

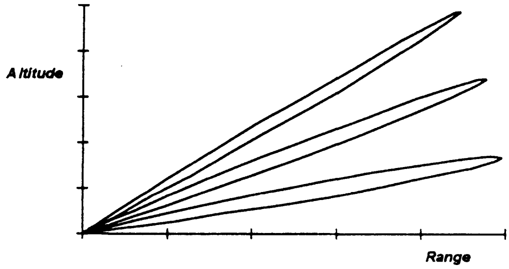

FIG. 7. Multipath interference lobing structure.

2.6 Electromagnetic Interference

2.6.1 Natural Interference Sources of naturally occurring signals that interfere with proper radar operation include

1. those external to the radar that enter through the antenna or other components and
2. noise signals generated by the radar receiver itself, as discussed under system temperature.

Examples of the former include solar and galactic noise as well as that due to Earth surface temperature. These enter through both the main lobe and sidelobes of the receiving antenna.

2.6.2 Electronic Countermeasures The term *electronic countermeasures* refers to the intentional transmission of electromagnetic signals toward a victim radar to prevent the radar from detecting or tracking a target. The term *jamming* is usually applied to such intentional transmission. The ultimate degrading effect on the victim radar's detection capability may be simply one of a decreased target signal-to-interference ratio within the target cell of resolution, or it may be the complete overload of the radar signal processor through the creation of numerous targetlike signals.

Noise jamming is the most common form of electronic countermeasures. It denies target detection by simply raising the effective noise floor of the victim radar receiver. The quantitative effect is to raise the effective radar system temperature T_s of Eq. (2) by an amount T_j given by

$$T_j = \frac{P_j G_j A_r F_j^2}{4\pi k B_j R_j^2 L_j}, \tag{26}$$

where $P_j G_j$ is the effective radiated power of the jammer, F_j is the directivity of the radar aperture in the direction of the jammer, B_j is the bandwidth of the jammer spectrum within the bandwidth of the radar, R_j is the range to the jammer, and L_j is the one-way propagation loss between the jammer and the radar. The total receiver noise temperature is then the sum of its natural amount T_s and that of the jammer, T_j (Barton *et al.*, 1991).

Common uses of noise jammers include self-protection jamming, where the jamming platform seeks to deny its own detection by the radar, and escort jamming, where the jammer is on a separate platform from the targets whose detection is being degraded. Jamming, however, does provide a signal source that can be tracked in bearing using a *home-on-jam* mode.

A separate type of electronic countermeasures is *deception jamming,* wherein false, targetlike signals are transmitted to the victim radar. These false target signals attempt to capture the radar's range or angle tracking circuits, then suddenly cease. The radar then must attempt to reacquire the true target range and bearing.

3. RADAR DESIGN

3.1 Radar Architecture

Radar design architecture is first driven by the application requirements and then bounded by the technology available. The probability of detection, range and volume to be covered, time to perform the search, and measurement accuracy are direct requirements. Target characteristics, which are statistical, and the electromagnetic and physical environment set the stage in which the radar must perform. The major variables in the radar design are wavelength, transmitter power, and antenna size. The hardware and software technology available and their costs establish another boundary.

The wavelength, antenna area, and transmitter energy are usually the key variables in the design of a radar system. Generally, the search function will require most of the energy, and high-power sources are more readily available at the longer wavelengths. Shorter wavelengths give more precise measurements in angle for a given size aperture. If search and track functions are both performed by a single radar, such as a fire-control phased-array system, there must generally be a compromise in frequency selection. Depending on the application, however, any one of the variables or combinations may be bounded by political treaty, e.g., the energy bound of radiated power for antiballistic missile radars; by the antenna size bounds established by aircraft, spacecraft, or transport vehicles; or by the losses in propagation for the shorter wavelengths. For a new design, there are generally a large number of trade-offs; consequently, an iterative selection process is required. Performed in a systematic manner, the trade-off process can converge to a realistic design.

3.1.1 Search The search function is accomplished by having the radar antenna beam scan a solid angle of Ω_s. If a surface-based search radar with a vertical fan-shaped beam of azimuth width θ_a is being rotated mechanically in azimuth at a rate ω_a and is transmitting at a PRF of f_p, the number of pulses n_p that will strike a target is approximately $n_p\theta_a/\omega_a$ on each scan. Integration of those pulses during each scan by a matched filter will improve the S/N ratio by a factor of n_p, less a beam-shape factor loss due to the target being other than at the antenna beam maximum. If the integrated-signal S/N ratio of the first scan is inadequate initially to pass the threshold required for detection, successive scans provide a cumulative probability of detection, i.e., $P_{dc} = 1 - (1 - P_{d1}) \cdots (1 - P_{ds})$, where P_{ds} is the probability of detection on a single scan. Composite search performance is usually determined by cumulative detection.

Fire-control radars, which have a pencil beam used to perform both search and track, may use a bar scan for search. A full azimuth scan is made for the first bar. At the limit of the scan a step up or down in elevation is made by approximately the antenna beamwidth, and a second azimuth scan is made in the reverse direction of the first. This is continued for several bars to cover the solid angle required. When the solid-angle scan is completed, a repeat of the scan is made, but the bars are repositioned so that the peak of the beams covers the intersection of the beams between the bars on the first solid-angle scan. When the scan is mechanical, its period is comparatively long, i.e., 1–10 s. Electronically scanned phased-array radars that sweep faster may transmit only a single pulse per beamwidth in an azimuth scan, then step down a beamwidth for the next scan, transmitting and receiving where the upper and lower beam positions intersect to form a triangular lattice pattern. A second scan may be performed with the same triangular lattice pattern, but the peaks of the pattern are positioned at the intersection of the three beams of the first scan. Detection is also accomplished through a cumulative process.

Equation (1) may be rewritten to function as a design or evaluation tool for the search and track functions. The energy E_s required of the transmitter for a single-pass search of a solid angle Ω_s, with n_b the number of beams required, i.e., $n_b = \Omega_s/\Omega_t$, is given by

$$E_s = n_b P_t \tau \geq \Omega_s \frac{1}{\eta_r A_r} \frac{(S/N) 4\pi R^4 k T_s L_t L_r L_p L_{sp} L_o}{\sigma}, \tag{27}$$

where the transmitted beam has a solid angle of $\Omega_t = \lambda^2/\eta_t A_t$. The S/N is specified to provide the requisite single-pulse detection probability for the range R and the target RCS. The other values in the equation are functions of the radar implementation. For the condition where the received beam is the same dimension and same direction as the transmitted beam, i.e., $\eta_r A_r = \eta_t A_t$, the time to perform a single-pass search is

$$t_s \geq (\Omega_s/\Omega_t)(2R/c) \tag{28}$$

for nonoverlapping coverage. Where one may be limited in detection capability by the energy available in a single pulse, overlapping coverage may be utilized and detection probability increased through the cumulative process on either a single scan or multiple scans. In such a case, the search time t_s required for a single pass is increased by the number of beams that are used to cover the search volume. The average power required of the transmitter for the search function is E_s/t_s. The average power multiplied by the effective area of the receiving antenna is referred to as the power-aperture product and is sometimes used as a figure of merit for assessing the performance of radars in performing the search function.

The formulation given does not necessarily represent an optimum search strategy for a particular radar. Target cross-section statistics and metric parameters are external constraints. The radar implementation including its average power, sensitivity, mechanically or electrically scanned antenna, and its repertoire of wave forms are internal constraints. Mechanically scanned antennas have a relatively rigid search implementation. The electrically scanned phased array usually has several more degrees of freedom, including a wider repertoire of wave forms and rapid positioning of the antenna beam. Developing an optimum search strategy in either type of radar system is one of the biggest challenges for the designer—particularly in low-*S*/*N* ratio environments (Billetter, 1989).

In the search scan, there is usually a loss in *S*/*N* ratio due to the nonuniform coverage, since the peak of the beam coinciding with target position occurs infrequently. An allowance is made in the radar equation under L_o to account for this beam-shape loss, which may be as high as 1.6 dB in mechanically scanned radars and 6 dB in phased-array radars. The latter value is primarily due to the loss in effective aperture area caused by scan angle. Losses that are incurred in the receiver and signal processor, i.e., L_{sp}, include those where the target is not centered in the filter either in range or in Doppler shift and are known as the range-gate straddle loss and Doppler-filter straddle loss with values in the ranges of 1–4 dB and 0.5–2 dB, respectively. The CFAR detection process results in typically 1.0 dB of loss.

A search radar may also include a track function in the data processor. It is referred to as track-while-scan (TWS). The search mode of a radar effectively determines the presence and current position of a target. If the estimated position of a target from a scan is stored in the data processor, the next scan position estimate enables a velocity vector to be established and a track to be established for that target. No additional energy is required to perform the track function, and the number of tracks is limited only by the data processor. A major challenge in TWS systems with a large target-number capacity is the association of position estimates on a scan-to-scan basis with existing track files and the potential of establishing false tracks. Fan-beam search radars develop tracks in two dimensions, whereas pencil-beam search radars develop three-dimensional tracks.

3.1.2 Track In search radars, the ranging and antenna pointing direction is independent of the target; in tracking radars, they are dependent. The signal from the target is used for range, Doppler-shift, and angle estimates for positioning the time and frequency filters and for pointing the antenna beam to follow the target. The single-pulse random or noise error in the range estimate for a fixed target is

$$\sigma_r = \frac{\eta_w c}{2\beta K_r \sqrt{2(S/N)}}, \tag{29}$$

where η_w is a weighting factor used in the convolution of the signal and the signal processor filter, c is the velocity of light, β is the signal bandwidth, K_r is an interpolation factor, and the *S*/*N* ratio is given by Eq. (1). For angle estimates on a fixed target, the expected error for either axis is

$$\sigma_{\alpha x,\alpha y} = \frac{\lambda / d_{x,y}}{K_{mx,my}\sqrt{2(S/N)}}, \tag{30}$$

where $d_{x,y}$ is the dimension of the antenna in either x or y, and K_m is the monopulse slope with values ranging from 1.0 to 1.8. After substituting Eq. (1) for the *S*/*N* ratio into Eq. (30) for both axes, the energy E_t required for a specified noise error in each axis for an angle measurement is

$$E_t = P_t\tau = \frac{\lambda^4}{A_r^3}\cdot\frac{2\pi R^4 k T_s L_t L_r L_p L_o}{\eta_t \eta_r^2 K_{mx} K_{my} \sigma_{ax}\sigma_{ay}\sigma}. \tag{31}$$

Since range and Doppler estimates are performed at the same time as angle estimates, there is no additional energy requirement. The Doppler-shift estimate error σ_d as limited by white noise is given by

$$\sigma_d = \frac{\eta_d}{t_o K_d \sqrt{2(S/N)}}, \tag{32}$$

where η_d is the weighting factor in the convolution of the received signal and the receiver signal processor filter, t_o is the observation time, and K_d is an interpolation factor.

The total energy required for tracking is dependent on not only the single-pulse estimate requirement but also the number and frequency of samples to provide both current and predicted positions to the required degree of precision. Losses in the tracking radar are generally considerably less than those for a search function. Since the targets are tracked continuously, the peak of the beam is always pointed toward the target, the range and Doppler-shift filters are centered on the target, and CFAR is not required. The wave-form weighting losses discussed in Sec. 3.5 have to be considered for inclusion in the signal-processing loss.

3.2 Transmitters

The variety of available tubes and solid-state rf sources permits a wide range of architecture in radar transmitter design for the more complex radar systems. A modern phased-array radar with thousands of radiating elements may utilize a tube or solid-state amplifiers in each element. A few years ago, transmitter designs were predicated upon either one or a few high-power tubes with a microwave distribution system feeding the array elements. The transmitter was a separate entity. The development of solid-state devices has led to transmit–receive (TR) modules that, when coupled to each element, form an integrated transmitter, antenna, and receiver. Current designs utilize thousands of modules in one phased-array radar face. Small tubes are also available that can fit into such modules when higher peak power levels are required.

Modern radars require transmitter spectral purity and coherence. Spectral sidebands due to power-supply–induced phase modulations as well as nonlinear phase characteristics as a function of wavelength (especially for wideband linear-FM wave forms) occur when ripple voltages from the transmitter power supply and modulator are translated into phase and amplitude modulations on the output rf signal. Extremely tight regulation and ripple reduction of the voltages required to operate both tube and solid-state devices are critical.

Linear beam tubes, such as the traveling-wave tube (TWT) and the klystron, will exhibit small-signal gain fluctuations as a function of input signal frequency due to small-signal reflections within the tube structure. These small-signal gain variations translate to insertion phase and amplitude variations at the output when the tube is operated at saturation. For pulse-compression systems that require low range sidelobes, these variations must be actively canceled out (by predistorting the input drive signal or by closed-loop cancellation around the tube, for example) or known to an accurate degree so that they can be canceled out during receiver signal processing.

3.3 Antennas

The radar antenna design starts with the function it has to perform, i.e., surveillance, tracking, fire control, imaging, communications, or combinations of functions. Single-function antennas are generally single-reflector systems that are directed mechanically. Some of the larger single-function systems such as an over-the-horizon (OTH) radar use phased arrays. Multiple-function systems, performing search and tracking, either use a single antenna per function or a phased array whose beam is directed electronically by controlling the phases among the radiating elements of the array.

The radar equation demonstrates the importance of the antenna aperture in terms of the range of the system. The larger the aperture of the antenna, the greater the energy density on the target, and the greater the amount of reflected energy received by the radar. A figure of merit for the antenna is the power gain, i.e.,

$$G_t = \frac{4\pi\eta_t A_t}{\lambda^2 L_a} = \frac{D_t}{L_a}, \qquad (33)$$

where η_t is the illumination efficiency, A is the area, λ is the operating wavelength, D_t is the directive gain, and L_a is the antenna loss. Power gain expresses the increase in power density along the axis of the antenna beam, relative to that radiated by an isotropic antenna. Directive gain considers only the impact of the aperture size and illumination and is equal to the power gain with a lossless antenna. With the advent of phased arrays and the use of TR modules and their combination of radiator, transmitter, and receiver, directivity is sometimes a more useful term as a figure of merit, since it enables one to focus on the aperture directly rather than an indeterminate antenna input.

The values of η_t and η_r are indicators of the illumination efficiency and the sidelobe level of the transmitting and receiving pattern of the antenna, respectively. Signal returns through the sidelobes of the antenna from clutter, multipath propagation, or electronic countermeasures interfere with the signal return through the main antenna beam and have adverse impacts on detection probability and measurement accuracy. In a hostile operating environment for the radar, high antenna sidelobes during radar transmission are a source of homing energy for antiradiation missiles (ARMs). In most systems $\eta_r = \eta_t$; but in more recent designs, changes in the transmission or reception illumination may be made on a pulse-to-pulse basis, depending on needs in the operating environment. Uniform illumination across the aperture gives the highest efficiency and the highest sidelobes. Illumination tapers similar to the weighting functions in Table 2 may be used to lessen sidelobes. Sidelobe levels approaching 50 dB below isotropic may be obtained, but at the expense of reducing efficiency and gain.

3.4 Receivers and Exciters

The rf reference signal and the modulation wave form are generated by the exciter for the transmitter. In an adaptive system such as a phased-array radar, the wave form and rf signal may be different on a pulse-to-pulse basis. This reference signal is also offset in frequency and furnished to the rf portion of the receiver to enable down-conversion of the received signal to the intermediate-frequency (IF) section of the receiver to ease hardware implementation requirements. In monopulse systems, separate receivers are utilized for the sum and angle channels. A factor in the monopulse angle measurement error is the match of the separate receivers in phase and amplitude response over a wide dynamic range of received signals.

Table 2. Characteristics of representative weighting functions.

Weighting function	Peak sidelobe (dB)	*S/N* loss L_{sp} (dB)	Relative 3-dB resolution
Uniform	−13	0	1
$\cos(2\pi f/\beta)$	−32	1.8	1.6
Hamming $a + b\cos(2\pi f/\beta)$ $a = 0.1, b = 0.9$	−43	1.3	1.5

3.5 Signal Processors

Signal processing in radar is the process of extracting information about the presence of radar targets and their characteristics from received echoes of the transmitted signals. Signal processing is conventionally distinguished from data processing according to whether the processing is performed on data received from single or multiple dwells. The term *dwell* refers to a single measurement period in a particular antenna beam direction with one or more transmissions. Signal processing consists of the functions carried out on a single-dwell basis, i.e., resolution, detection, and single-dwell estimation. Data-processing functions involve data from multiple dwells, and the term *observation time* is used with respect to estimation and prediction.

Radar signal processing is generally characterized by simple algorithm structures implemented on high-throughput processors. Sliding-window (nonrecursive) linear filters and correlators are used for pulse compression, Doppler filtering, image formation, and interference power estimation. Fourier analysis, implemented via the fast Fourier transform (FFT), provides an efficient means of implementing pulse compression via the frequency domain. The FFT efficiently implements a uniform bandpass filter bank for pulsed Doppler processing, and it is also used for image formation and angle-of-arrival estimation. Weighting functions for sidelobe control are used in most filtering and FFT operations. Table 2 lists characteristics of a few representative weighting functions. The loss indicated is part of L_{sp} in Eq. (1). Less common, but still important, operations are recursive (feedback) filters and rank-ordering operations.

Radar signal processors are implemented with combinations of analog and digital circuitry or, increasingly, all-digital circuitry. Current (1994) technology generally favors digital implementation for low- to moderate-bandwidth operations such as Doppler filtering and pulse compression for narrow-band (<10 MHz) wave forms. Wide-band (>10 MHz) wave forms are often candidates for analog implementation, at least through the pulse-compression stage.

The trend in signal processor technology is increasingly toward programmable digital implementations. The primary technological limitation is analog-to-digital (A/D) converter technology; however, A/D converters providing 16 bits of resolution at sampling rates up to 2 MHz, falling to 9 bits at 500 MHz, have been demonstrated (Hicks, 1992). There is also a loss associated with A/D conversion that also contributes to L_{sp} in both search and tracking radars. Commercial off-the-shelf signal processors can obtain throughputs of 100 million floating point operations per second (Mflops) on a single 6-in. by 9-in. (9-cm by 23-cm) circuit board, and this performance is rapidly improving. Several more complex radar systems use massively parallel computers offering performance in the 1 giga-floating point operations per second (Gflops) range for real-time signal processing. These performance figures, which will be obsolete in a few years, are still adequate for many radar applications.

3.6 Data Processors

The receiver and signal processor perform the detection process and then extract short-term parameter estimates from the received signal. The data processor stores and operates on these estimates to provide control for the radar and outputs to the user. With the introduction of the adaptive phased-array radar system, the data processor is an integral part of the system rather than a link between the radar and the user. In the control function, the data processor must provide direction to the radar regarding the target to be tracked, the frequency to be used, the wave form to be used, and the times for transmission and reception of the signal. It must perform short-term prediction to determine where the next range gate and antenna beam position must be. Longer-term predictions might be concerned with averting potential collisions between aircraft or directing intercepts between missiles and targets. The computer also provides a means of checking the radar hardware and the software algorithms in the computer. In the processing of data for the user, targets can be characterized and potentially identified by evaluation of their trajectories, and target priorities can be established.

In the single-target tracking radar, the data-processor role is relatively small; it performs the estimation and prediction processes required for pointing the beam and range gate and performs limited processing before sending data to the user. In a search radar used in a TWS mode, the role of the data processor and its software is more complex and is dependent on the number of targets to be tracked. In the phased-array radar, the role grows to the extent that it can be more than one-third the cost of the radar, where the cost is in the designing, programming, and testing the algorithms for controlling the radar and processing the data for the user. The software in modern phased-array radars may represent more than a third of the total development costs and may be the dominant risk area. Most data processors today are general-purpose computers, and the hardware cost is a fraction of the total cost.

Some data processing, such as beam steering and coordinate conversions in phased-array radars, is performed by special-purpose rather than general-purpose computers, since such repetitive processes can take up a large percentage of a central-processor computational time. In a multiple-target environment, the limitations may be in the speed and memory capacity of the digital interface between the radar and the data processor.

3.7 Wave Forms

3.7.1 The Ambiguity Function As already indicated, with adequate *S/N* ratio, the transmitted wave-form bandwidth determines the range resolution and range measurement capability. The dwell time determines the resolution and measurement capability in terms of Doppler shift. The capability of a radar system wave form to resolve and perform measurements on a scatterer or element of a scatterer when it is in proximity to another scatterer is indicated by the *ambiguity function,* or *ambiguity diagram,* described by Woodward (1963). Mathematically, the ambiguity function χ is

$$\chi^2(T_d,f_d) = \int_{-\infty}^{+\infty} u(t)u^*(t + T_d)\exp(-j2\pi f_d t)dt, \tag{34}$$

where $u(t)$ and $u^*(t)$ are the normalized signal returns from the first and second scatterers, respectively, T_d is the time difference in range, and f_d is the difference in frequency shift between the two. If the integral is equal to 1, no resolution of the two scatterers can occur. If the integral is equal to 0, then the targets are fully resolved. The function $\chi(T_d,f_d)$ is essentially the correlation function for a *combined* time and frequency shift, or, equivalently, range and Doppler shift.

The ambiguity function also describes the output of a radar receiver with a matched filter. Woodward pointed out that the Fourier transform of this correlation function or the signal energy spectrum as an output of the matched filter is a sufficient description of the radar system resolving power in time and frequency.

The ambiguity function does not give a figure of merit of one wave form with respect to another. It specifies a distribution in the time–frequency domain from which one may estimate the relative degree of resolution. A wave form that might be ideal for measurements of a particular class of targets may be inadequate for another class.

3.7.2 The Ambiguity Diagram The *ambiguity diagram* has the time and frequency domain as two coordinates, with the energy density plot $|\chi(T_d,f_d)|^2$ orthogonal to the time–frequency plane. An ambiguity diagram of a rectangular pulse train with constant-frequency pulses from a target signal passing through a matched filter is given in Fig. 8, with the magnitude of $|\chi(T_d,f_d)|^2$ represented by the size of the spectral components as displayed on the diagram. The width of the pulse (dwell to null) in the time domain is 2τ after passing through the matched filter. The bandwidth of a single pulse in the frequency domain is $1/\tau$. A train of four pulses would require a dwell time of t_d, and the frequency-domain bandwidth of the individual line spectra would be $2/t_d$ (null to null). This gives much better resolution in the frequency domain than from the single pulse. If one examines the frequency axis at $t = 0$, for a single rectangular pulse, a $\sin^2 x/x^2$ spectrum would be observed representing the self-convolution of the transmitted spectrum. For a train of pulses, the $\sin^2 x/x^2$ would be the envelope of the spectral lines

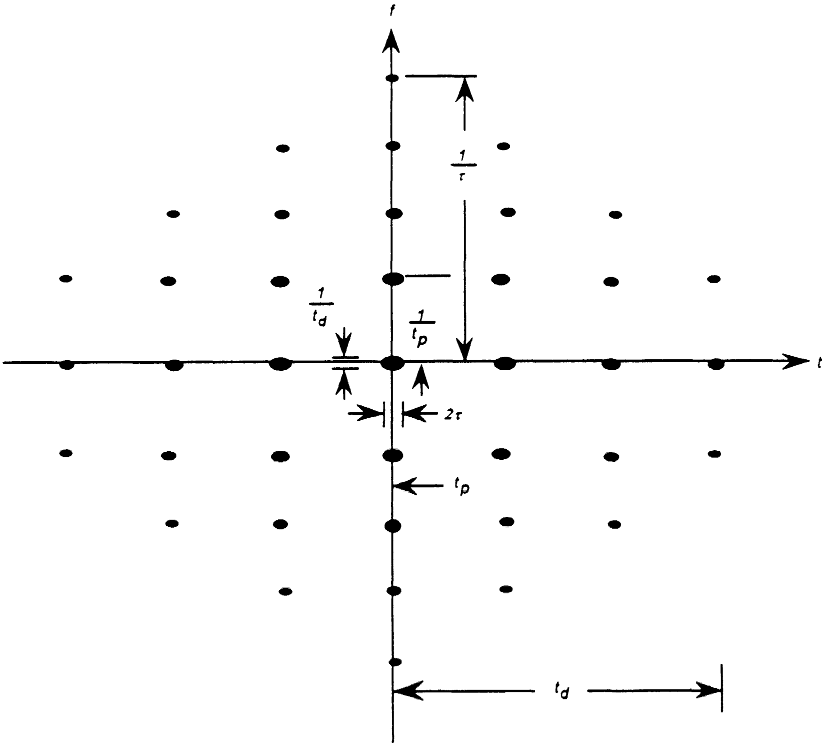

FIG. 8. Ambiguity diagram of four-pulse train.

whose spacing is approximately the PRF, or $1/t_{\mathrm{PRF}}$, but individually modified by the Doppler-shift difference at each frequency.

Many search and tracking radars work unambiguously, i.e., their instrumented range is less than the range corresponding to the PRF period (t_{PRF}) and their instrumented Doppler shift is less than the PRF. Long ranges and high radial velocities of a target may require a radar to operate ambiguously in either range or Doppler shift, or both. This process is equivalent to undersampling a signal. This is particularly true of an airborne radar in a search mode covering long extents of ground clutter, where the search is performed at a high PRF (>100 kHz) so that a target can be readily resolved from the ground clutter by virtue of its Doppler shift. The target return will be highly ambiguous in range. A fundamental problem in developing radar systems designed to detect target returns in the presence of large clutter returns via Doppler filtering is the suppression of such range/Doppler ambiguities. Ambiguities are typically resolved by changing the PRF from one coherent integration interval to the next and then using residue arithmetic techniques to estimate the true range and Doppler coordinates of the target.

3.7.3 Wave-Form Selection As with the ambiguity function, the ambiguity diagram is a useful tool in determining the resolving power of a wave form. The design of wave forms to meet requirements for resolution, estimation, and ambiguity usually starts with simple wave forms of known characteristics. Through an iterative process, using the target and its environment as one set of bounds and limitations imposed by the hardware and software mechanization as a second set, a repertoire of wave forms may be developed for a particular radar. The more complex radar systems may need a set of 20 or more wave forms to meet all requirements. Table 3 lists a variety of wave forms used in radar. The choice depends on the target and the environment. Nathanson (1991) provides excellent descriptions of the appropriate criteria and the selection process.

Table 3. Typical wave forms used in radar.

Wave form	Modulation
Continuous wave	Unmodulated
Train of cw pulses	No frequency modulation
Train of FM/cw pulses	Linear frequency modulation
	Nonlinear frequency modulation
Train of phase-coded pulses	*N*-bit biphase (Barker)
	N-bit polyphase (Frank)
Train of pulses with subpulses frequency coded	*N* subpulses noncoincidental in time and frequency

3.8 Radar Measurements

The primary function of radar is to perform measurements in order to furnish data on target position with a specified degree of accuracy at a rate consistent with user needs. Accuracy is defined as the quality of freedom from error and is expressed in terms of the error. The total error in radar measurements is the root sum square (rss) of the precision σ_n and residual systematic error σ_{rse}, i.e,

$$\sigma_e = (\sigma_n^2 + \sigma_{\mathrm{rse}}^2)^{1/2}. \tag{35}$$

Precision is defined in terms of the repeatability of measurement data and is generally equated to the random or noise error component, i.e., σ_n. The random error is a component of error whose magnitude and direction vary in a random manner in a sequence of measurements. It is primarily a measure of the error due to the thermal noise in the radar receiver, though there are other random errors in the radar and the propagation path. The systematic error is an inherent bias (offset) in the radar or propagation path. The residual systematic error σ_{rse} is that error left after correction or calibration of a systematic or bias error and may include registration error with the coordinate system of the user.

In a well-designed radar system of given resolution capability, i.e., bandwidth and beamwidth, that has been calibrated to reduce the systematic errors, the errors due to thermal noise may tend to dominate the accuracy, particularly if the radar data are being used to predict the future position of the target. The expected random or noise error on a single-pulse basis, i.e., Eqs. (29) and (30), can be reduced through integration, either predetector or postdetector, or in a data-processor tracking filter and through observation time.

Since most users of radar data are interested in predicting the future target position, the lower bound of the random error for a constant-velocity target is given by Gelb (1974) as

$$\sigma_n^2 = 4\frac{\sigma_m^2}{n} + 12\frac{\sigma_m^2}{nt_0}t_p + 12\frac{\sigma_m^2}{nt_0^2}t_p^2, \qquad (36)$$

where σ_m is the standard deviation of the measurements given by Eqs. (29) and (30) translated from the curvilinear radar coordinate system into a linear coordinate system for estimation and prediction. The terms t_p and t_o are the prediction and observation times, respectively, and n is the number of independent samples. The output samples from a matched filter that integrates more than one pulse would not be independent, and n would need to be adjusted accordingly. The first term in Eq. (36), which is an endpoint estimate for constant-velocity targets rather than Eqs. (29) and (30), is the noise-error component of the total tracking error for constant-velocity targets, though several texts refer to Eqs. (29) and (30) as the tracking errors. All three of these equations apply equally well to TWS systems and tracking radars. The primary difference between the two is the amount of predetector and postdetector integration prior to the data furnished to the tracking filter in the TWS system. Larger amounts of integration tend to reduce noise errors at the expense of increasing residual systematic or bias errors.

Equation (36) shows the importance of both the number of pulses integrated and the time interval over which a target is observed for prediction. From empirical data, however, there appears to be a limit on the integration that can be accomplished for a number of reasons, i.e., target motion, correlation between samples, measurements contaminated by radar instrumentation errors, and target and propagation noise with spectra much lower in frequency content than thermal noise. While not found in the literature, empirical data indicate that a total variance reduction of approximately 10 to 20 may be expected, though higher values are achieved in instrumentation systems.

The systematic error σ_{rse} in the accuracy equation is the error that is correlated over time or position with respect to an external reference and that can be measured and removed, i.e., calibrated. Consequently, the limit of systematic error is that due to the calibration errors and the electrical and mechanical stability of the radar. These residual errors are the antenna beam position and the range-resolution cell position.

Propagation errors due to refraction and multipath interference have systematic and random components that contribute primarily to elevation angle and range errors. Knowing the refractive index, one can correct propagation error to less than 10% of the original error. Short-term variations cannot be corrected. Often, when only a relative measurement between two targets is required, the error due to refraction is minimized. Though a number of techniques have been proposed to reduce multipath interference, there are none known to be particularly effective. The impact of multipath interference can be minimized by keeping the main antenna beam above the surface of reflection and reducing the antenna elevation sidelobes.

Clutter also has an impact on elevation and range measurement accuracy. The limit is established by the stability of the clutter and the ability of the radar to resolve the target from that clutter. The degree of resolution depends on the purity of the transmitted signal, stability of the radar, and the observation period or integration time. The errors due to clutter are proportional to the energy of the residual clutter in the time–Doppler-shift resolution cell and that of the signal.

In radars that utilize pulse compression as a means of getting more energy on target, the compression techniques produce not only the main return but also time sidelobes. Through these sidelobes, clutter and multipath interference returns can flood many of the range–Doppler-resolution cells. Their impact on measurements in a flooded cell can be reduced by 30–40 dB by weighting functions, such as those in Table 2.

Personal contact with highway speed radars may lead one to question Doppler-shift measurement accuracy. The small resolution cell available with long observation periods, as in pulsed-Doppler radars, enables a precise estimate of radial velocity well beyond the differentiation of position estimates. Cross-range velocities are still dependent on the time derivative of angle estimates; consequently, Doppler shift is most useful in resolution but has a place in situations where radial velocity estimates become of paramount importance.

4. APPLICATIONS

The applications of radar do not necessarily define the type of radar. In the process of air traffic control, one may find over-the-horizon (OTH) radars for tracking aircraft over the ocean, en-route surveillance radars for monitoring aircraft over land between terminal areas, terminal-area surveillance radars to monitor the aircraft near an airport, weather radars to determine optimum flight paths en route, landing radars as a complement to instrument landing systems, windshear radars to measure potential microbursts in the landing path, and surface detection equipment radars to monitor the ground movement of aircraft on the airport runways and taxiways. Aboard the aircraft will be the weather mapping radar and the radar altimeter.

Table 4 provides an indication of the relatively broad spectrum over which radar applications are found.

4.1 Search and Surveillance Radars

The search radar is one used "for detection of targets in a particular volume of interest," whereas a surveillance radar is used "to maintain cognizance of selected traffic within a selected area" such as an airport terminal area or air route (Radar Systems Panel of the IEEE Aerospace and Electronic Systems Society, 1990). Most radars operate with wavelengths in the 1-mm to 1-m regions. Their propagation characteristics are such that they are considered line-of-sight (LOS) radars with the propagation path in a straight line.

OTH radars operating in the 10- to 100-m wavelength region utilize either surface-wave propagation or sky-wave propagation, with the former having ranges of about 300 to 400 km, and the latter up to 4000 km on a single reflection from the ionosphere. OTH surface-wave systems depend on the low attenuation characteristics of the longer wavelengths when launched in a vertically polarized wave over a saltwater surface. Azimuth, range, and Doppler data can be obtained for aircraft and ships. Because of sea clutter, it is necessary to depend on Doppler information to separate the target from the background. Because of the long wavelength, the Doppler shift is low for aircraft targets, and careful design is required to separate the moving target from clutter from both the surface and the ionosphere. Sky-wave propagation is similar to that in communication systems, except that there is a two-way path. At these long wavelengths, the time of day and the impact of solar radiation on the ionosphere determine the frequency to be used and the ranges obtained. There are particular problems with auroras and the free-electron velocities encountered.

Table 4. Radar wavelengths and applications.

Band	Wavelength (m)	Frequency	Applications
HF	10–100	3–30 MHz	Over-the-horizon radar
VHF	1–10	30–300 MHz	Very long-range search
UHF	0.3–1	300–1000 MHz	Very long-range surveillance
L	0.15–0.3	1–2 GHz	Long-range surveillance, en-route air traffic control
S	0.075–0.15	2–4 GHz	Surveillance, long-range weather characterization, terminal air traffic control
C	0.0375–0.075	4–8 GHz	Fire control, metric instrumentation, short-range weather characterization
X	0.025–0.0375	8–12 GHz	Fire control, air-to-air missile seeker, marine radar, airborne weather characterization
K_u	0.0167–0.025	12–18 GHz	Short-range fire control, satellite altimeter, airborne surveillance radar equipment, remote sensing
K	0.011–0.0167	18–27 GHz	Water vapor attenuation band
K_a	0.0075–0.011	27–40 GHz	High-resolution remote sensing, weapon guidance
V	0.004–0.0075	40–75 GHz	Remote sensing, weapon guidance
W	0.0027–0.004	75–110 GHz	Remote sensing, weapon guidance
MM	0.001–0.0027	110–300 GHz	Experimental, weapon guidance

Both airborne and ground-based, line-of-sight, search and surveillance radar ranges are generally limited by the S/N ratio of the target return or by clutter and attenuation at the shorter wavelengths. These radars are primarily used for airborne targets, though there are some, such as the airport surface detection equipment (ASDE), that are utilized to monitor ground targets. Civilian use is primarily directed toward air traffic control, whereas military use is directed toward the detection of threat targets so that defensive action can be taken.

The limitation on the maximum number of simultaneous targets in search radars is the data processor. There are limits on the accuracy of the data, primarily because of the number of samples available from each target, the low update rate of the search scan, the bandwidth of the transmitted signal (which is small to reduce the number of range cells to be searched), and the beamwidth in elevation (which is large to provide coverage from the horizon to zenith).

4.2 Tracking Radars

The narrow pencil-beam tracking radar is used to achieve high-accuracy position data. Accuracy is usually considered the root mean square sum of the precision of the radar and the residual errors after calibration. Theoretical range- and angle-measurement precision for a fixed target are defined in Eqs. (28) and (29), and the tracking precision for a constant-velocity target is defined by Eq. (35). The radar can provide excellent range data but is generally limited in angle, as compared to optical systems, because of the λ/d ratio, where d is the antenna diameter. The overall accuracy is limited by

1. calibration errors in range gate and beam position of the radar with respect to a reference, and
2. propagation errors.

The highest-accuracy tracking radars are those whose antenna angle position is calibrated utilizing a collimated telescope and known stars and where measurements of the propagation condition allow correction of atmospheric refraction effects. Partially correlated instrumentation and propagation errors, in turn, produce phase and amplitude errors in the signal and limit multiple-pulse tracking accuracy.

Tracking radars were initially developed during World War II to direct antiaircraft artillery. Derivatives of these radars were developed for not only fire-control functions in ground and airborne air-defense operations but also instrumentation for military development and civilian space programs. They are utilized to determine accurate current and projected positions of powered and ballistic targets, both airborne and in space. Search and surveillance radars can provide two-dimensional data trajectories but of much lower accuracy. The state-of-the-art accuracy for end-point estimates of monopulse tracking radars performing satellite tracks is less than 0.1 mr in angle and 3–5 m in range. The performance of tracking radars for air-defense and fire-control systems is limited by the RCS of the target. Transponders operating at the radar frequencies are used on cooperative targets to improve the S/N ratio; these systems are called Information, Friend or Foe (IFF), in military use and have civilian counterparts.

4.3 Phased-Array Radars

Since most tracking radars are single-beam systems, the number of targets is limited to those in the narrow pencil beam, usually one. The need to track a multiplicity of threat targets, however, drove the development of phased-array radars. Though the theory of phased-array antennas has been known for many decades, development was limited because of the cost of phase shifters and time-delay units and the inability to control the flexibility of the system. The number of these units needed for a phased-array radar antenna is approximately the area divided by $0.3\lambda^2$. A second limitation, not recognized early, was lack of a control system that could take advantage of the adaptability of the antenna, transmitter, and signal processor. Development of the control system paralleled, but ran behind, the development of the digital computer. In the last two decades, multiple systems have been fielded. Though most are surface based, there are a number of airborne systems.

Its adaptability means that the design of the phased array to perform both the search and the track functions in a multiple-target environment is generally a compromise of wavelength, time, energy, and costs. The search function leads to the need for longer wavelengths to cover a large volume, and the track function leads to the need for shorter wavelengths. Algorithms for radar control must permit real-time compromise between search and track for energy and time resources while providing immediate access to these resources for the search for and track of high-priority targets. The final limitation is cost.

The initial systems were developed for surface-based air defense and ballistic-missile defense in several countries. Examples include the PATRIOT, AEGIS, PAVE PAWS, and BMEWS (Ballistic Missile Early Warning System) in the United States and the AMB-3, the Hen House, and the SA series of air- and missile-defense radars in the U.S.S.R. (Blake, 1989). It might be noted that the BMEWS radars were originally separate search and single-target tracker radars that were upgraded to phased-array radar systems. A number of other countries have built phased-array radars for air-defense and air traffic-control applications. In the latter, they are utilized for en-route surveillance and monitoring and controlling the landing of aircraft.

4.4 Weather Radars

In weather radars, in addition to the azimuth, elevation, and range measurements, there is an estimate of the zero, first, and second moments of the returned power spectral density, which in the case of precipitation are measures of the reflectivity, mean Doppler shift, and Doppler frequency dispersion. These data provide information about precipitation accumulation, storm identification and tracks, tornadoes, and atmospheric turbulence. Precipitation accumulation can be used to predict flooding, and storm identification and tracks can be used for warning.

The Terminal Doppler Weather Radar (TDWR) focuses directly on the problem of air travel and air safety. There have been a large number of fatalities and accidents due to wind shear during the landing of aircraft. The TDWR provides automatic detection of microbursts and low-level wind shear through the Doppler measurement of the radial velocity of rain or airborne microparticulates to obtain a direct indication of the presence of wind shear.

4.5 Ground-Probing Radars

Some degree of success has been achieved employing radar to characterize the depth profile of subsurface conditions. These so-called ground-probing radars generate a pulse of energy from a very broad-bandwidth antenna positioned in close proximity to the ground. Pulse lengths tend to be very short, in the 1- to 5-ns range, depending on range resolution and probe depth. The objective of such a radar is to detect and map subsurface interfaces and buried objects. The range to a subsurface layer or target is proportional to the two-way propagation time, which is influenced by such factors as the relative dielectric constant, loss tangent, and bulk attenuation characteristics of the media probed. These factors, in turn, are functions of mineral content, soil homogeneity, stratification, discontinuities, packing density, and surface conditions. Environmental factors that also affect performance include temperature, seasonal and diurnal variation, and especially the moisture content of the soil.

Applications of ground-probing radar systems have tended to use microwave frequencies below 3 GHz and have included detection and identification of nonmetallic mines, location of buried pipes, and location of air voids within highway pavements. Penetration performance is optimum under dry-medium conditions. The effectiveness of all of these applications is adversely affected when the pavement or underlying soil is wet. Salt penetration of roadbeds can create excessive signal attenuation in addition to high surface reflections.

4.6 Imaging Radars

4.6.1 Synthetic-Aperture Radars The synthetic-aperture radar (SAR) effects very fine cross-range resolution by artificially creating a very large linear-array antenna as discussed under Resolution in Sec. 2.3.1. Radar backscatter signals are recorded from an aircraft or satellite over several seconds time as if they had been captured by a real antenna array. The recorded data captured over a particular dwell time are then coherently summed to create an image of the surface, where the ideal cross-range resolution is one-half the actual antenna aperture, independent of range. Range resolution is obtained through traditional short-pulse or pulse-compression techniques.

The Fourier-transform–based SAR signal processing exploits the Doppler frequency relationship between the radar backscatter from a resolution cell on the surface with that abeam of the moving platform. Within a fairly broad angular approximation, the Doppler-shifted frequency from a resolution cell is linearly proportional to the distance from a point at the same range on the surface abeam of the platform, where the Doppler shift is zero.

SAR imaging has enabled cartographers to map regions of Central and South America, for example, that are usually shrouded from optical camera surveillance by constant cloud cover. Spatial resolutions of a meter or less are routinely achieved. Satellite imaging of the Earth and Venus has been routinely performed by satellite-borne and space-shuttle–based synthetic-aperture radar systems. Earth images have been used for such diverse purposes as remote sensing of geographical features, surveillance of military emplacements, and location of ships at sea. Magellan SAR-derived imagery of the planet Venus has been providing contour and reflectivity information about the Venerian surface, from which important geophysical information on that planet has been obtained.

4.6.2 Inverse Synthetic-Aperture Radars Synthetic-aperture radar signal processing creates imagery from the mathematical relationship between the instantaneous Doppler frequency shift of the backscattered signal from a surface resolution cell and the cross-range resolution cell position. This Doppler frequency shift can be the result of the target's rotational motion instead of that of the radar platform. If a target is rotating about an axis perpendicular to the radar line of sight, there will exist a Doppler-shifted signal from a resolution cell of the object that can be correlated with cross-range position. This signal-processing concept is called inverse synthetic-aperture radar, or ISAR.

Applications of ISAR signal processing include imaging of several planets and our own moon from a radar located on the Earth, imaging of ships from their slow rolling motion in the water, and imaging of satellites and reentry vehicles due to their apparent rotation with respect to a radar line of sight. ISAR images of military vehicles are routinely obtained by recording radar backscatter from targets placed on a turntable as it rotates within the illuminated volume.

4.7 Ground Vehicular Radar

4.7.1 Police Radars The well-known police radar used to monitor automobile speeds has a small antenna and requires operation at *X* (3 cm) and *K* bands (1.5 cm) to achieve resolution. These are usually homodyne radars in which the received signal is beat against the transmitted signal. For a 90-km/h velocity at *X* band, the Doppler frequency is about 1167 Hz. The output is amplitude limited, and the signal is passed into a digital counter that counts the zero crossings over a short period of time. The number of crossings per unit time gives the measured speed. Where the police radar is moving, the Doppler signal from nearby clutter intercepted by the radar beam is used as the measure of the police radar velocity, and the target vehicle has a Doppler frequency plus or minus that of the police vehicle. This type of radar is also used to measure baseball velocities or the speed with which a pitch is delivered.

4.7.2 Collision-Avoidance Radars Recent research efforts have been under way in Germany, France, the United States, and Japan in the development of short-range radar systems for automatic collision avoidance for automobiles and trucks. The concept usually takes the form of detecting the closing rate between the platform automobile and another vehicle, based on detecting a Doppler-shifted backscatter signal. Detection then triggers an automatic response of braking the automobile at a rate commensurate with the rate of range closing that was determined.

False-alarm reduction has remained a challenging area of development. False detections can result from antenna sidelobe detection of backscatter from roadside objects such as building, signs, and other cars. Other challenges include reducing the overall system cost and increasing the system robustness to make the radar application more commercially attractive.

4.8 Missile Radars

The first missile radars were the proximity fuzes developed during World War II. These were simple cw homodyne radars, where the received signal was mixed directly with the transmitted signal. The fuze was activated when the detected target-return amplitude achieved a preset threshold value. Today's more complex systems may utilize cw or pulsed electromagnetic waves but with modulations and signal processing that enable resolution in both the time and frequency domains. Many anti–air-missile seekers have such wide beamwidths that they require no search. Some antennas may be dual purpose, however, scanned to provide search coverage and acquisition, with a monopulse feed that enables the missile to track.

Some of these radars operate in a bistatic mode, that is, the host radar illuminates the target with a radar signal and the missile radar receives the reflection from the target. A rearward-pointing antenna on the missile may also allow the missile to determine its location with respect to the host radar and its range from the target. Modern missiles fired in a fire-and-forget mode, i.e., a monostatic mode, operate in a completely autonomous manner, both illuminating the target and receiving and processing the target's backscattered signal, without requiring the host's illumination of the target.

GLOSSARY

Accuracy: Freedom from error.

Backscatter Coefficient: The radar cross section per unit illuminated area (for surface clutter) or illuminated volume (for rain, smoke, fog, etc.).

Bandwidth: The frequency extent of a signal or the passband of an electrical component, usually measured between frequencies whose probability density function value is 3 dB below the average peak value.

Beamwidth: The angular extent of a one-way antenna power pattern, typically between points 3 dB down from angular position of maximum antenna gain.

Clutter: Any unwanted radar echoes, e.g., ground or sea surface, rain, etc.

Dwell: The period of time that the antenna beam is pointed at a specific resolution cell or cells in search radars.

ECCM: Electronic counter-countermeasures, i.e., radar hardware, signal-processing, or operational techniques that preserve radar detection and tracking performance in the presence of jamming.

ECM: Electronic countermeasures, i.e., jamming/antijamming techniques designed to deny or degrade radar detection or tracking.

Jamming: Electronic signals designed to generate interference in the receiving band of the radar.

MTI: Moving target indication: radar signal-processing techniques that detect targets having a component of velocity along the radar line of sight.

Observation Time: The period of time that the antenna beam is pointed at a target—particularly for targets being tracked. Can be equal to dwell time or multiple dwells in search radars.

Polarization: The spatial dependence of the electric field direction of an electromagnetic wave: linear, circular, or elliptical. Note that the engineering definition of circular polarization is defined looking in the direction of energy propagation and is opposite to the physics convention.

Precision: The repeatability of a measurement as limited by noise.

Pulse Compression: Any technique that uses coding on transmission and decoding on reception to transmit a long pulse length and receive a short pulse length, resulting in fine range resolution.

Pulse Length: The time duration of a transmitted radar signal.

Pulse Repetition Frequency (PRF): The number of transmitted pulses per second.

Pulsed Doppler Radar: A pulsed radar that utilizes the Doppler effect to determine the component of a target's velocity along the radar line of sight.

Radar Cross Section: A measure of the reflectivity of an object: 4π times the ratio of the power per unit solid angle scattered in a specified direction to the power per unit area in a plane wave incident on the object from a specified direction.

Range: Distance between the radar and a reflecting object (target).

Range Resolution: The ability to distinguish between two objects at the same radar bearing, separated only in range.

Swerling Model: A mathematical target model based on the echo-amplitude distribution-function characteristics and temporal dependence.

Track-While-Scan (TWS): A radar process that automatically tracks objects in range and bearing, with periodic position updates from a scanning antenna.

INTRODUCTION

Irradiation with energetic particles such as neutrons, ions, and electrons, or with hard x rays, causes structural and/or chemical changes in practically all solids. This phenomenon is called "radiation damage" irrespective of whether the associated property change is beneficial or detrimental to the envisaged application. Modern radiation damage research started with the installation of the first nuclear reactors. On that occasion, Fermi and, especially, Wigner pointed out the danger of severe property changes of core components under the extended neutron irradiation. Subsequent intensive research on radiation effects led to a branching into major directions: Solid-state physicists recognized that bombardment with energetic particles offered a unique possibility to create well-defined defects in solids in a controlled manner. They carried out low-temperature, low-dose irradiations of pure metals, often in single-crystalline form, to establish the properties of the most basic radiation defects, vacancies and interstitial atoms, i.e., Frenkel pairs. As a result of this fundamental research, the basic production mechanisms and properties of radiation-induced defects are now understood in pure metals and simple ionic crystals. For semiconductors, oxides, and intermetallic compounds, however, the properties of even the simplest radiation-induced defects are still controversial or unknown. The other direction of research was dictated by the need to predict the rather complex property changes (e.g., embrittlement, swelling, or in-pile creep) that would occur in commercial multicomponent materials during many years of reactor irradiation at elevated temperatures. Over the last years an increasing cross linking between basic and applied radiation effects research can be recognized: One reason is that the development of radiation-resistant materials for future fusion reactors re-

quires—because of the lack of powerful sources for the high-energy fusion neutrons—irradiation testing with reactor neutrons or fast ions. To transfer the results of such "simulation irradiations" to actual fusion conditions, the underlying defect production and accumulation processes must be understood in detail. Also affecting radiation effects research is the widespread industrial application of ion-beam techniques for microelectronics and thin-films technology. These techniques rely on a detailed understanding of the associated ion-induced radiation damage (see also ION BEAM MODIFICATION OF MATERIALS).

In the following section we discuss the production of the primary defects, the structure of Frenkel pairs, and the local arrangements of defects in displacement cascades. In Sec. 2 we review mobilities of Frenkel defects and the defect reactions that lead to recovery and to different microstructures during long-term irradiations at elevated temperatures. The final Sec. 3 summarizes technologically relevant changes of macroscopic properties in different classes of materials during irradiation and their relation to the radiation-induced microstructures.

1. PRODUCTION OF PRIMARY DEFECTS

1.1. Interaction between Radiation and Solids

It is now established that all macroscopic radiation effects are caused by one of the following elementary interactions between radiation and atoms: electronic excitations, nuclear transmutations, or elastic collisions. Electronic excitation usually leads to ionization of the atoms in the crystal. In most materials, the resulting electron-hole pairs do not produce lasting damage. Exceptions are organic materials, where the molecular bonds broken by the ionization may combine to form new chemical species, e.g., by cross linking, as well as special ionic crystals (see Sec. 1.4). The transient electrical photocurrents that are produced in semiconductors and insulators during the ionizing irradiation, however, are usually not considered radiation damage.

The effects of nuclear transmutations are particularly important for neutron irradiations. An example is the transmutation doping of silicon by thermal neutrons via the reaction $Si^{30}(n,\gamma)Si^{31}$ and the subsequent β decay of Si^{31} into P^{31} with a half-life of 2.6 h. By this technique large Si crystals used, e.g., in high-power devices can be precisely doped with good homogeneity. Another important class of nuclear reactions are those in which α particles are emitted, e.g., from (n,α) processes induced by fast neutrons. The helium atoms remaining after the α particles have come to rest are insoluble in most materials and will therefore precipitate in the form of bubbles. The associated problem of helium embrittlement is discussed in Sec. 3.1.4. Since the cross section for (n,α) reactions increases strongly with neutron energies above ~1 MeV, helium embrittlement will be a severe problem for future fusion reactors where the materials will be exposed to high fluxes of 14-MeV neutrons.

In the elastic collision process, the irradiating particle transfers a recoil energy T to a lattice atom, which is then called the primary knock-on atom (PKA). If this recoil energy exceeds a material-dependent threshold energy T_d, so-called displacement damage is created in the crystal. Details of this damaging process are summarized in Table 1 and is discussed in the subsequent sections.

The magnitude and the distribution of T depend on the nature and energy E of the irradiating particle. T varies between zero and the maximum energy transferred in a head-on collision,

$$T_{\max} = \frac{4Mm}{(M+m)^2}E \quad \text{and}$$
$$T_{\max} = \frac{2m_e}{M}\left(\frac{E}{m_e c^2} + 2\right)E, \tag{1}$$

for nonrelativistic particles and relativistic electrons, respectively. M and m are the masses of the recoil atom and the bombarding particle, respectively. The probability that an atom after irradiation with dose Φ has received a recoil energy between T and $T + dT$ is given by $\Phi d\sigma(T)$ (Φ is the number of particles per incident unit area or total path length of all particles per unit volume). The form of the differential cross section $d\sigma(T)$, which reflects the type of interaction between irradiating particle and lattice atom, determines the distribution of recoil angles.

Table 1. Steps in the production process of primary defects.

Time (ps)	Event	Result	Characteristic parameter
0	Transfer of recoil energy to a lattice atom	Primary recoil atom (PKA)	T = PKA energy T_{dam} = damage energy $d\sigma(E,T)$ = cross section
0–0.3	Slowing down of PKA	Collision cascades and subcascades	T_d = displacement threshold
0.3–3	Spike formation, interstitial ejection	Hot spike core, atomic mixing, replacement collision sequences (RCS)	T_{sp} = maximum spike temperature n_{sc} = number of subcascades
3–10	Spike core solidification and cooling to ambient	Stable Frenkel defects (FD), depleted zone, disordered zone, amorphous zone	$\nu(T)$ = number of stable FD's per PKA η_{diso} = disordering efficiency η_{amo} = amorphization efficiency

For a quantitative characterization of the damage introduced by a given dose of irradiating particles, each recoil event must be weighted by the amount of damage it introduces into the crystal. In this manner, the so-called damage or displacement cross section has been defined by a convention of the American Society for Testing Materials (ASTM, 1989):

$$\sigma_{\mathrm{dam}} \equiv \int_{T'=T_d}^{2.5T_d} d\sigma(T') + 0.4 \int_{T'=2.5T_d}^{T_{\max}} \frac{T_{\mathrm{dam}}(T')}{T_d}\, d\sigma(T'), \qquad (2)$$

where T_d is an effective displacement threshold energy and is tabulated partly by the ASTM (1989) and Table 2 or otherwise taken as $T_d \approx 25$ eV. The damage energy, $T_{\mathrm{dam}}(T')$, in Eq. (2) takes into account that during the slowing-down process of the PKA part of its energy is converted into electronic excitations. These electronic losses are most important for recoil energies above $T/\mathrm{keV} \geq 0.1M$ (where the mass M of the recoil atom is in atomic mass units). Equation (2) is based on the idea, originally proposed by Kinchin and Pease (1955), that recoils with $T < T_d$ do not produce displacement damage, that recoils with $T_d < T < 2.5T_d$ produce just one displacement (or Frenkel pair), and that recoils with energies above $2.5T_d$ produce a number of displacements which increases linearly with T_{dam}. In the semiconductor literature on radiation effects, instead of σ_{dam}, an "introduction rate" $\Sigma = n\sigma_{\mathrm{dam}}$ is generally

Table 2. Defect parameters for typical metallic and nonmetallic materials. $T_{d,\min}$ is the minimum recoil energy to create a stable Frenkel pair. T_d is the recommended displacement energy for dpa calculations. E_i^m and E_v^m are the activation energies for thermal migration of interstitials and vacancies, respectively.

Material	Structure	$T_{d,\min}$ (T_d) (eV)	E_i^m (eV)	E_v^m (eV)
Al	fcc	16 (25)	0.1	0.6
Cu	fcc	19 (30)	0.1	0.7
Ni	fcc	23 (40)	0.15	1.05
Fe	bcc	17 (40)	0.3	0.55
Mo	bcc	34 (60)	0.08	1.3

KCl	Rock salt	Radiolysis	0.1 [Cl_i]	0.85 [V_{Cl}^+]
				0.7 [V_{K}^-]

quoted, where n is the atomic density of the target material.

To compare the damaging effect of different irradiating particles, the irradiation dose, Φ, is calibrated in units of displacements per atom (dpa), where

$$\text{dpa} = \Phi \sigma_{\text{dam}}. \tag{3}$$

If there is a distribution in the energy E of the irradiating particles, σ_{dam} must be averaged accordingly.

For a quantitative characterization of the recoil spectra produced by different irradiating particles, the normalized damage distribution $W(T)$ is a convenient quantity. It is calculated by taking the integrals in Eq. (2) only up to $T' = T$ instead of $T' = T_{\max}$ and normalizing this cross section by σ_{dam}. In this manner, $W(T)$ gives the fraction of damage produced by recoils with energies smaller than a given value T. Examples for different irradiating particles are shown in Fig. 1. It is evident from the logarithmic scale for T that the different particles transfer their energy to the atoms in quite different regimes. For example, the median recoil energy $T_{1/2}$ (i.e., the recoil energy below which half of the displacements are produced), is about 60 eV ($\approx 2T_d$) for 5-MeV electrons and about 160 keV ($\approx 2000T_d$) for fast reactor neutrons. Other projectiles lie somewhat between these extremes. Note that neutrons produce recoils in a relatively narrow range whereas MeV protons produce recoils uniformly between T_d and $T_{\max}$.

1.2 Production of Individual Frenkel Pairs

Pairs of individual interstitials and vacancies, Frenkel pairs (FP), constitute the basic elements of radiation damage. They are generated by low-energy knock-ons, typically below 200 eV. The production mechanism and structure of Frenkel pairs have been determined only for simple metals for which molecular-dynamics computer simulations could be used. In these simulations, the classical equations of motion are solved for an assembly of 10^3–10^5 atoms interacting via a suitably chosen interatomic potential. The motion of all atoms can be followed as a function of time after one of the atoms is given an energy T. Unfortunately, reliable yet tractable interatomic potentials are only available for a few metals.

The atomic motion involved in a typical single displacement event is shown in Fig. 2 for fcc Cu. The most prominent feature is the creation of a replacement collision sequence (RCS) that propagates at supersonic velocities. Each atom in the sequence successively replaces its neighboring atom, along a close-packed atomic row. The replacements continue until so much energy has been lost to the surrounding lattice that the last atom in the sequence can no longer displace its neighbor. This last atom falls back toward its starting point which, however, is now occupied by the preceding atom in the collision sequence. Therefore, two atoms must share one lattice site at this position, i.e., an inter-

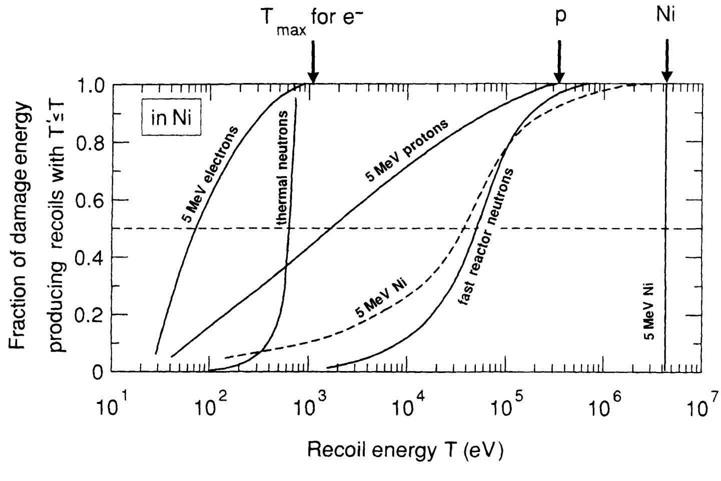

FIG. 1. Fraction $W(T)$ of the damage energy with T' smaller than a given value T produced by recoils from different irradiating particles in nickel. For the 5-MeV self ion, two curves are shown: The solid line (step at 5 MeV) applies if no distinction is made between Ni as a bombarding particle and a PKA, respectively. The dotted curve considers only energy transfers to Ni atoms and excludes the bombarding Ni. The recoils generated by thermal-neutron irradiation primarily result from the γ rays emitted after the neutron capture.

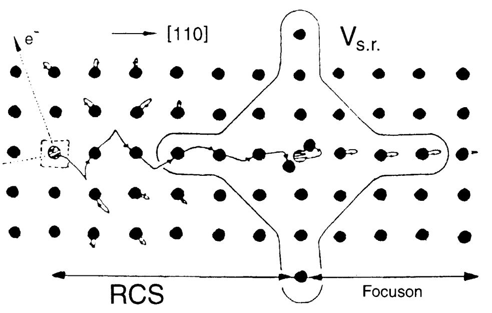

FIG. 2. Molecular-dynamics simulation of a single displacement event in fcc Cu. The figure shows the trajectories of the atoms generated by a PKA with $T = 50$ eV and recoil direction 10° off the [110] axis in the (100) plane. The PKA (shaded in its initial position) comes to rest next to the generated vacancy. The interstitial is created at the position of the other shaded atom where the replacement collision sequence (RCS) got stuck. $V_{s.r.}$ indicates the spontaneous recombination or instability volume of Frenkel pairs.

stitial is formed. Beyond the interstitial position, momentum, but no mass, continues to propagate in the collision direction as a so-called focuson. Because of the action of the RCS, the PKA usually ends up next to the vacancy.

RCS are an essential element in Frenkel pair production, at least for the close-packed metals, because they provide an efficient mechanism to separate the interstitial from its vacancy. A minimum separation is necessary to avoid subsequent athermal recombination of the interstitials and vacancies. As indicated in Fig. 2, the recombination volume V_{sr} defines the volume around the interstitial in which a vacancy is mechanically unstable to recombination. The threshold energy T_d for Frenkel-pair production can therefore be considered as the minimum energy required to separate the interstitial and vacancy beyond the range of instability. Since replacement collision sequences spread easiest along close-packed lattice directions, minimum values of T_d are expected for recoils along these directions and are, indeed, observed. The minimum threshold energies $T_{d,\min}$ listed in Table 2 thus pertain to displacements around the directions ⟨110⟩ and ⟨100⟩ in fcc and around ⟨111⟩ and ⟨100⟩ in bcc metals. For defect production calculations, a threshold energy that is averaged over all crystal directions must be employed. These energies are also listed in Table 2.

The $T_{d,\min}$ values listed in Table 2 are at least three times larger than the energy stored as formation energy of the created Frenkel pair. Apparently during the rapid formation of the Frenkel defect by the displacement process within 10^{-12} s, a large fraction of the energy $T_{d,\min}$ must be lost to neighboring atoms during the collision sequence event. Only a small fraction of $T_{d,\min}$ is stored as potential energy in the lattice.

Displacement processes in diatomic materials, with the atoms having different masses, arranged on different sublattices, and having different interaction potentials, are complicated. In addition to two kinds of vacancy and interstitial type defects on the different sublattices, antisite defects can also be produced in these materials. This complicated situation is illustrated in electron-irradiated GaAs. At the onset of damage around $T_{d,\min} \approx 9$ eV, the production of interstitials and vacancies on only the As sublattice is reported. The threshold energy for the production of Ga interstitials seems to be higher and, perhaps, associated with double displacements, generating an As interstitial simultaneously with a Ga interstitial. At recoil energies below 19 eV, it seems that recoils starting from the As sublattice, aside from Frenkel defects, can create also Ga_{As}/As_{Ga} antisite pairs. The corresponding exchange between an As and Ga lattice atom is triggered by a replacement collision with subsequent spontaneous recombination of the so-created instable interstitial with the vacancy at the starting point of the PKA. Defect production in oxides, like MgO or Al_2O_3, is similarly complicated, although antisite defects are not formed. One general trend, however, is that the threshold energies on the oxygen sublattice seem to be remarkably high, ~60 eV.

The atomic configuration of the interstitials produced by the displacement process is now established for metals and for the anion defects in alkali halides. In all cases, the interstitial consists of two atoms sharing one lattice site forming a "dumbell" whose axis is along ⟨100⟩ for fcc metals (experimentally verified for Al, Cu, Ni) along ⟨110⟩ for bcc metals (experimentally verified for Mo, W, and Fe), along ⟨110⟩ on the anion sublattice of fcc halides (experimentally verified for KCl and KBr), and along ⟨100⟩ for the bcc halides (e.g., CsBr) (see Figs. 3 and 9). The reason why dumbell configurations are preferred over the more symmetric octahedral or tetrahedral interstitial sites in metals stems from the strong repulsive interaction between the interstitial atoms and their neighbors. In the halides, on the other hand, the neutral anion interstitial seems to be stabilized by covalent bonding between the dumbell atoms and their neighbors in the ⟨110⟩ row. Whatever the detailed reason for their configuration, the strong repulsion between the atoms squeezed into the interstitial configuration creates large local displacements and leads to interstitial relaxation volumes of the order of 1–3 atomic volumes.

For other materials, especially semiconductors and oxides, little is currently known about interstitial structures and properties. This is due to the experimental difficulty that the interstitials generated during electron irradiation are mobile at low temperatures, so that their reaction with impurities cannot be avoided. Theoretical calculations, moreover, suffer from the difficulty to take properly into account the large Jahn–Teller splitting of the electronic defect levels and the accompanying large spontaneous distortion of the molecular defect center.

1.3 Displacement Cascades

Primary knock-on atoms with energies $T \approx 1\text{–}10^3$ keV produce displacement cascades. In contrast to the single-displacement event, the PKA slows down over distances much larger than a lattice distance, and it can displace many more than one atom. The secondary recoils, in turn, displace other lattice atoms and so on, creating a displacement cascade (see Table 1). Molecular-dynamics simulations, performed on modern high-speed computers, have clarified many details of the damage production in displacement cascades. According to these studies, the cascade evolution comprises three consecutive stages (see Table 1): The initial stage, called collision cascade, lasts about 0.3 ps, i.e., approximately the period of a lattice vibration. In this stage, the PKA and higher-order knock-ons slow down by two-body collisions until they reach energies below T_d and can no longer displace additional lattice atoms.

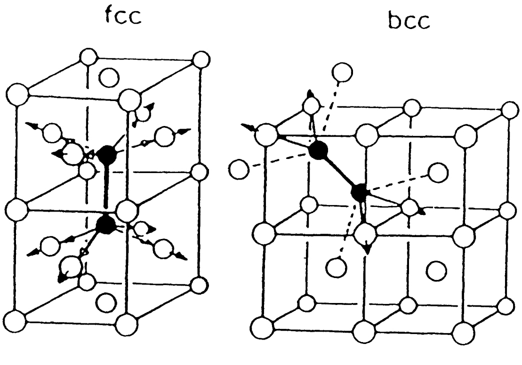

FIG. 3. The stable configurations of self-interstitials in fcc and bcc metals: Two lattice atoms (black) share one lattice site forming a so-called dumbell with the dumbell axis along ⟨100⟩ in fcc and along ⟨110⟩ in bcc metals.

In the subsequent time, from 0.3 to about 3 ps, the collision cascade develops into a heat spike during which most of the atoms localized in this region are set into violent motion. The energy density within the spike core can exceed several tenths of an eV/atom, corresponding to maximum temperatures T_{sp} of a few times the melting temperature. The atomic arrangement in the spike resembles a liquid droplet with a density lower than the surrounding lattice. This lower density is a consequence of a shock wave, thermal expansion, and the ejection of interstitial atoms. The snap shot shown in Fig. 4 illustrates these features: A highly disordered liquidlike spike core with a lower atomic density is surrounded by a shock front in which the lattice is compressed at pressures of order of the theoretical shear strength. Although the spike concept was introduced in the 1950s by Seitz and Koehler (1956), it had remained controversial whether the energy from the collision cascade dissipates slowly enough to the surrounding lattice to allow significant atomic rearrangement by diffusional processes. Today, the molecular-dynamic simulations of large cascades and much circumstantial experimental evidence strongly support the spike concept.

After a time of about 3 ps, the central molten spike zone rapidly cools and solidifies, attaining ambient temperatures after about 10 ps. In principle, both phonons and hot electrons can contribute to the heat dissipation from the hot spike core. In simple metals such as Cu or Al, however, the elec-

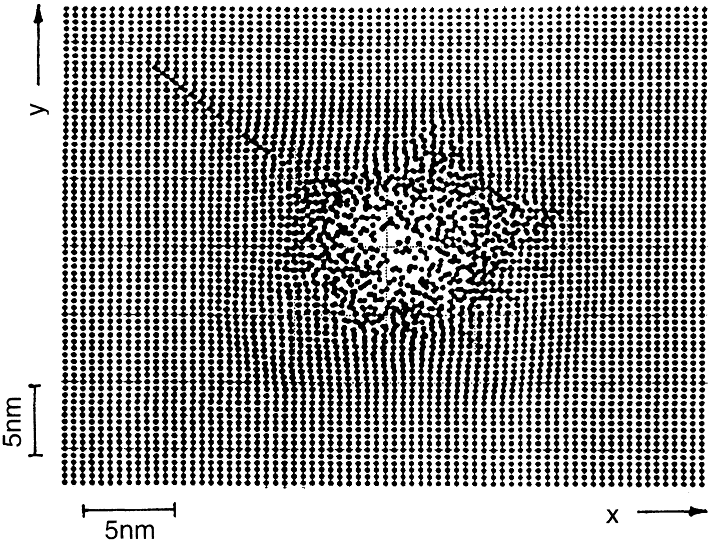

FIG. 4. Atomic configuration at 1 ps after a 10-keV PKA event in Au. The atom positions within a cross-sectional slab of three atomic planes near the spike center are projected on a {100} plane. Molecular dynamics simulations (MDS) by Ghaly and Averback (private communication). Note that the computer print shown has slightly different scales in the *x* and *y* directions of the atomic positions. By an inclined viewing of the graph the shock front and the wave along the RCSs are clearly visible.

tron-phonon coupling is too weak for the electrons to contribute to spike cooling. In other materials such as Ni, Fe, or alloys, the question whether electrons or phonons dominate the cooling rate is still open. During the rapid cooling of the spike, with rates of the order of some 10^{14} K/s, the interface between the central molten spike core and the surrounding crystal must regress with a very high velocity, of the order of the velocity of sound. This can only be achieved by a high degree of undercooling of the spike, of the order of $0.3T_m$. Only in simple lattice structures like fcc or bcc metals can atoms manage to rebuild the original crystal structure epitaxially at such high speeds. In more complicated structures, e.g., in ordered alloys in which the atoms occupy different sublattices, in compound semiconductors, or in oxides, the original crystal structure cannot regrow so quickly and a highly disordered nonequilibrium phase is frozen in. In most semiconductors (see, e.g., Fig. 5 for Si) and many oxides, e.g., SiO_2, an amorphous phase is usually produced by cascade damage. Intermetallic compounds tend to become amorphous under irradiation if their ordering energy is high but only chemically disordered if their ordering energy is low.

Because of the ejection of interstitials, the spike core will be depleted of atoms also after its solidification. During the rapid cooling the "free volume" existing in the spike is driven toward the center in a way resembling zone refining. Consequently, a compact vacancy-rich zone is formed at the end of the cooling process ("depleted zone"). Experimental investigations using field-ion microscopy, transmission electron microscopy, and

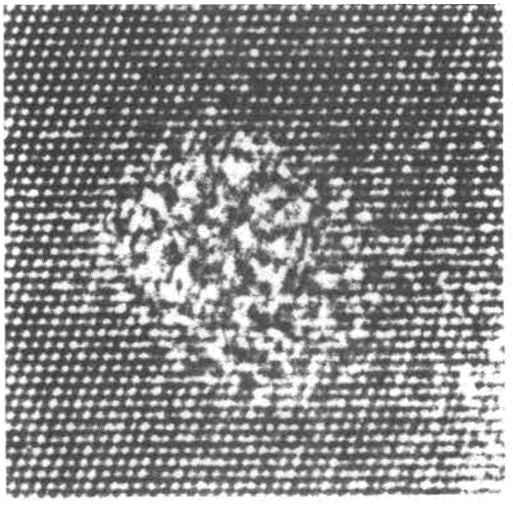

FIG. 5. High-resolution TEM micrograph of a cascade produced in Si by implantation of a 100-keV Bi^+ at 77 K. The amorphous zone in the center of the {111} slab has a rather sharp boundary. The surrounding lattice contains considerable disorder in form of disrupted ⟨110⟩ atomic chains. (From Narayan *et al.*, 1985.)

diffuse x-ray scattering have verified this structure. Since interstitials cannot survive within the initially very hot spike center, all interstitials present at the end of the spike cooling must reside at the periphery of the cascade. Figure 6 illustrates schematically the resulting defect arrangement.

Another fundamental feature of the defect arrangement produced by displacement cascades is the formation of subcascades. As illustrated in Fig. 7, for recoil energies above a critical value T_{sc}, the collision cascade branches into individual subcascades. The basic reason for the branching is that the average distance traveled by a recoil atom between energetic secondary recoil collisions increases rapidly with increasing recoil energy. When this distance is larger than the linear dimension of the secondary cascades, subcascade formation is inevitable. The formation of subcascades is, however, a statistical process and fluctuates strongly from one displacement event to the other. According to the laws for the stopping of self ions, T_{sc} depends sensitively on PKA mass; e.g., $T_{sc} \approx 25$ keV for Cu and 170 keV for Au. The average number n_{sc} of subcascades per PKA is approximately given by $n_{sc} \approx T_{\text{dam}}/T_{sc}$. This linearity suggests that at higher recoil energies subcascades can be considered as new independent damage units. For light materials, e.g., Al or Si, where $T_{sc} < 1$ keV, the spike concept is no longer applicable, because too few atoms are contained in each subcascade to establish a liquidlike core with a clear transition region to the surrounding crystalline lattice.

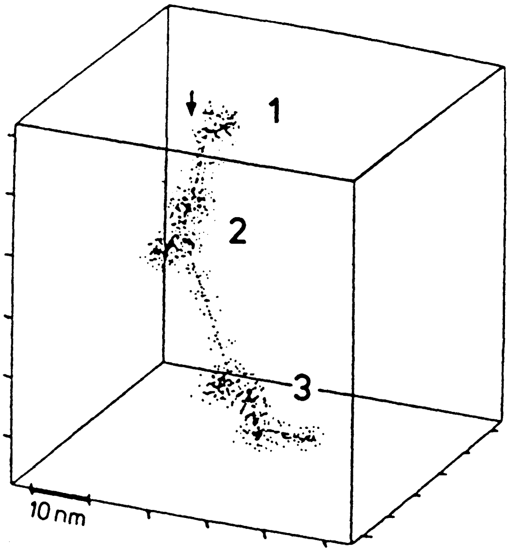

FIG. 7. Three-dimensional view of a 100-keV collision cascade in Cu ($T \approx 4T_{sc}$) generated by the MARLOWE computer code (after Heinisch, 1990). The dots represent vacancies as well as displaced atoms. All displaced atoms having a distance less than 0.8 nm to a vacancy have been eliminated from this plot (simulating spontaneous recombination). Three well separated subcascades (1 to 3) are recognized; subcascade 2 and 3 each have three lobes.

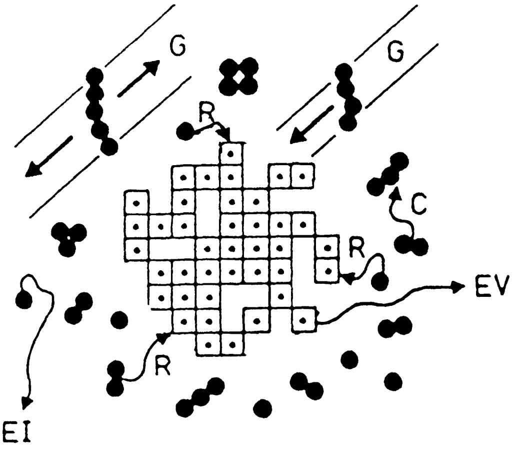

FIG. 6. Schematic representation of the defect arrangement in a displacement cascade showing the vacancy-rich core (depleted zone) and the interstitial shell containing single-, di-, tri-, ··· interstitials up to small loops. The possible interactions during defect migration are indicated as follows: R = intracascade recombination, G = glide of small interstitial loops toward, or bypassing, the depleted zone, leading to intracascade recombination or interstitial escape, respectively. EV and EI denote escaping vacancies and interstitials, respectively. C denotes intracascade clustering of interstitials.

For a quantitative characterization of the total number $\nu(T)$ of vacancies or interstitials produced per PKA of energy T, a damage efficiency is defined, i.e., $\xi(T) = \nu(T)/$dpa. As shown in Fig. 8, at $T > T_{sc}$ the damage efficiency attains a constant value ξ_{fn} of about 0.25, that is most characteristic for fast neutrons (hence the subscript) and reflects the fact that the subcascades contribute independently to the defect production. This low value shows that the energy necessary to produce a stable Frenkel defect in a cascade is about 3 to 4 times larger than in isolated low-energy recoil events and reflects

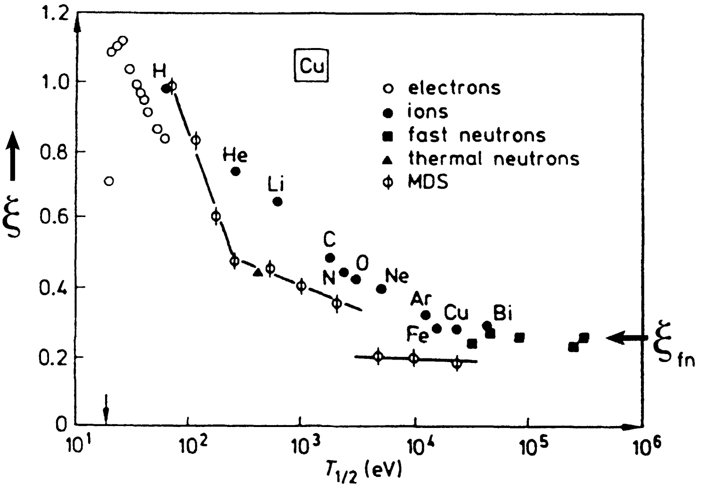

FIG. 8. Damage efficiency ξ (i.e., stable FD produced per dpa) as a function of the median recoil energy $T_{1/2}$ in copper, deduced from resistivity measurements on specimens irradiated with different particles at 4.2 K. Compilation of data by Averback *et al.* (1978) and Kinney *et al.* (1984), using T_d = 30 eV (see arrow on abscissa) and a Frenkel-pair resistivity ρ_F = 2.5 $\mu\Omega$ m. The symbols connected by the solid lines give results from MDSs by Foreman *et al.* (1992) and by Diaz de la Rubia and Guinan (1991), respectively. For the irradiations with heavy ions, e.g., 500-keV Cu, $T_{1/2}$ refers to the (secondary) recoils giving partly overlapping DCs. If the implanted ion is counted as a PKA the datum point for Cu must be plotted at $T_{1/2}$ = T_{dam} = 240 keV (from Schilling and Ullmaier, 1993).

the fact that for cascade damage only interstitials ejected far from the core of the cascade can survive. All atoms displaced within the spike core will end up at lattice sites during the resolidification process.

Similar to the efficiency for the production of interstitials and vacancies, efficiencies for disordering or amorphization by displacement cascades can be defined. These efficiencies, η_{diso} and η_{amo}, give the number of atoms contained in disordered or amorphous zones per dpa, respectively. Typical values of η_{diso} and η_{amo} are 10–30 dpa^{-1}, demonstrating a very efficient local atomic mixing within the spike, in comparison to typical efficiencies $\xi \approx 0.2$ to 0.4 dpa^{-1} for Frenkel defect production.

1.4 Ionization-Induced Defect Production

In addition to the elastic collisions, electronic excitations can also lead to permanent atom displacements in many inorganic insulators including alkali halides, alkaline-earth halides, silver halides, and several carbonates and silicates. This process, called radiolysis, results from the decay of excitons generated by the ionizing radiation. For radiolysis to occur with significant efficiency, the electronic excitations must have energies in excess of Frenkel-defect formation energies, and an efficient means for transferring the stored electronic energy into atomic motion must be available. The details of this conversion mechanism are best understood for the alkali halides (Fig. 9). A characteristic feature of this process, as shown in the figure, is that only one sublattice is involved in the formation of the Frenkel pairs. For the alkali halides, quantum efficiencies for this exciton decay mechanism as high as 0.8 have been reported; however, only a small percentage of the associated recoil processes actually lead to stable Frenkel pairs. In KCl, an average energy of $\approx 10^3$ eV is absorbed before a stable Frenkel pair is formed, and even larger amounts of energy are required for many other crystals. Nevertheless, the radiolytic process can often far exceed the defect production by atomic collisions, e.g., during irradiations in the electron microscope. There are obvious similarities between this process and the photographic process in AgBr; however, the latter process involves the presence of the surface. Other beneficial applications of radiolytic defect production include photochromic materials, crystal memories, and color centers in tunable lasers.

Completely different mechanisms of defect creation have been observed for the very high local electronic excitations achievable by GeV heavy-ion bombardment. Under these conditions the electronic energy loss of the particle is much larger than the nuclear stopping:

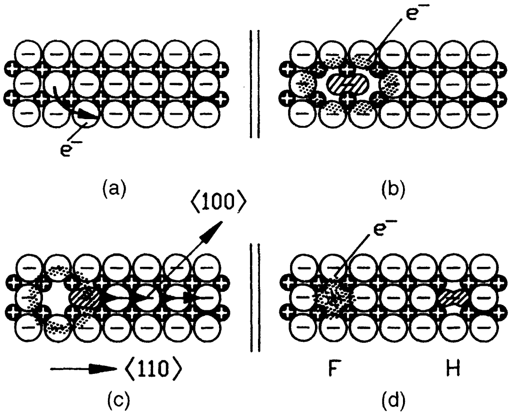

FIG. 9. Schematic view of the different steps of the radiolysis process in the (100) plane of an alkali halide with NaCl structure. (a) Ionization of an anion that yields an electron-hole pair (exciton). (b) Relaxation of the hole into the self-trapped configuration (X_2^- molecular ion on the halogen sublattice). The electron remains in a diffuse hydrogenic orbital. (c) Asymmetric decay of the exciton and initiation of a replacement collision sequence along ⟨110⟩ (or, not shown, an off-center rotation of the X_2^- molecule out of the plane). (d) Final configuration of the Frenkel pair, consisting of a so called *H* center (neutral anion interstitial) and *F* center (anion vacancy with neutral effective charge).

$$\left.\frac{dE}{dX}\right|_e \geq 2000 \left.\frac{dE}{dX}\right|_n \approx 1\ \text{keV/Å}.$$

Although the details of the damage process are still unresolved, the basic effect involves a Coulomb explosion caused by the electrons being scattered out of the track of the fast ion and subsequent rearrangement of the remaining positive ions. In many insulators, for example, amorphous tracks with diameters typically 6–10 nm along the ion paths are produced. By chemical etching, these tracks can be enlarged to diameters in the μm range, and homogeneous "nuclear track filters" can be manufactured. The ion tracks have also been shown to act as pinning centers for flux lines in ceramic high-T_c superconductors. Recently, ion tracks have even been observed in semiconductors (Fig. 10) and in intermetallic alloys.

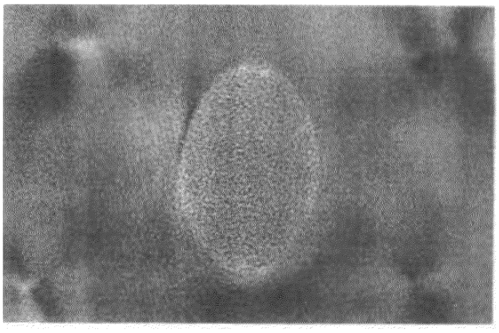

FIG. 10. High-resolution electron micrograph of an amorphous ion track in single-crystalline GeS after bombardment with 1.4-GeV U ions. The direction of the ion beam was perpendicular to the image plane and the sample has been thinned to obtain transparency for the electrons. The elliptical shape of the track (24 nm high and 16 nm wide) correlates with the anisotropy of the orthorhombic crystal (from Scholz *et al.*, 1993).

2. DEFECT MIGRATION AND REACTIONS

The primary defect arrangement considered in Sec. 1 can only be studied if the defects are frozen in during an irradiation at low temperatures. At higher temperatures, the radiation-induced interstitials and vacancies become mobile. They can then react either with each other, with impurities, or with extended sinks such as dislocations, grain boundaries, or free surfaces. In the following sections, we first review the basic information available on interstitial and vacancy mobilities and then discuss the reactions of the mobile defects in typical recovery experiments. Finally, we focus on the microstructures that evolve from defect reactions during long-term irradiations.

2.1 Jumps of Interstitials and Vacancies

Atomic motion in crystals nearly always involves jumps of interstitials or vacancies between neighboring equilibrium positions. Such jumps are activated by thermal fluctuations with a jump rate $\nu_X = \nu_0 \exp(-E_X^m/kT)$ where E_X^m is the activation energy for the jump of defect X, ν_0 is the attempt frequency, and T in this case is the absolute temperature. Using a typical value of $\nu_0 \approx 10^{13}\ \text{s}^{-1}$, one arrives at a rule of thumb for the temperature T_X^a at which the defect X can perform one jump per second of $T_X^a = (380\ \text{K/eV})E_X^m$. Typical migration energies for interstitials and vacancies are listed in Table 2. These values have usually been inferred from kinetic studies of the defect recovery after irradiation or quenching (see Sec. 2.2).

For vacancies the atomic jump mechanism is simple: a neighboring atom jumps into a vacant lattice site. In contrast, the jump mechanism for self-interstitial atoms is rather complicated, and presently it is known only for metals. In this case, the interstitials migrate by a collective process involving the interstitial dumbbell atoms and their neighbors, as shown in Figs. 11(a) and 11(b). The center of the dumbbell moves one nearest-neighbor distance while the axis of the dumbbell rotates into another crystallographic direction. Note that each atom within the interstitial configuration moves only a small distance during the jump in comparison to the translation of the interstitial center. This fact, together with a kind of local shear instability (due to the high local compression of the atoms in the interstitial configuration), accounts for the unusual low migration temperatures $T_i^a < 100$ K of interstitials in metals. In some metals, such as Au, Nb, or Cd, interstitials even migrate below 1 K, possibly under the influence of zero-point fluctuations (tunneling). Small agglomerates of interstitials can migrate at low temperatures by similar collective processes.

Interstitials and vacancies in elemental semiconductors also have low migration energies, but in III-V and II-VI semiconductors defect motion on one sublattice appears to be hindered by the presence of atoms on the other sublattice, resulting in higher migration energies—see Table 2.

For defects in nonmetals, saddle-point configurations like their equilibrium structures depend on their charge state. Therefore the same defect may have quite different migration energies in different charge states, i.e., at different positions of the Fermi level (see, e.g., the values for *n*-Si and *p*-Si in Table 2). In addition, the strong influence of the charge state on the atomic displacements at the defect center is indicative of a strong local coupling between the electrons and phonons. This coupling creates the possibility of inducing defect jumps, even at 0 K, by cycling the defect between different charge states, e.g., by successively capturing free electrons and holes in an ionizing irradiation field or during carrier injection. The electronic energy released by the electron-hole recombination is then funneled into local atomic motion which, like thermal agitation, can induce a jump of the defect into a neighboring equilibrium position. Another possibility for athermal defect migration is the Bourgoin–Corbett mechanism. In this case, the saddle-point configuration of the defect in one charge state is centered at the equilibrium site of the same defect in another charge state and vice versa. Hence, changing the charge state brings the defect from its initial equilibrium position into the saddle-point configuration of the other charge state, from where it can relax into the adjacent new equilibrium position. Cycling between two charge states can thus induce long-range defect migration, even at 0 K. A classic demonstration of athermal defect motion was performed in a series of electron paramagnetic resonance experiments (Watkins, 1975). They showed that silicon interstitials produced by electron irradiation in *p*-type silicon at 4.2 K migrated over long distances to substitutional Al impurities where they were converted and detected as Al interstitials.

2.2 Defect Recovery

Reactions among radiation-induced interstitials and vacancies can be classified as recombination, clustering, and impurity trapping. These reactions are commonly studied in recovery or annealing experiments. For

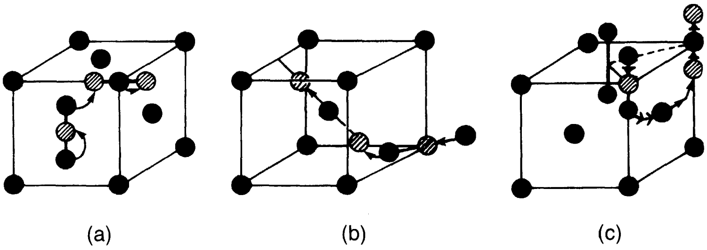

FIG. 11. Migration of (a) the ⟨100⟩- and of (b) the ⟨110⟩-split single interstitial in fcc and bcc metals, respectively. The configurations after the jump are indicated by the shaded atoms. (c) Migration of a di-interstitial (two parallel ⟨100⟩ dumbbells on nearest-neighbor sites) in the fcc lattice by a two-step jump of one of the dumbbells.

these experiments, the defects are first introduced by irradiation at low temperatures. Subsequently, the samples are warmed in a controlled manner, and the change in the defect population is monitored by measurements of suitable physical properties such as residual electrical resistivity in metals and thermal conductivity or optical absorption in semiconductors and insulators. A typical recovery curve for metals is shown in Fig. 12. It exhibits a number of annealing stages labeled stage I through stage V. After a long-lasting controversy, the following assignment of defect reactions to these stages is now widely accepted:

Stage I: In this stage, interstitials recombine either with their own vacancies or with another vacancy after free migration through the lattice. In addition to recombination, freely migrating interstitials can also form clusters or be trapped at foreign atoms. These latter two processes are responsible for the incomplete recovery in stage I (see Fig. 12). Recall that in cascades, interstitials and vacancies are separated (see Fig. 6) so that interstitial clustering reactions are strongly favored. This explains why defect survival is much larger for fast-neutron–irradiated samples than for electron-irradiated ones. After electron irradiation, stage I shows a number of substages, $I_{A,B,C}$, which are due to the collapse of close Frenkel pairs. As indicated in Fig. 13, the attractive interaction between the defects lowers the activation barrier for the jump of the interstitial toward the vacancy. Substage I_D results from the recombination of the free migrating interstitials with their own vacancies (correlated recombination) whereas substage I_E results from the free migrating interstitials recombining with distant, foreign vacancies. The latter process requires a larger number of jumps and, therefore, somewhat higher annealing temperatures. Some metals such as Au, V, Nb, or Cd do not show a well-defined annealing stage I. In these metals, it has not been possible to freeze in isolated interstitials even at the lowest irradiation temperatures, e.g., 0.3 K for Au.

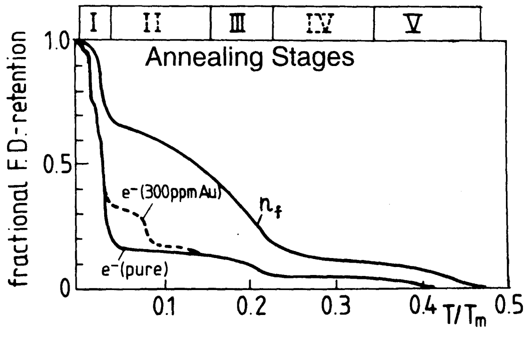

FIG. 12. Frenkel-defect retention in Cu irradiated at 4 K with fast neutrons (n_f) or 3-MeV electrons to about 10^{-5} dpa after 10-min isochronal annealings at increasing homologous temperatures (T/T_m). The dashed line indicates the influence of alloying with 300 ppm Au. The roman numerals and boxes show the common labeling and extent of the major recovery stages.

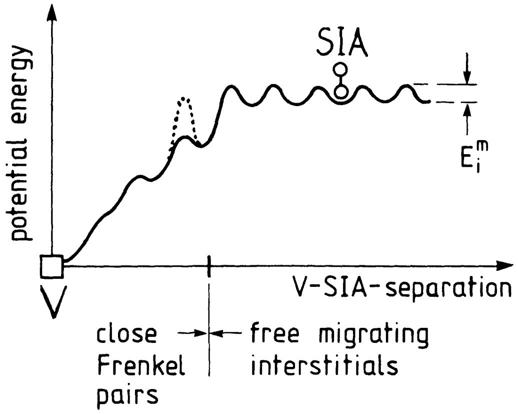

FIG. 13. Schematic representation of the potential energy of a Frenkel pair as a function of separation between the vacancy (V) and the self-interstitial (SIA) atom for metals (solid line) and semiconductors (dashed line).

Stage II: Stage II refers to the interval in temperature between the generic recovery stages I and III, but, for historical reasons, it is also called "recovery stage." In this temperature interval, interstitial clusters grow to larger sizes by mutual coalescence, a process that continues up to recovery stage V. In impure samples, interstitials that were trapped at impurities in stage I can be detrapped. This leads to distinct substages within recovery stage II (see Fig. 12).

Stage III: In this stage, vacancies begin to migrate and to annihilate at the interstitial clusters. Vacancy agglomeration also begins. If these vacancy clusters survive (together with interstitial loops) at the end of stage III, the recovery is not complete. On the other hand, some metals such as Al, Pt, and Au (only after electron irradiation) do show complete recovery. In these metals, apparently too high losses of mobile single and multiple vacancies at the interstitial clusters prevent the nucleation of stable vacancy agglomerates.

Stage IV: Similar to stage II, this is not a unique recovery stage but rather the interval between stage III and V. In this temperature interval, the vacancy clusters surviving stage III grow in size by mutual coalescence or by an Ostwald ripening process.

Stage V: In this stage, defect clusters thermally dissociate. The evaporation of single vacancies that annihilate the interstitial loops is generally the dominating annealing process and all radiation-induced Frenkel defects are removed at the end of the stage.

In contrast to metals, there is no comparable systematic understanding of the evolution of the overall defect pattern during annealing of irradiated semiconductors and oxides. The complexities stemming from athermal and charge-dependent thermal-defect mobilities and the formation of many different defect–impurity complexes (samples used for spectroscopic studies of defect recovery must unavoidably contain only very small defect concentrations) make it difficult to identify the intrinsic recombination and clustering processes of Frenkel defects. The general trend in these materials, however, is that clustering of interstitials and vacancies is more difficult than in metals, because of the long-range electrostatic repulsion of defects with equal charges (see also Sec. 2.3). In a similar vein, the recombination between interstitials and vacancies also seems often to be suppressed by the existence of deep trapping positions for interstitials near vacancies (see Fig. 13). In this case, the interstitials can overcome the final barrier for recombination with the vacancy only at higher temperatures than the temperatures at which they migrate freely.

An important aspect of interstitial trapping at impurities is the possible enhancement of impurity diffusion by the so-called kick-out mechanism. Upon trapping of a self-interstitial atom, a substitutional impurity can be "kicked out" into an interstitial site. If the so-formed interstitial impurity is able to jump from one interstitial position to another (without decaying again into a substitutional impurity plus self-interstitial), impurity diffusion can be dramatically enhanced. Examples for rapid radiation-induced diffusion via the kick-out mechanism are Ni(Si), Au(Fe), Si(Al), and Si(B).

2.3 Secondary Radiation-Induced Defects

Under prolonged irradiation at elevated temperatures, a large variety of secondary defects is observed in all kinds of materials. Examples are shown in Fig. 14. These secondary defects result from the aggregation of mobile interstitials and vacancies created continuously as primary defects by the displacement process. In contrast to the defect clusters that form in a typical recovery experiment (see Sec. 2.2), the interstitial and vacancy agglomerates considered here as secondary defects are much larger.

Interstitial-type secondary defects always have planar character (see Fig. 15). By forming a piece of a new lattice plane that is confined by an edge-dislocation loop, the interstitials are able to relieve most of their strain energy. In metals, the interstitial loops tend to precipitate on the most densely packed planes, e.g., on {111} planes in fcc and on {110} planes in bcc metals. Small loops contain an extrinsic stacking fault. In materials with high stacking-fault energy, large loops tend to unfault and are then called perfect loops [see Fig. 15(b)].

In Si and Ge, interstitial-loop morphologies that result in a minimum number of dangling bonds are observed: rodlike ⟨110⟩ dislocation dipoles and faulted loops on {311} planes.

In polyatomic nonmetals, the precipitation of interstitials requires that both stochiometry and sublattice order must be conserved on the new lattice planes. In MgO or NaCl, this requirement leads to the formation of two-layered loops on {110} planes, as illustrated in Fig. 16. The formation of such two-layered interstitial loops requires equal numbers of anions and cations to precipitate. Since most irradiation conditions—especially radiolyses—produce many more anion than cation interstitials, there must be some mechanism operating by which the missing cations are supplied for the loop formation. In the mechanism proposed by Hobbs *et al.* (1973) and outlined in Fig. 16,

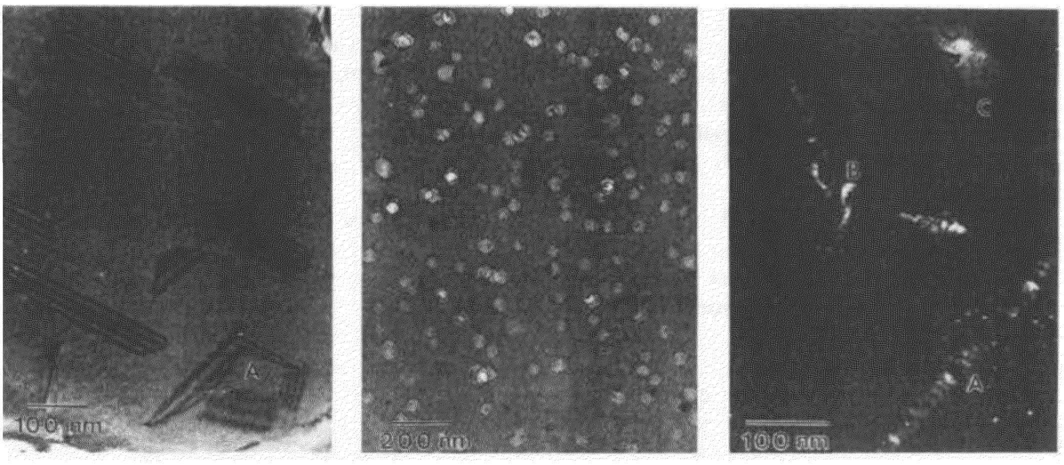

FIG. 14. TEM micrographs of typical radiation-induced secondary-defect structures in metals (W. Kesternich, private communication). Left: faulted interstitial dislocation loops produced in a NiCr-Mo alloy by irradiation with 28-MeV α-particles (dose 3.5×10^{21} α/m^2) and annealing at 750 °C. The loops are cut off by the back and front surfaces of the TEM sample. At *A*, loops on all four possible variants of {111} planes can be recognized under the ⟨110⟩ illumination of the sample. Middle: Phase-contrast picture of faceted voids in Al produced by irradiation with fast neutrons (dose 4.5×10^{25} n/m^2) at 55 °C. Right: radiation-induced Ni_3Si precipitates produced in a Ni-8%Si alloy by irradiation with 28-MeV α particles (dose 3×10^{21} α/m^2) at 475 °C. Bright-field contrast using a superlattice reflection of the ordered precipitates. At positions A, B, and C the precipitates were formed by dragging of Si atoms to grain boundaries, network dislocations, and dislocation loops, respectively.

the cations incorporated into the two-layered loop are supplied by the formation of an equal number of anion antisite defects in the surrounding lattice. To make the energetics favorable, the anion antisites form molecular bonds with neighboring anions on a lattice site.

Vacancy-type secondary defects—in contrast to the interstitial ones—may have different morphologies. One morphology is again a planar condensation of vacancies as a dislocation loop, now encircling a piece of a missing lattice plane [Figs. 15(c) and 15(d)]. In metals with low stacking-fault energy, like Au, stacking-fault tetrahedra may be energetically more favorable than planar loops. Most important, however, is the formation of three-dimensional vacancy ag-

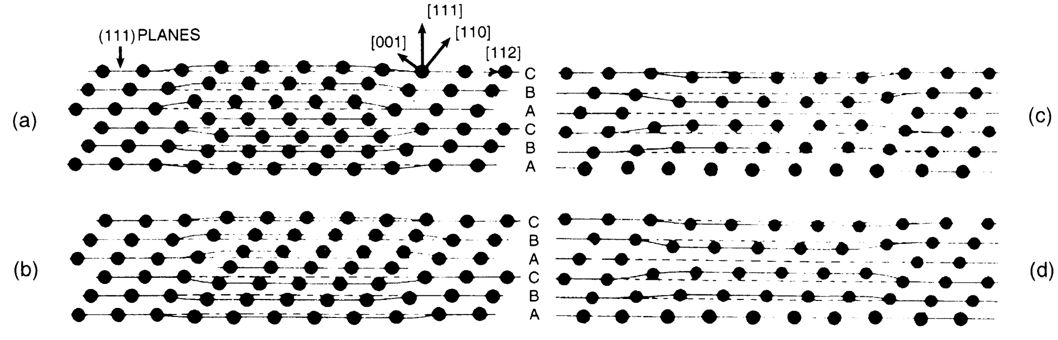

FIG. 15. Cross section along a {110} plane through interstitial- and vacancy-type dislocation loops in an fcc metal. The stacking of {111} planes in the fcc lattice is denoted by ABC. . . . (a) The additional interstitial atoms form a faulted loop with Burgers vector $b = \frac{1}{3}a$ [111]. (b) Perfect interstitial loop with $b = \frac{1}{2}a$ [110]. The stacking fault has been removed by shearing the atomic arrangement by $\frac{1}{6}a$ [112]. (c) Faulted vacancy loop created by removing atoms from a {111} plane. Note the intrinsic stacking fault. (d) Perfect vacancy loop.

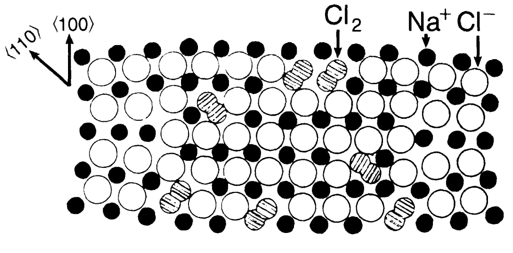

FIG. 16. (001) section through an interstitial dislocation loop with Burgers vector $\frac{1}{2}a\langle 110\rangle$ in NaCl. The two-layered loop contains equal numbers of cations and anions. To form the loop by the condensation of Cl interstitials alone, according to the Hobbs mechanism, the needed Na ions are supplied by the formation of equal numbers of Cl_{Na} antisite atoms shown as Cl_2 molecules replacing a substitutional NaCl molecule.

glomerates in the form of bubbles or voids. Such three-dimensional agglomerates are not possible for interstitials because of strain-energy considerations. In the early stage of the nucleation of voids, some gaseous impurities, such as fission gases, helium atoms from (n,α) reactions, or self-gas molecules (in oxides and halides) are necessary to prevent the collapse into a planar loop. The distinction between void and bubble derives from the gas pressure p_C inside the cavity. If $p_C < 2\gamma/r_C$ the cavity is called a void; otherwise it is a bubble. γ is the specific surface energy and r_C the cavity radius. The anisotropy of γ causes faceting of the voids along crystallographic planes with the lowest surface energy [see Fig. 14(b)].

In polyatomic nonmetals, void formation like planar defects requires the condensation of equal numbers of vacancies on all sublattices in stoichiometric proportions. In spite of this complication, three-dimensional vacancy agglomerates are frequently observed, e.g., in oxides and halides. This is true even under situations where practically only anion vacancies are produced by the irradiation. In this case, colloids are often formed. They can be considered as a local condensation of anion vacancies of neutral effective charge (i.e., containing a trapped electron) with the remaining cations precipitating out as small metal particles. Another possibility is the formation of pressurized self-gas bubbles. Such bubbles can result, e.g., from the precipitation of the molecular anion antisite defects, e.g., Cl_2 produced along with the interstitial loops.

In a broader sense, radiation-induced phase changes such as amorphization and precipitation of alloying atoms should also be included as possible secondary defect structures. For example, even if there is no direct amorphization within displacement cascades, an accumulation of disorder produced by electron irradiations of intermetallic or nonmetallic compounds may trigger a transformation of the damaged lattice into an amorphous phase after a critical irradiation dose has been achieved. In many metallic alloys, a local redistribution of their constituents is observed under irradiation. Examples are the dissolution of small, thermally stable precipitates by the atomic mixing action of displacement cascade or the precipitation of nonequilibrium phases at point-defect sinks, such as grain boundaries, dislocations, and surfaces (radiation-induced segregation; see, e.g., Fig. 14). This precipitation results from the interaction of the impurities with the migrating interstitials and/or vacancies so that the impurities are efficiently dragged to the sinks where they accumulate and finally precipitate.

2.4 Microstructural Evolution during Long-Term Irradiations

The entirety of the secondary defects, together with the network of dislocations, grain boundaries, and precipitates, comprises the microstructure of an irradiated material. Its evolution during long-term irradiations depends on the irradiation conditions (temperature, type, and flux of irradiation particles) and on the sample history (cold worked, annealed, impurity content, etc.). With such variable conditions, quite different scenarios for the buildup of the secondary defects can be envisaged, and, indeed, a large variety of different radiation induced microstructures is observed.

To predict the evolution of radiation-induced microstructures, one must model the nucleation, growth, and final interaction of the different types of secondary defects, taking into account the supersaturations of mobile interstitials and vacancies (and often gas atoms; see Sec. 1.1) that are created continuously as primary defects by the ongoing irradiation. This is a very complicated problem, because the defect supersaturation depends sensitively on the irradiation parameters and on the density and distribution of internal sinks, including the secondary defects that have accumulated from the beginning of irradiation. The usual procedure is to approximate the spatially and temporally discrete events of defect introduction and defect losses by a continuum description using chemical rate equations. This results in a large set of coupled nonlinear first-order differential equations for the time-dependent concentrations of all the different primary and secondary defects. Such equations are difficult to handle, and, quite often, they obscure the basic physics involved. In view of this complexity, we do not include elemental redistributions in the following comments.

In most technical applications, the irradiations are performed at temperatures at which the radiation-induced interstitials and vacancies are both thermally mobile. These primary defects will then either recombine locally at an antidefect generated in the same displacement event, or escape their birthplace before this region suffers another displacement event. The latter defects are called escaping interstitials and vacancies, and only these defects contribute to the microstructural evolution. Typical efficiencies for the production of escaping interstitials and vacancies are $\sim 0.5\xi_{fn}$/dpa.

After the start of an irradiation, there is always a short transient period in which the concentration of mobile defects first increases and then quickly approaches a stationary value. After this transient, the number of escaping defects that are lost per unit time by mutual recombination or annihilation at sinks equals the rate at which they are produced. (This does not mean, however, that at lower irradiation temperatures Frenkel defects can accumulate indefinitely. In this case, Frenkel defect concentrations saturate at atomic fractions $\sim 10^{-3}$ because of spontaneous recombination processes from overlapping cascades.) The time necessary to establish stationary concentrations of escaping defects is of the order of the migration time of the defects to their sinks. Since interstitials generally move much faster than vacancies, the stationary concentrations of escaping vacancies are orders of magnitude higher than those of the escaping interstitials.

After quasisteady state has been established, there are two limiting cases for the subsequent microstructural evolution: At lower and at very high (typically $>0.6\ T_m$) irradiation temperatures, recombination is the dominant loss mechanism for defects (recombination-dominated regime). Here the stationary concentrations of either the escaping or thermal-equilibrium vacancies are much larger than those of the other interstitial sinks. Therefore, the escaping interstitials will primarily recombine at vacancies, and only a few of them will arrive at fixed sinks. In this situation, the microstructural evolution is drastically slowed down.

At intermediate temperatures ($0.3 < T/T_m < 0.6$ in metals), on the other hand, the stationary vacancy concentration is much smaller than that of the other sinks. Then, practically all escaping defects will arrive at secondary defects or other sinks (sink-dominated regime), and they will contribute to the further evolution of the microstructure. Although the escaping defects are collected at the sinks in this case, the structure of these sinks changes only slowly. The reason is that escaping interstitials and vacancies are produced in equal numbers by the displacement events and, therefore, equal numbers of interstitials and vacancies must also arrive at the sinks. Thus, given only one type of sink, e.g., only dislocations or only voids, equal numbers of atoms will be added as interstitials and removed by vacancies. On the average, therefore, no climb of the dislocation or growth of the void can occur. A change in the microstructure can occur only if atoms are redistributed between different sinks under the steady supply of arriving interstitials and vacancies. The basic reason for this redistribution is that some sinks can capture interstitials more efficiently than vacancies. This bias in the sink action may have different origins. For example, dislocations, which have long-range stress fields, will elastically interact more strongly with interstitials than with vacancies, because of the larger lattice strains produced by interstitials. Cavities, on the other hand, which have only small stress fields, will capture interstitials and vacancies with similar efficiencies. If both types of sinks are present, as outlined in Fig. 17(a), there will be an imbalance in

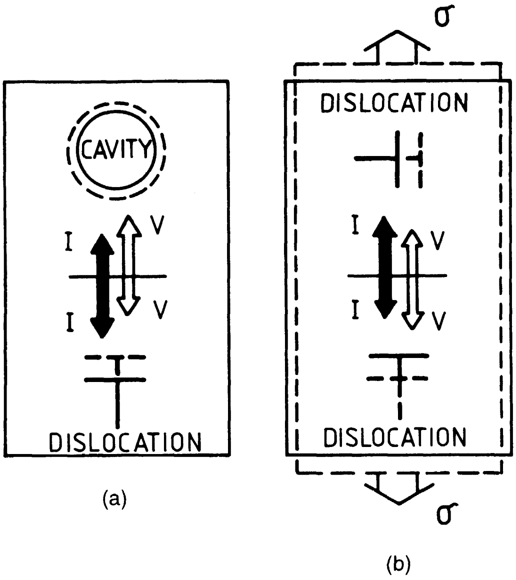

FIG. 17. Schematic representation of the partitioning of the fluxes of radiation-induced interstitials (filled arrows) and vacancies (empty arrows) to different sinks. (a) Cavities and dislocations as sinks: cavities grow by receiving more vacancies than interstitials. (b) Dislocations in different orientations with respect to a uniaxial external stress σ. At $\sigma = 0$: no climb. At $\sigma > 0$: dislocations climb producing a sample elongation along and a shrinkage perpendicular to the stress axis.

the individual fluxes of interstitials and vacancies to dislocations and cavities. As a consequence, the dislocations will climb and the voids will grow (see Sec. 3.1.2). Another reason for a "bias" in the capture of mobile defects may be a poisoning of sinks by deposited impurities or the existence of an asymmetric stress field. As outlined schematically in Fig. 17(b), such a stress field causes elastic polarization effects at the interstitials moving in different directions with respect to the stress axis. This polarization gives rise to different climb velocities of differently oriented dislocations and thus to in-pile creep (see Sec. 3.1.3). Especially large bias effects are expected when the mobile interstitials move one-dimensionally via small glissile loops, since these loops can be attracted at rather large distances from existing line dislocations or larger sessile loops. The rapid growth of these interstitial loops results in a partial incorporation of them into existing grain boundaries and/or their mutual entanglement. The associated dislocation annihilations lead to the formation of a stationary density of network dislocations, independent of the initial dislocation content of the sample. Stationary dislocation densities of the order of 10^{14}–10^{15} m^{-2} are observed in quite different materials under a large variety of irradiation conditions.

Frequently, self organization of the secondary defects is observed during prolonged irradiations. Examples are the formation of dislocation cell structures and defect walls [Fig. 18(a)], the ordering of voids [Fig. 18(b)] and bubbles in the form of a superlattice, and periodic precipitate patterns in decomposing alloys. As in other self-organization phenomena, this instability of the defect pattern arises under special circumstances because of a nonlinear feedback in the defect reactions and because the system is "thermodynamically open," i.e., because a significant amount of energy is pumped continuously into the system by the irradiation.

3. CHANGES OF MACROSCOPIC PROPERTIES

3.1 Metals and Alloys

3.1.1 Hardening and Embrittlement at $T \leq 0.35T_m$ It is often found that the yield stress σ_Y of metals and alloys increases considerably upon irradiation. The increase in yield stress σ_Y, or "radiation hardening," saturates at doses above some dpa. In contrast, the ultimate tensile stress σ_{UTS} increases much less and the work-hardening coefficient is only slightly decreased. The consequence is a reduction in the strain to fracture, ϵ_u, i.e., a loss in ductility upon irradiation (Fig. 19).

In fcc metals and alloys such as austenitic stainless steels, radiation hardening in the temperature range considered is attributed to dislocation loops at low doses and network dislocations at higher doses, acting as obstacles for dislocation movement. Employing dispersed-barrier hardening models, a reasonable agreement between the observed change in microstructure and the measured increase in yield stress can be achieved.

The often very complex behavior of bcc metals and especially alloys such as ferritic/

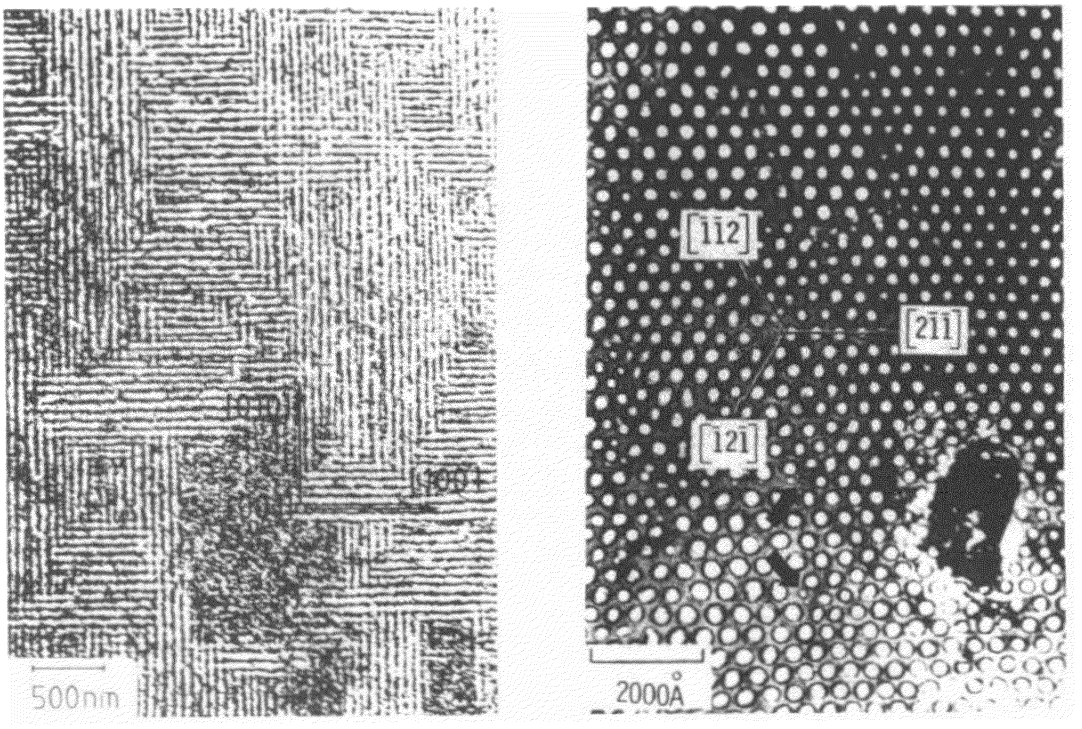

FIG. 18. TEM micrographs of ordered defect structures: (a) {100}-planar defect arrangement produced in copper under 3-MeV proton bombardment at 100 °C to 2 dpa. Regions of high cluster density appear dark (after Jäger *et al.*, 1988). (b) Void lattice in niobium irradiated with 7.5-MeV Ta^+ ions at 800 °C to 300 dpa (after Kulcinsky and Brimhall, 1973). Arrows indicate crystallographic directions within the plane of the micrograph.

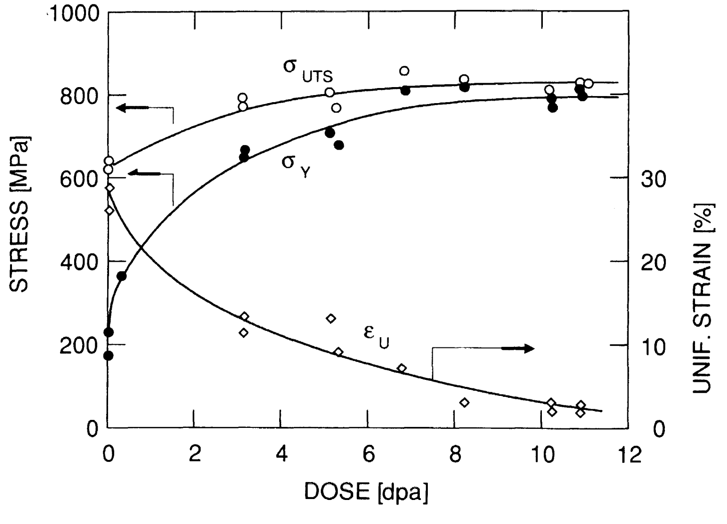

FIG. 19. Yield stress σ_Y, ultimate tensile stress σ_{UTS}, and uniform ductility ϵ_u as a function of dose of type 316 austenitic stainless steels, *neutron irradiated and* tested at 250 °C (after Elen and Fenici, 1992).

martensitic steels or Mo alloys is more difficult to analyze because of two main problems. In most bcc metals, the minor alloying or impurity elements (C, N, O, S, P, Cu, Ni, etc.) have a large influence on both the radiation behavior and the mechanical properties. The other problem is the strong increase of σ_Y with decreasing temperature which is due to the low mobility of screw dislocations in the bcc structure and often interferes with alloy or radiation hardening in a nonadditive way. The bcc-intrinsic low-temperature hardening is also the reason for the well-known ductile-to-brittle transition at a temperature DBTT, below which the yield stress exceeds the (almost temperature independent) cleavage stress. The material then fails by brittle cleavage fracture, which is accompanied by a sharp drop in fracture toughness (Fig. 20). In low-alloy ferritic steels for reactor pressure vessels, the DBTT is around 0 °C. Irradiation increases the temperature-dependent yield stress but not the cleavage stress and therefore causes a shift of the DBTT to higher temperatures. In earlier pressure-vessel steels, this shift can be so large (e.g., Fig. 20, top) that brittle behavior may be encountered in the temperature regime of normal reactor operation or of reactor shutdown. Microstructural studies using field ion microscopy, electron microscopy, and small-angle scattering have identified precipitates rich in Cu and P and microvoids, possibly stabilized by Cu and P, and metal carbides as responsible for the hardening. Modern pressure-vessel steels contain less than 0.1% Cu and 0.01% P, and they exhibit a greatly improved resistance against low-temperature irradiation embrittlement (Fig. 20, bottom). Large DBTT shifts are also of concern for Mo and its alloys, which are considered for heat-sink materials of divertors and limiters in future fusion devices.

3.1.2 Swelling Swelling by the nucleation and growth of voids was discovered by Cawthorne and Fulton (1967) by electron microscopic observations of a stainless steel irradiated in the Dounreay Fast Reactor in Scotland. In the following years, swelling was one of the dominant topics in radiation-damage research since the relative volume increase, $\Delta V/V$, can reach tens of percent (Fig. 21) at the high doses prevailing in advanced reactors. Void swelling is generally observed at irradiation temperatures between 0.3 and 0.6 of the melting temperature, T_m, with a peak around (0.45–0.5)T_m for typical

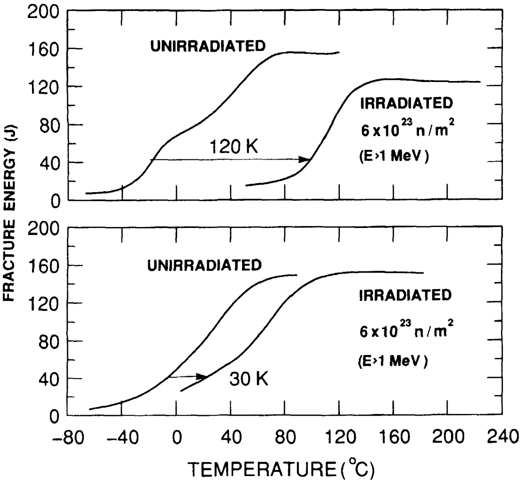

FIG. 20. Charpy V-notch ductility results showing the shift of the ductile-to-brittle transition temperature (DBTT) of A533-B ferritic pressure-vessel steel caused by irradiation to about 0.1 dpa at 290 °C, corresponding to 30 years of reactor operation. Upper plot shows material in which Cu content was not controlled; lower plot shows improved material with low Cu level (after Hawthorne, 1975).

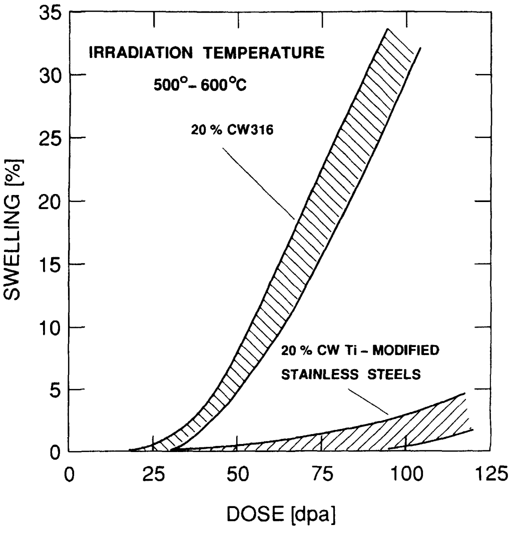

FIG. 21. Swelling as a function of dose of cold-worked 316 stainless steel and a Ti-modified variation irradiated in a fast reactor at 500–600 °C (after Maziasz, 1984).

reactor dose rates of ~10^{-6} dpa/s. Higher dose rates shift the swelling range to higher temperatures. The dose dependence of swelling is characterized by three stages (Fig. 21): an incubation period with little or no swelling, a transition stage, and a high-dose region where $\Delta V/V$ increases approximately linearly with dose, at rates on the order of 1%/dpa for many alloys.

The swelling rate in the linear dose regime is rather insensitive to materials parameters such as alloy composition, density of dislocations and precipitates, helium content, etc. However, these parameters strongly influence the duration of the incubation period. This fact is utilized in the development of swelling-resistant alloys, e.g., the addition of <1% Ti to 316 stainless steel shifts the onset of high swelling from 25 to almost 100 dpa (see Fig. 21). How the crystal structure affects void swelling is not well understood. For the technologically important steels, it is well established that bcc ferritic/martensitic steels are generally much more swelling resistant than fcc austenitic steels. On the other hand, fcc gold is highly resistant to swelling, but bcc vanadium swells readily.

Soon after its discovery, swelling was identified as being the consequence of an imbalance ("bias," see Sec. 2.4) of the fluxes of irradiation-induced vacancies and interstitials to dislocations and void embryos, respectively [Fig. 17(a)]. Rate theories based on this concept (Bullough and Perrin, 1969, and others) were able to predict qualitatively the dependences on temperature, dose rate, and dose observed in the fast-swelling regime. However, to obtain agreement with the observed absolute swelling values, unrealistically low values for the bias factors had to be assumed. More recent recognition of the importance of interstitial loops escaping from displacement cascades via unidirectional glide process has initiated a new modeling effort. This new idea promises to lead to an improved understanding of void swelling, and it seems also to have the potential for treating the incubation and transition stages for which an adequate theory is currently lacking.

Although several swelling-resistant steels are now available for fast-breeder applications, experimental and theoretical research in this field is needed, as swelling promises to be a more severe problem in fusion materials. In these machines, materials will be subjected to displacement doses of more than 100 dpa and a strongly increased helium production from nuclear transmutations induced by the 14-MeV fusion neutrons. Furthermore, the variety of elemental tailoring is restricted by the requirement to use only elements with low radioactive activation.

3.1.3 Irradiation Creep and Growth

Irradiation or in-pile creep is the plastic deformation of materials caused by the simultaneous action of irradiation and mechanical stress. It is observed at temperatures as low as $0.2T_m$. After a transient period (duration corresponding to a dose of ≈1 dpa), a constant irradiation creep rate $\dot{\epsilon}$ is observed that is essentially proportional to the displacement rate K and the applied stress σ (Fig. 22). $\dot{\epsilon}$ depends only weakly on temperature (Fig. 23), in contrast to the thermal creep rate, which increases exponentially with temperature.

The magnitude of irradiation creep depends on materials parameters. For several pure metals and solution-hardened alloys with fcc structure, an empirical correlation with the yield stress of the unirradiated material holds, showing a decrease of the normalized creep rates $\dot{\epsilon}/K\sigma$ from 3×10^{-10} to 1×10^{-11} Pa^{-1} dpa^{-1} when the yield stresses increase from 20 to 200 MPa. These values are insensitive to the initial dislocation struc-

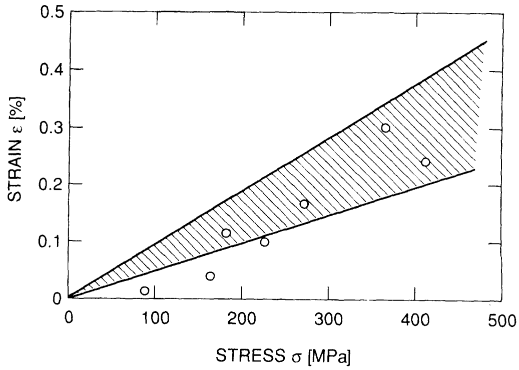

FIG. 22. Stress dependence of strain ϵ due to irradiation creep after n irradiation to 4.8 dpa in a fast reactor (FFTF, cross-hatched region) and a mixed-spectrum reactor (ORR, open circles) in cold-worked 316 stainless steel. The irradiation temperature was 330 °C (after Rowcliffe and Grossbeck, 1984).

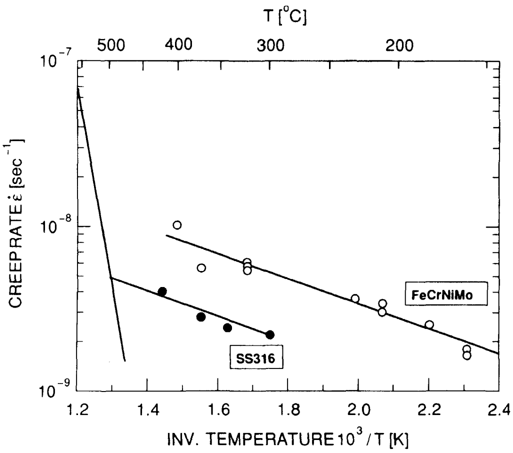

FIG. 23. Temperature dependence of irradiation creep rate $\dot{\epsilon}$ in proton-irradiated FeCrNiMo alloy and in 316 stainless steel. The applied stress was 250 and 200 MPa, respectively. The displacement rate was 10^{-6} dpa/s. The solid line on the left indicates thermal creep in 316 (after Jung and Ullmaier, 1990).

ture and to the presence of precipitates. Similar irradiation creep behavior is found in hcp Zr and its alloys, whereas no enhancement of the creep rates above the thermal values could be detected in bcc martensitic steels under irradiation.

Irradiation creep is thought to be caused by the stress-induced preferential absorption (SIPA—Heald and Speight, 1975) of interstitials and vacancies at dislocations of different orientation with respect to the applied stress [Fig. 17(b)]. The resulting dislocation climb then leads to the observed volume-conserving deformation under load. However, there are experimental results that cannot be explained by SIPA alone, and thus several other mechanisms (e.g., climb-glide, swelling driven, cascade-induced creep) have been proposed to contribute to irradiation creep.

Whereas radiation-induced swelling and embrittlement always have negative consequences on the behavior of materials in nuclear environments, irradiation creep can also have positive aspects, e.g., by relaxing high stresses generated by inhomogeneous swelling and thereby avoiding premature failure.

Irradiation growth is the shape change at constant volume that occurs during irradiation of unstressed materials of noncubic structure. Two technologically important examples are orthorhombic U metal and hcp Zr and its alloys. There is some microstructural evidence that interstitial atoms and vacancies condense unequally on the different crystallographic planes (e.g., on the prism and the basal planes in hcp metals) and most theoretical attempts to model irradiation growth are based on this anisotropy.

3.1.4 High-Temperature Embrittlement

Whereas the embrittlement effects described in Sec. 3.1.1 diminish with increasing temperature, there are other mechanisms that become operative at $T \geq 0.5\ T_m$ and that can lead to severe ductility losses in structural components in fast-breeder and particularly in future fusion reactors. It is now generally agreed that helium created by (n,α) processes is the most critical factor, and other possible mechanisms such as radiation-induced impurity segregation to grain boundaries, second-phase precipitation, voids, etc. are less important.

Under deformation with slow strain rates due to creep or fatigue loads, helium-containing materials often fail by intergranular fracture (Fig. 24). In many alloys, helium concentrations of a few appm are sufficient to induce this brittle fracture mode, which is generally accompanied by a decrease of the elongation and time to rupture (Fig. 25). The extent of this degradation increases with increasing helium concentration and temperature and with decreasing strain rate. The

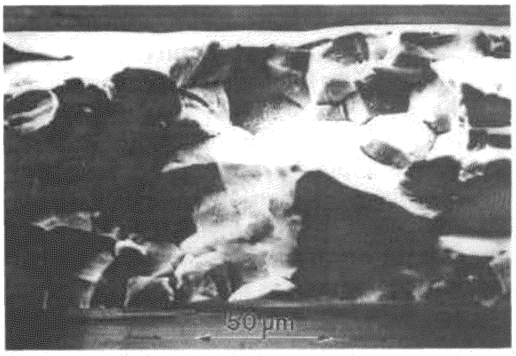

FIG. 24. Fracture surface of an austenitic stainless steel that failed after creep testing at 873 K with simultaneous He implantation. The final He concentration at rupture was 8000 appm (from Schroeder and Stamm, 1990).

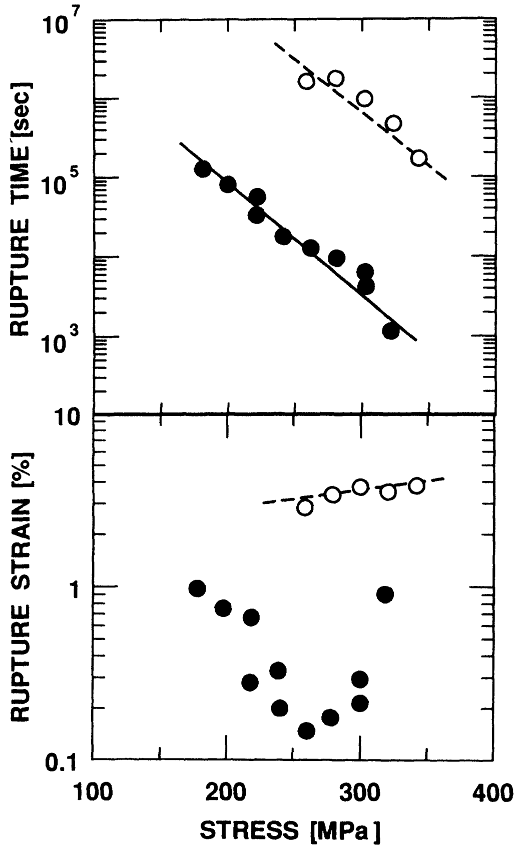

FIG. 25. Degradation of rupture time (top) and ductility (bottom) of cold-worked 316 stainless steel under creep stress at 873 K: ○ reference specimens, ● creep tests with simultaneous He implantation (after Yamamoto and Schroeder, 1988).

vulnerability of materials to "helium embrittlement" strongly depends on their initial composition and microstructure. Among the technologically important materials, Ni-based superalloys are most affected, whereas Fe-Cr ferritic/martensitic steels are resistant up to 3000 appm He and 700 °C. In austenitic steels, the addition of some minor alloying elements (e.g., Ti, which forms finely dispersed TiC precipitates) can greatly reduce the detrimental effects of helium.

There is ample experimental evidence that the microstructural cause for helium embrittlement is helium bubbles that preferentially nucleate in grain boundaries. With ongoing irradiation the bubbles grow by absorbing the continuously produced He until they initiate or accelerate grain-boundary cracks. At very high He concentrations, they perforate the grain boundaries until their contact area becomes too small to support the applied stress. The theory of helium embrittlement describing the bubble evolution in grain boundaries is rather well advanced. The available models (Trinkaus, 1986; Trinkaus and Ullmaier, 1994) are able to identify the failure criteria for the relevant ranges of temperature, stress, strain rate, and He production rate and to reproduce the observed dependencies of the creep and fatigue lifetimes on these parameters.

The main impetus for future research on high-temperature embrittlement derives from materials development for fusion power reactors. Here the availability of embrittlement-resistant alloys fulfilling several other requirements (e.g., low radioactive activation, low swelling) will be essential for a safe and economic operation of these future energy sources.

3.2 Carbon-Based and Ceramic Materials

3.2.1 Dimensional Changes and Stored Energy In spite of the complications discussed in Sec. 2.3, the basic high-dose damage mechanisms discussed for metals apply also to this class of materials and swelling is observed for many insulators as well. Here we restrict the discussion to two specific topics.

For many noncubic polycrystalline materials, internal strains are built up in addition due to anisotropic growth. The magnitudes of these dimensional changes per unit dose are most important in graphites [Fig. 26(a)]. Electron microscopy observations and a comparison of the changes in length and lattice parameter show that the growth in the *c*-axis direction is due to the growth of relatively large planar clusters of interstitial atoms, which are inserted between the existing basal planes (Kelly, 1981). The basal-plane contraction is attributed to irregular lines of the corresponding vacancies, which collapse when they reach a certain length.

Carbon-based materials used in technology (polycrystalline "graphite," pyrolytic carbon, carbon-fiber enforced carbon, etc.) are a complex and not well definable mixture of graphite crystallites of different size, density, and texture, binder materials, and pores. Ac-

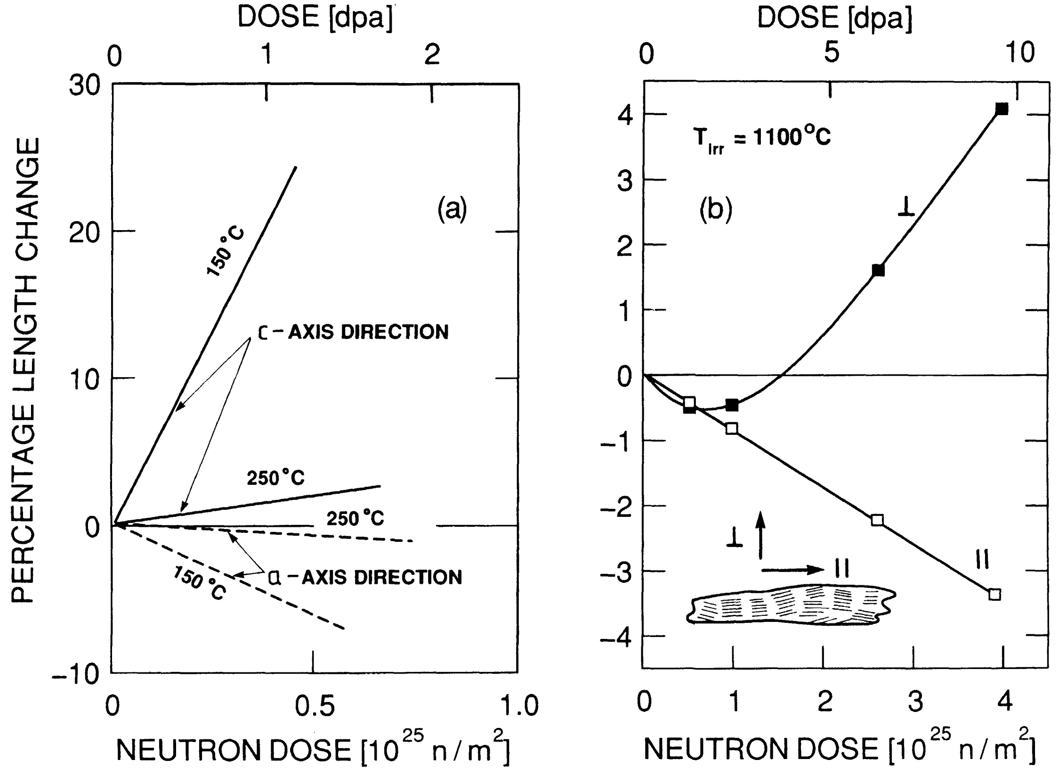

FIG. 26. Dose dependence of length changes for (a) single crystals of graphite (after Kelly, 1981) and (b) polycrystalline blocks parallel and perpendicular to the orientation of the elongated grains (after Delle *et al.*, 1974).

cordingly, the irradiation-induced dimensional changes are also very complex. Qualitatively, the dose dependence exemplified in Fig. 26(b) is typical for many carbon materials: At low doses, the material shrinks (densifies) both perpendicular and parallel to the mean orientation of the usually elongated grains. With increasing dose, the parallel dimension continues to shrink, at a decreasing rate, whereas the perpendicular dimension starts to grow. Dimensional changes under various irradiation conditions have been extensively studied for a great variety of carbon-based materials, mainly because of their importance as structural core and moderator materials in high-temperature gas-cooled reactors.

In any material, the production of defects by irradiation results in an increase of internal energy, which is stored mainly as strain energy around the lattice defects. If, upon heating, the defects annihilate or regroup, this stored energy (Wigner energy E_W) is released and can lead to a fast rise in temperature. This effect is particularly pronounced in graphites where the formation energy of Frenkel defects is high (~10 eV), and the specific heat c_p is small (~10^{-4} eV/atom·K). In graphites heavily irradiated around ambient temperatures, the energy is released upon heating in a rather narrow recovery stage, somewhat below 200 °C, and it is sufficient to raise the temperature spontaneously to 300–500 °C.

The Wigner energy rapidly decreases with increasing irradiation temperature because the stationary concentration of defects given by the balance between their production and their annihilation decreases with increasing *T*. Stored-energy effects have thus been investigated mainly in connection with the design and operation of early graphite-moderated reactors, which were operated at lower temperatures. From these studies, criteria were defined that ensure that the effective specific heat $c_p - dE_W/dT$ of the graphite will remain positive, i.e., self-sustaining releases cannot occur.

3.2.2 Thermal Conductivity and Mechanical Strength The applicability of graphite and ceramic materials for structural components in nuclear technology is often characterized by a "figure of merit," given by $\lambda\sigma_B/\alpha E$. Whereas the coefficient of thermal expansion α and Young's modulus E are rather insensitive to irradiation, considerable reductions of the breaking strength σ_B and particularly of the thermal conductivity λ are observed. λ decreases rapidly even at low doses [Fig. 27(a)] and then saturates at a level roughly between 10% and 20% of the original value for most materials investigated (graphites, Al_2O_3, SiC, AlN, MgO, etc.). The degradation of the thermal conductivity is attributed to phonon scattering at irradiation-induced point defects and their clusters. Since this contribution to the heat-flow resistance depends only weakly on temperature, the initial T^{-1} dependence of λ due to phonon-phonon interactions changes to an almost T-independent behavior. At very high irradiation and/or test temperatures, the λ values of irradiated materials merge into the curve for the unirradiated material because of defect annealing [Fig. 27(a)].

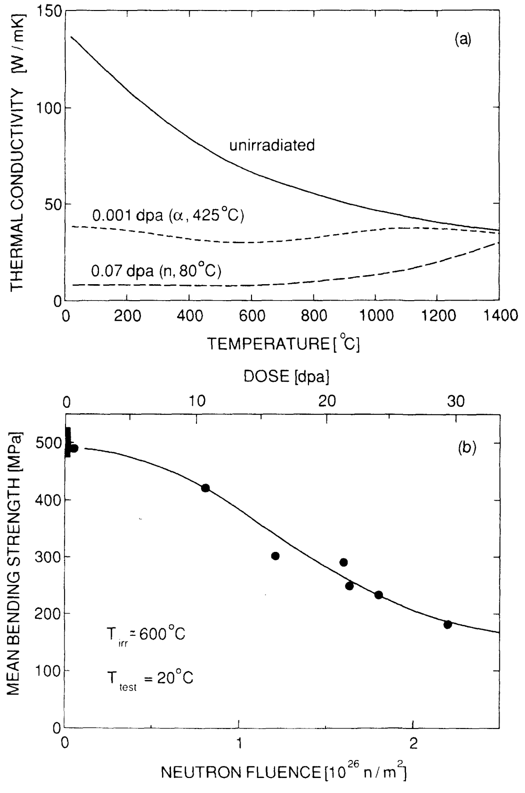

FIG. 27. (a) Decrease of thermal conductivity of isostatically hot-pressed SiC as a function of temperature due to irradiation with α particles and reactor neutrons, respectively. (b) Decrease of mechanical strength of the same material as a function of neutron fluence (after Dienst, 1992).

In contrast to the sharp decrease of λ at low doses, a threshold dose of several dpa is required before noticeable decreases in the breaking strength σ_B [Fig. 27(b)] are observed. As before, the extent of the degradation decreases with increasing irradiation and/or test temperature. Because microstructural information is lacking, no detailed explanation of the failure degradation in terms of the underlying physical processes can be offered. For a number of ceramics, however, a clear correlation between the decrease in σ_B and swelling has been found. It is also of technological importance that the irradiation-induced decrease in strength is accompanied by a considerable broadening of the strength distribution (Dienst, 1992).

3.3 Electronic and Optical Materials

Degradation of the electrical and optical performance of devices is observed at much lower defect concentrations than those discussed above for the mechanical properties. Hence, defects introduced during the processing (e.g., ion implantation) must be annealed out at high temperatures in an additional processing step. The particle fluences received during a one-year operation period in space [typically 10^{17} protons/m^2 (≥ 10 MeV) and 10^{20} electrons/m^2 (≈ 1 MeV) in a near-Earth orbit] may be considered as a typical example for the fluences that are of concern at the operation temperature of devices.

Although not specifically a topic for this section, some remarks on ionization are in order since it may influence device operation as a result of photocurrents, e.g., within the field of built-in p-n junctions. The total number of steady-state e^--h pairs produced by illumination or irradiation of doped semiconductors rarely exceeds that of the minority carriers, and therefore these currents are important only for unusual conditions, e.g., nuclear test explosions, or pulsed accelerators. Local currents of the same type may lead, however, to a discharge of built-in condensers (e.g., "single event upset") or to similar malfunctions in imaging devices (i.e., "white-out").

Device operation can also be influenced by the buildup of a net positive charge in oxide films since it can produce an inversion layer in the silicon. These inversion layers give rise to leakage currents. Similar malfunctions may arise from the disruption of chemical bonds at interfaces between semiconductors and insulators. In optical devices, the trapping of e^- or h may change the charge state of existing defects or dopants, which in turn changes the absorption band of these defects (color centers); as detrapping is efficient only above room temperature, these changes are especially important for optical waveguides and fibers.

3.3.1 Electrical Properties Irradiation-induced point defects in semiconductors generally seem to provide deep levels and act as trapping and scattering centers for the electrical carriers. With increasing fluence the carrier lifetime, the carrier concentration, and the carrier mobility are reduced appreciably. The consequences of the reduced carrier lifetime, or reduced carrier diffusion length, on the performance of silicon solar cells are shown in Fig. 28. The observed degradation shows characteristic trends that are also observed in GaAs solar cells; however, the quantitative changes depend on the detailed structural features of the devices, the materials, and the dopings. Databases have been collected on these characteristics.

Carrier removal rates (change in the number of carriers per m^3 per incident particle per m^2) may be of the order of 10^2 m^{-1} for MeV electrons and of the order of 10^3 m^{-1} for n irradiations at room temperature. After irradiation to high fluences, the defects control the position of the Fermi level, and the number of carriers, e.g., in Si (n and p type) as well as in GaAs, reaches intrinsic values, Ge becomes p type with a limiting hole concentration of $\approx 5 \times 10^{22}$ m^{-3}; InP, InSb, AlSb, InAs, CdTe, HgCdTe become n type and GaSb becomes p type.

For insulators, an increase of the ionic conductivity is often observed at higher temperatures as a result of the production of va-

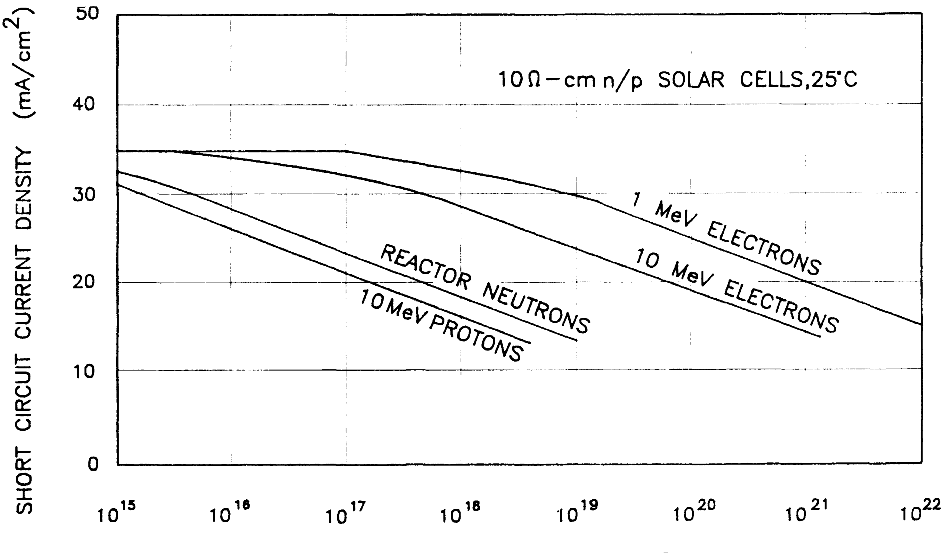

FIG. 28. Degradation of silicon solar cells with fluence for various types of irradiation. The decrease of the short-circuit current density under a solar simulator illumination (135 mW/cm^2) is shown for fluences of protons and electrons that are typically absorbed during the lifetime of a device in a near-Earth orbit (after Carter and Tuda, 1973).

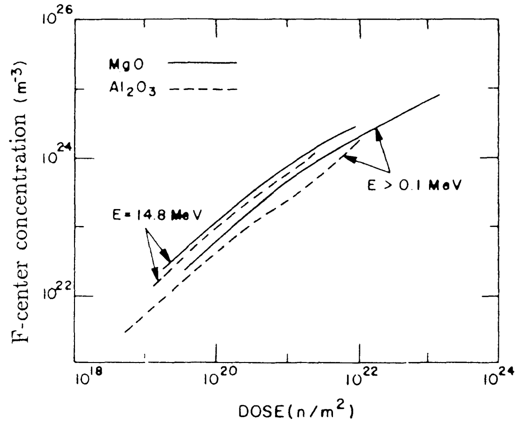

FIG. 29. Increase of the concentration of *F* centers in Al_2O_3 and MgO as a function of the fission and fusion neutron fluence. The *F*-center concentration was determined from the optical absorption within the absorption band around a photon energy of 5 eV (after Clinard and Hobbs, 1986).

cancies. An additional radiation effect, which can be important for rf windows in fusion reactors, is the increase of the dielectric loss at microwave frequencies (in addition to the loss that is proportional to the ionization-induced conductivity), as defects can act as resonance absorption centers. Displacement damage increases the dielectric loss, particularly at frequencies below 1 MHz (e.g., the loss tangent at 10^4 Hz is increased in Al_2O_3 by an order of magnitude after 10^{22} n/m^2; Fowler, 1984). In addition, defects yield changes of the dielectric breakdown fields, although the influence of surface defects and cracks is more serious for high-dose application.

3.3.2 Optical Properties Defects with electronic levels within the forbidden gap may be optically excited with bandgap light and are characterized by the corresponding absorption band or thresholds. Noteworthy examples are the vacancy-related color centers, particularly the *F* centers. Since even small changes of the absorption coefficient are unacceptable for optical fibers, materials must be carefully selected considering the optical wavelength of the signals and potential defect absorption bands.

The increase of the *F*-center concentration in MgO and Al_2O_3 for neutron fluxes that might be characteristic for window materials of future fusion reactors is shown in Fig. 29. Although there is an indication of a saturation behavior for the concentration of the centers, this behavior does not necessarily reflect the total damage, as vacancies may react and agglomerate during irradiation and no longer be optically detectable. In addition to these absorption bands, the overall absorption background increases, especially close to the gap energy.

GLOSSARY

Amorphization: Formation of amorphous phases. Special for irradiation: freezing-in of liquidlike "glassy" structures during rapid spike cooling or amorphization by defect accumulation. Amorphous zones are nonequilibrium phases that recrystallize upon annealing at elevated temperatures.

Bias: Imbalance of fluxes of interstitials and vacancies, respectively, to sinks of different capture strengths.

Bubble: Cavity filled with gas under high pressure.

Cluster: Generic term for (small) agglomerate of defects.

Damage Efficiency ξ: Number of stable Frenkel pairs per dpa. For small recoil energies $\xi \approx 1$; for very high recoil energies ξ approaches a value of $\xi_{fn} \approx 0.25$ for fast neutrons.

Damage Energy T_{dam}: Portion of the recoil energy that is available for atomic displacements (and not converted into electronic excitations).

Depleted Zone: Vacancy-rich core of displacement cascade after cooling to ambient temperature.

Dislocation Loop: Planar agglomerate of interstitial atoms or vacancies, respectively, which is equivalent to a closed dislocation line.

Disordering: Destruction of an ordered phase. Special for irradiations: freezing-in of disordered atomic structure during rapid spike cooling or disordering by defect accumulation.

Displacement Cross Section σ_{dam}: Number of displacements per atom (dpa) per unit fluence.

Displacement Energy: Energy required in order to produce a stable Frenkel pair.

Displacements Per Atom (dpa): Calculated number of displaced atoms per lattice atom [see Eq. (2)] produced by a fluence Φ of incident particles per unit area. Using dpa as a dose unit facilitates the comparison of displacement damage caused by irradiations with different particles and energies.

Ductile-to-Brittle Transition Temperature (DBTT): Temperature where the ductile failure of bcc metals and alloys (at high temperatures) changes to brittle behavior (at low temperatures).

Electronic Excitations: Energy losses of charged particles causing excitation, ionization, and charge transfer in the electronic system of irradiated matter.

Frenkel Pair (FP): Crystal lattice defect consisting of interstitial atom and vacancy.

***F* Center:** Negative-ion (anion) vacancy with trapped electron.

Ion Track: Region around the path of a GeV heavy ion with very high electronic excitation.

MDS: Molecular dynamics computer simulation. In these simulations, the classical equations of motion are solved for an assembly of atoms interacting via a suitably chosen interatomic potential. The motion of all atoms can be followed as a function of time after a recoil energy T has been given to one of the atoms.

Migration Energy: Activation energy necessary for a thermally activated jump of a defect (see Table 2).

Nuclear Transmutation: Change of a chemical element by a nuclear reaction with irradiation particles, especially neutrons.

Primary Knock-On Atom (PKA): Lattice atom that has made a direct collision with the irradiating particle and has obtained a recoil energy T.

Radiolysis: Production of stable Frenkel pairs as a consequence of the decay of electronic excitations in insulators.

Rate Equations (Chemical): Continuum description of the defect introduction rates and defect losses by recombination and capture at different secondary defects and sinks. This generally leads to a coupled set of nonlinear first-order differential equations.

Recoil Energy: Energy transferred to a lattice atom by a collision with the irradiation particle; the maximum recoil energy is given by Eq. (1).

Recombination-Dominated Regime: Regime on the temperature (and flux) coordinate where during continuous irradiation the dominating fraction of the produced interstitial atoms recombines with vacancies (or vice versa) before they can reach other defect sinks.

Recombination Volume (Spontaneous): Volume $V_{s.r.}$ around an interstitial atom (or vacancy) where the antidefect is not stable and can recombine athermally.

Recovery Stages: The annealing or recovery of a damaged crystal usually proceeds in several steps as a function of the annealing temperature. These steps or stages can be related to different defect reactions.

Replacement Collision Sequence (RCS): A linear chain of collisions along a close-packed lattice direction whereby one colliding atom replaces its neighbor.

Sink-Dominated Regime: Regime on the temperature (and flux) coordinate where during continuous irradiation the stationary vacancy concentration is much smaller than that of other sinks. Hence, the major part of the mobile interstitial atoms arrives at external sinks.

Spike (Thermal): Local region where the majority of atoms are in violent motion and where the kinetic and potential energies are randomized and converted to heat. The thermal spike is observed typically 0.3 ps after the start of a collision cascade.

Stress-induced Preferential Absorption (SIPA): Mechanism proposed for the explanation of the creep processes observed under irradiation. The absorption of mobile vacancies and interstitial atoms at dislocations depends on the orientation of the dislocations with respect to the applied stress.

Threshold Energy: Minimum energy that has to be transferred to a PKA in order to produce a stable Frenkel pair (see Table 2).

Void: Three-dimensional agglomerate of vacancies that may attain the shape of faceted spheres for large sizes.

Wigner Energy: Internal energy stored in the form of lattice defects.

INTRODUCTION

The large proportional change in quantum energy and wavelength across the infrared (IR) region, defined in wavelength as 1 to 300 μm, or in terms of wave number 30 to 10 000 cm^{-1}, leads to the need for a variety of detection techniques over this range. The low power of most laboratory IR sources, and the ubiquitous and strong background in most environments, have made the development of sensitive detectors a particularly important aspect in IR applications. Solid-state semiconductor developments have revolutionized infrared detection since the 1950s.

An infrared detector is a device that transforms infrared radiation into a signal, today universally taken to be an electrical signal. This contribution reviews the mechanisms exploited for achieving this and the criteria used for evaluating a given detector element. The categories of currently available detector types are introduced. Finally, for each region within the IR, suitable detectors for one basic application are specified.

The material covered for the far infrared (FIR), which overlaps the submillimeter-wave region, is distinguished from that covered in the entries for RADAR and RADIOASTRONOMY by the limitation here to incoherent detectors, which do not retain phase or frequency of detected radiation, whereas receivers for radar and radioastronomy rely on coherent, or heterodyne, detection. The principles and materials for the near infrared (NIR) are relevant also for the visible. Applications of IR detectors will be found in the entries CHARGE-COUPLED DEVICES and SENSORS, INFRARED.

1. GENERAL ASPECTS OF INFRARED RADIATION DETECTION

The mechanisms of detection specific to infrared radiation follow from the fact that the quantum energies involved are those of the vibrations of molecules, or, in solid-state devices, the energies are of the order of band gaps characteristic of many semiconductors. Although the detector in principle is just the fundamental element acting as a transducer, the detector generally includes a heat sink, a nonreflective coating, and electrical leads.

1.1 Thermal Effects

Infrared radiation was historically first detected by the thermal effect: Radiation is absorbed nonselectively by a black (or blackened) detecting element. This energy is then equilibrated by relaxation or collision into the translational degrees of freedom, thus appearing as heat. The heat (historically itself the signal) is transformed into an electrical signal by exploiting the temperature dependence of an electrical property of the detecting element, or of a secondary element, as a component in an electrical amplification circuit. The thermal effect may be considered to be a macroscopic effect, and is therefore broad banded. Thermal detectors include bolometers, thermistors, pyroelectric devices, thermopiles, and Golay cells.

1.2 Photoacoustic Effect

The photoacoustic or *optoacoustic effect* goes back even further than the photoelectric effect (Bell, 1881; Tyndall, 1881; Roentgen, 1881). Although with a black absorber it can be used for what is then called a photothermal device, the important application is the absorption of modulated radiation selectively, due to quantum transitions, by a sample. The absorbed energy is equilibrated, inducing a temperature change in a gas, which is exploited to generate an electrical signal in the acoustic frequency range. The effect is not limited to IR radiation, but is employed in the IR because for some applications it competes successfully with other detectors in this region of the spectrum.

1.3 Photon Effects

If the broad-banded absorption of infrared quanta by electrons in the detector material influences directly the properties of an element in an electrical circuit, we speak of a photon effect. Such specifically quantum effects are usually limited in the wavelength range of their effective use by a quantum cutoff. Photon detectors include photovoltaic devices, photoconductive and hot-electron detectors, photoemissive detectors, and photodiodes. Josephson-junction and superconductor–insulator–superconductor (SIS) devices are also photon detectors, but are only employed for coherent detection and will not be discussed here.

1.4 Rectification

The semiconductor diodes used from the radio-frequency region up into the far infrared (FIR), including Schottky-barrier diodes and metal–insulator–metal (MIM) diodes, function as mixers that preserve frequency and phase information in coherent detection systems, and will not be discussed explicitly here. However, used directly as *rectifiers*, point-contact diodes were used until the advent of the InSb hot-electron detector as incoherent detectors in the submillimeter range up to about 600 GHz. Schottky-barrier diodes are also used in the visible. The mechanism of rectification can be seen as the motion of charge carriers in the oscillating electric field of the incident radiation; current is induced in the device at the frequency of the radiation, while the nonlinearity of the voltage–current relationship results in a dc component.

1.5 Charge-Coupled Devices (CCDs)

CCDs have since 1970 come to replace many other detector systems, but, most important, they have been used for measurements not deemed realistic to attempt previously. Semiconductor photon-detector elements are deposited into a continuous array on a large semiconductor chip, creating a grid of localized potential wells and read-out conduction paths, allowing a spatial and temporal resolution not approached by any other type of system. These devices are covered in a separate article (see CHARGE-COUPLED DEVICES).

2. DETECTOR PERFORMANCE CRITERIA

No one parameter characterizing detector performance is sufficient to determine the suitability of a given detector to a given application. The definitions and some limitations on the values of the most important parameters are sketched here.

2.1 Noise in Detectors

The *noise-equivalent power* (NEP) is the rms value of the modulated incident radiant power required to produce an rms signal-to-noise (S/N) ratio of unity. The value is for a specific (postdetection) bandwidth of the modulation frequency, detector area, and field of view, and is given in watts. This parameter is determined by both the response of the detector and its noise characteristics.

Noise can be classified according to its source, so that, in theory, the square of the noise power can be written as the sum of various components:

$$
\begin{aligned}
(\text{noise})^2 = {} & (\text{thermal or Johnson noise})^2 \\
& + (\text{photon noise: background and thermal-emission photon noise, exhibited as shot noise or generation–recombination noise})^2 \\
& + (\text{shot noise due to bias current})^2 \\
& + (\text{phonon or temperature noise})^2 \\
& + (1/f \text{ and amplifier noise})^2.
\end{aligned}
$$

2.1.1 Thermal or Johnson Noise The minimum noise in a detector is that inherent in the resistive element, and is proportional to the resistance and the temperature. The temperature can be reduced by cooling the detector, but reducing the resistance generally reduces also the responsivity.

2.1.2 Background Photon Noise *Photon noise* is due to the uncertainty in the arrival time of photons at the detector, and characterizes the source noise (Rieke, 1994, p. 49). For the IR region, especially in the region of the room-temperature background-emission maximum, this is a critical quantity. It is reduced by limiting the field of view of the detector by a cooled aperture, or by limiting the background-noise bandwidth with a band-pass filter—indeed, particularly in the FIR, by using a cold band-pass filter. Since it is proportional to detector size, minimum detector size is again advantageous.

If the incident photon flux due to the signal, rather than the background, is the dominant source of noise, we speak of "photon-limited" operation of photovoltaic or photoconducting detectors. Under these conditions they exhibit the highest sensitivity.

2.1.3 Emission Photon Noise The photon noise due to thermal emission or generation of carriers in the detector itself is seldom dominant, but since it adheres to Planck's law, it is reduced by cooling the element. The thermally generated carriers are responsible for the dark current in photoconductors. This noise is also proportional to the area of the detector.

2.1.4 Current or Shot Noise Any system with current flow across a potential barrier will generate shot noise, which is proportional to the square root of the current. This contribution is the manifestation of photon noise in photovoltaic detectors, but includes the noise due to all carriers.

Systems requiring a bias current, classified as passive detectors (bolometers, photoconductors, hot-electron detectors), have a shot-noise contribution not found in active detectors (photovoltaics, pyroelectrics, photoemitters), which are run open circuit.

2.1.5 Generation–Recombination Noise Photoconductive detectors are subject to randomness in both the generation and the recombination, or relaxation, of carriers. Since photovoltaic detectors only produce generation noise, but photoconductors also have recombination noise, photoconductors have $\sqrt{2}$ times the contribution from these processes to the NEP as photovoltaics. This contribution falls off as the modulation frequency approaches the inverse of the carrier lifetime, but the responsivity also falls off in this region. Figure 1 shows the relationship between responsivity and detectivity, defined in Secs. 2.2 and 2.3, and bias current. A flat operating region in the middle of the detectivity curve is found for photoconductive detectors, dominated by generation–recombination noise and giving a linear response.

Since the dominant contributions in both cases are due to photon-generated carrier fluctuations, shot noise and generation–recombination noise are frequently treated together (Dereniak and Crowe, 1984, pp. 40–41).

2.1.6 Phonon or Temperature Noise Random fluctuations in the temperature of the detector contribute to the noise of thermal detectors.

2.1.7 1/*f* and Amplifier Noise As in most electrical circuits, semiconductors generally show 1/*f* noise. Thus this detector-noise component as well as the usual amplifier-noise contributions is reduced by operating in the frequency region where current or generation–recombination noise rather than 1/*f* noise dominates.

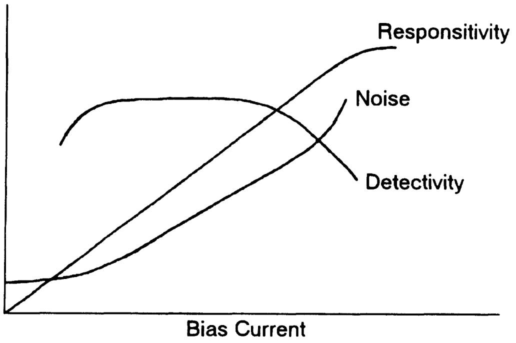

FIG. 1. Relationship between responsivity, noise, and detectivity for a photoconducting photon detector. Adapted from Morten (1971).

2.2 Responsivity

The primary measure of detector sensitivity, the signal per unit rms incident radiant power, is the *responsivity* $\mathcal{R}$ of a detector. This is usually given as a voltage signal, but may also be given as a current signal, as indicated by the units used, volts/watt or amperes/watt. The responsivity may be determined for a blackbody source or as a spectral quantity, but in either case is given for a specific modulation frequency, $\mathcal{R}(T,f)$ or $\mathcal{R}(\lambda,f)$. The noise characteristics of a detector and its responsivity together determine the NEP.

2.3 Detectivity

The parameter that summarizes the information contained in NEP and $\mathcal{R}$ and that allows a comparison of detector-element performance is the *detectivity* D^*, defined as

$$D^* = \sqrt{A_d B}/\mathrm{NEP} \tag{1}$$

in units of cm Hz$^{1/2}$/W, where A_d is the area of the detector and B is the modulation bandwidth in Hz. Some authors normalize NEP to bandwidth, in which case B can be omitted from Eq. 1 (Rieke, 1994, pp. 74, 79). Since it is normalized with respect to detector area and bandwidth, it is a suitable parameter for comparing the performance of detectors not only of different materials, but of different areas and used for different bandwidths. The value of D^* is given for a specified wavelength, modulation frequency in Hz, and postdetection bandwidth also in Hz, i.e., $D^*(10\ \mu\mathrm{m}, 900, 1)$. The bandwidth specification is not strictly necessary, since D^* is normalized with respect to this parameter. A value of D^* may also be given for a blackbody source, in which case the temperature rather than wavelength is specified.

The theoretical limiting performance of photoconductive and photovoltaic IR detectors is conventionally summarized with a plot of D^*_{BLIP}, the "background-limited infrared photoconductor" detectivity, which is defined as the spectral detectivity measured for monochromatic radiation at the wavelength of the peak detectivity for a given cooled detector, having a 2π-steradian field of view of 300-K background radiation over all wavelengths. This quantity is limited by shot or generation–recombination noise, and can be represented for a photoconducting detector as

$$D^* = \frac{\lambda}{2hc}\sqrt{\frac{\eta}{E_p}}, \tag{2}$$

where η is the quantum efficiency, defined in the next section, and E_p is the photon irradiance of the 300-K blackbody background. Photovoltaic detectors have a D^*_{BLIP} that is $\sqrt{2}$ larger than Eq. (2), since they have no recombination noise, as discussed in Sec. 2.1.6.

For many applications, the conditions under which a detector is to operate are far from BLIP conditions, so that D^*_{BLIP} is not really a useful parameter for comparing detectors, as will be shown in Sec. 3.3.3, but it is well established.

2.4 Quantum Efficiency

The fraction of incident photons that produce a free carrier in a photon detector is defined as η, the *quantum efficiency.* This is generally a function of photon energy and is therefore more precisely represented by $\eta(\tilde{\nu})$, the spectral quantum efficiency as a function of wave number $\tilde{\nu}$.

2.5 Frequency Response

The time constant τ of a detector determines its responsivity at a given modulation frequency, as seen in the relation

$$\mathcal{R} = \mathcal{R}_0/(1 + \omega^2\tau^2), \tag{3}$$

where $\mathcal{R}_0$ is the dc responsivity, $\omega = 2\pi f$, and f is the modulation frequency. The response time may be determined in a thermal detector by the thermal time constant, defined in terms of the thermal capacity and conductivity, or in a photovoltaic p-n junction device by the equivalent circuit time constant, defined by the cutoff or corner frequency $f_c = 1/2\pi RC$, where R and C are the equivalent overall resistance and capacitance of the detector and its preamplifier circuit. In most cases both time constants must be considered. The time response is a critical property in many applications.

2.6 Linearity and Dynamic Range

The output signal of most detectors is a nearly linear function of incident power up to some limit determined by intrinsic properties of the detector or by the preamplifier circuit, above which the response flattens in a saturation region. The response region in which the linearity is better than a few percent defines also the dynamic range, that is, the ratio of the largest "useful" signal to the lowest measurable signal, at $S/N = 1$. These properties are important when accurate intensity information about incident radiation is required.

2.7 Geometry

The optimum size of a detector depends on the uniformity of the material, on the relative dependence of the responsivity and noise and thus the detectivity D^* on the area, and on the spatial resolution required by the application. In general the detector element is of the order of 1 mm^2, but the exact size will depend on whether the element is part of an array, or is matched to the aperture of an optical system, and the relative priority given to detectivity vs spatial resolution.

2.8 Stability

Different detectors have different sensitivities toward mechanical stress, thermal cycling, and radiative overload. Most of the current solid-state detectors are relatively robust mechanically and thermally. Some photovoltaic detectors do not tolerate excessive radiation; cooled InSb goes into a saturated state, which, however, is reversible if the detector is warmed up to room temperature. Leads or bonding of many detectors can suffer permanent damage if badly overloaded.

3. TYPES OF DETECTORS

3.1 Thermal Detectors

3.1.1 Bolometers A *bolometer* is an element with a temperature-dependent resistance. It is usually coated with an absorbing layer, so that energy absorption by the transducer is maximized. With the temperature coefficient of the resistance defined as α, the voltage drop across a bolometer is given by

$$(\Delta V) = i_{\text{bias}}\alpha R\Delta T = i_{\text{bias}}\gamma\Delta T. \quad (4)$$

The coefficient α is defined as $\alpha = (1/R)\, dR/dT$, where R itself is a function of the temperature, and $\gamma = \alpha R = dR/dT$. The response time of a bolometer is dominated by its thermal time constant, the product of its thermal impedance and its thermal capacitance. The responsivity is also proportional to the thermal impedance, and so sensitivity and response time must be traded off. Most bolometers have response times on the order of milliseconds, limiting modulation frequencies to the kilohertz range.

3.1.1.1 Semiconductor Bolometers. The temperature dependence of the temperature coefficient and the noise behavior of semiconductor bolometers require operation at 4 K or below. Although bolometers have a flat D^* over the whole IR range, they are used primarily in the FIR, where they are not outperformed by photon detectors. Bolometer arrays are also available. Materials used for bolometers include Si, Ge, and a composite of CaF_2 and Ge (Dereniak and Crowe, 1984).

3.1.1.2 Thermistors. A bolometer consisting of a metal–oxide layer, usually on a sapphire substrate, has a coefficient γ proportional to $1/T^2$ and is called a thermistor. These devices are very robust, are broad banded, work at room temperature, and have a relatively high responsivity over the range from 0.4 to 10 μm; values of γ of up to 5%/K are obtained (Dereniak and Crowe, 1984). These detectors are Johnson-noise limited. They are frequently employed in ambient-temperature applications such as motion sensors.

3.1.2 Pyroelectrics A material that has an intrinsic electric polarization that can be changed by heating is called *pyroelectric.* A change in polarization results in a net flow of charge across the element. The signal current produced by a change in temperature in such an element is

$$i = p(T)A_d\frac{\delta T}{\delta t}, \quad (5)$$

where $p(T) = \delta P/\delta T$ is the pyroelectric coefficient, defined as the temperature derivative of the spontaneous electric polarization P, A_d is the detector area, and $\delta T/\delta t$ is the temperature rate of change. The polarization is a function of temperature, and operation at the temperature of maximum slope of this dependence is of course desired. The responsivity increases linearly with modulation frequency, but is limited by both the thermal and electrical time constants, so that there is an intermediate range of frequencies in which these detectors function optimally. Depending on the preamplifier resistors, the range can vary between 1 to 10 Hz and 10 to 100 kHz, each power of 10 in response time being bought at the price of a factor of 10 in responsivity.

Like thermistors, these materials can be used at room temperature, are relatively robust, and can have a moderately fast response. They are of course insensitive to a dc signal.

The most widely used pyroelectric material has been TGS (triglycine sulfate) and varieties thereof. Other materials used include strontium barium niobate, polyvinylidene fluoride, and lithium tantalate (Dereniak and Crowe, 1984, pp. 171–172).

3.1.3 Thermopile A sequence of thermocouples, yielding as voltage signal the sum of the corresponding work functions, provides a robust thermal detector. In the contemporary form of a thin-film stack composed of Bi and Sb in a variety of configurations, these detectors are commercially significant, especially for monitoring dc or near-dc signals.

3.1.4 Golay Cell The thermal detector devised by Golay uses a small, partially evacuated chamber, one surface of which is a blackened absorber. The residual gas in the chamber, heated by the blackened surface, exerts pressure on a diaphragm that carries a flexible mirror. The pressure distorts the mirror, which in turn determines how much of a light beam falls on a photocell. An increase in light incident on the photocell gives an electrical signal (Golay, 1949). The Golay cell has a very high responsivity but is tricky to make, is mechanically very delicate, and is slow. It was used primarily in the FIR but has now been replaced by semiconducting bolometers.

3.2 Photoacoustic Detectors

The photoacoustic effect is macroscopic in that it uses the equilibrated thermal energy of the sample, but it is a quantum effect when it responds only to radiation that can be absorbed selectively—by quantum processes—by the sample, i.e., when the sample is not black. One surface of the sample chamber, as shown in Fig. 2, consists of a microphone: a diaphragm carrying a plate or element of a capacitor. The change in capacitance produced by pressure on the diaphragm determines the electrical signal at the frequency at which the incident energy is modulated. The signal is directly proportional to the absorbed energy and thus to sample pressure in a gas cell. Like thermal detectors, photoacoustic detectors are slow. They may have a responsivity up to two orders of magnitude lower than semiconductor photon detectors (Perkowitz and Busse, 1986). However, since a photoacoustic detector does not measure total incident power or background power, but only power absorbed by the sample, it has a very low NEP. In an environment where any other detector would be saturated, but a weak signal is sought, photoacoustic detection is ideal. An example is the measurement of the weak vibrational overtone absorption of laser radiation in the near infrared (NIR) or visible by a gas in an intracavity cell (Zhan *et al.*, 1992). In the submillimeter-wave region, photoacoustic detection is used for detecting absorption of gases at low pressure, but especially with pressure-dominated line profiles (Krupnov, 1979). Recently photoacoustic detection has proved remarkably suitable together with time-resolved Fourier-transform techniques for measuring absorption-depth profiles in solid samples (Tam, 1986). Sensitivity to microphonics must be taken into consideration.

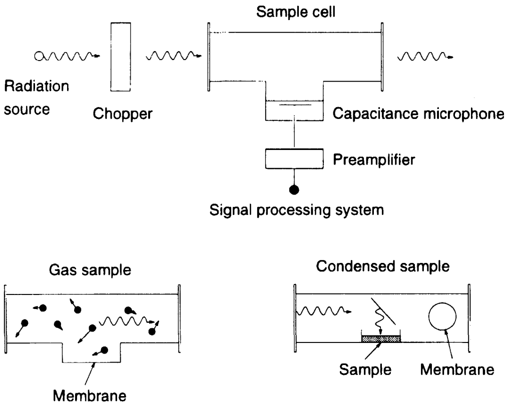

FIG. 2. Schematic structure of a photoacoustic detector, with details of cells for gas sample and solid sample.

3.3 Photon Detectors

Each of the following detector types relies on some variation of the photoelectric effect. Some semiconductor materials can be employed to exploit several of the detection mechanisms outlined here. As will be shown in Sec. 3.3.3, the parameter suitable for evaluating photon-detector efficiency, under conditions relevant to their use, is the quantum efficiency η. However, the commercial specifications are currently still given in terms of D^*.

3.3.1 Photoconductive Detectors Like bolometers, photoconductive devices are passive detectors: A bias current i_b is used to probe the conductivity, so that a change in the conductivity appears as a change in the current, δi_b. The mechanisms of various types of photoconductive devices are illustrated in Fig. 3. If an incident photon raises an electron by the photoelectric effect from the valence band to the conduction band of an intrinsic photoconductor (left-hand side of Fig. 3), the number of free charge carriers is increased, and the conductivity of the material increases correspondingly. This mechanism shows a cutoff wavelength determined by the valence–conduction energy gap, $\lambda_c = 1.23/E_g$ in microns when the gap energy is in eV. As illustrated, intrinsic photoconductors have lower cutoff wavelengths than extrinsic, or doped, photoconductors (middle of Fig. 3). The doping material serves to decrease the effective gap, and thus to increase the cutoff wavelength. These detectors have to be cooled far enough so that there are no carriers in the conduction band at equilibrium, specifically to a temperature $T_c \leq E_g/k$, where k is the Boltzmann constant; 77 K is sufficiently cold if $\lambda_c \leq 10\ \mu\text{m}$. For Ge:Zn, having the lowest E_g of less than 0.3 eV, one needs $T_c = 12$ K.

Photoconductive materials currently used include HgCdTe, in which a wide range of cutoff wavelengths, from ca. 3 to 20 μm, are

achieved by varying the ratio of Hg and Cd in the material. A fixed cutoff is found for each of the doped Ge detectors Ge:Au, Ge:Hg, Ge:Cu, and Ge:Zn. Other materials also have significant detectivities, including variously doped Si. Composite devices, known as blocking–impurity-band (BIB) detectors, allow simultaneous optimization of quantum efficiency and conductivity not achieved with single-material devices (Rieke, 1994, pp. 92–99).

The detectivity as a function of wavelength of a representative set of photoconductive detectors is plotted in Fig. 4 and compared with the curve of the theoretical D^*_{BLIP} introduced in Sec. 2.3.

3.3.2 Hot-Carrier Photoconductors

InSb is a material in which the mobility of the free electrons is large, and when the material is cold (ideally 1.5 K), the relaxation between the free electrons and the lattice is slow. InSb still has some electrons in the conduction band at this temperature. If incident photons have energies below the threshold of the energy gap between the valence and conduction bands, radiation is efficiently

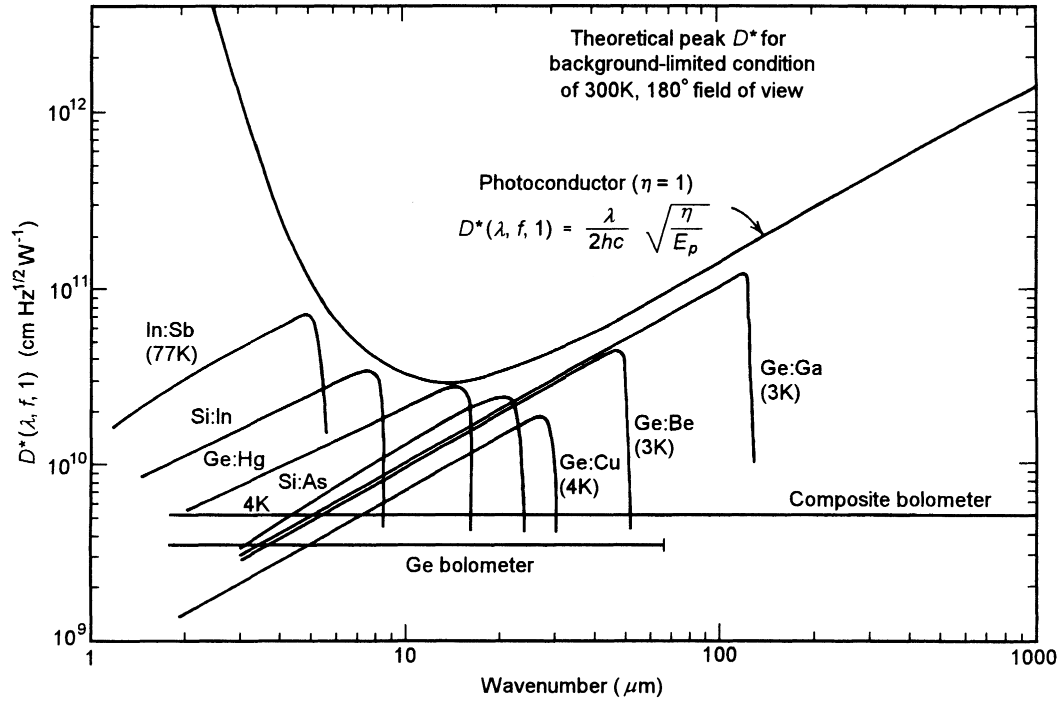

FIG. 4. Curves of D^* as a function of wavelength for a selection of photoconductive detector materials.

absorbed by the free carriers (electrons) in the conduction band at equilibrium, raising them to higher energy levels within the conduction band. This is illustrated in the right-hand side of Fig. 3. The mobility of the electrons depends strongly on their excitation, indeed as $T_{el}^{3/2}$ (QMC Instruments Ltd., 1987). (This detector type has also been classified as a bolometer.) Thus below the energy of the cutoff wavelength, InSb functions as a photoconductor (Putley, 1964a). The photoconductive efficiency is further dependent on λ^2 (Keyes, 1977, p. 23), rising to a constant value in the microwave region, so that this material is especially suited for detection of submillimeter and millimeter radiation. In addition to exhibiting the photoconductive effect, InSb and also Ge (used as a bolometer otherwise) absorb preferentially at the resonant energy of electron–cyclotron resonance, so that a peak in the responsivity can be tuned with a magnetic field. The relaxation to the lattice is fast enough that InSb can be modulated at up to about 5 MHz (Putley, 1964b). The low time constant of this detector, combined with its sensitivity, is quite unique, so that it is a competitor to bolometers in the very far IR.

3.3.3 Photovoltaic Detectors The photoelectric effect has two results in a *p-n* material with a junction potential Φ: Electrons are lifted from the valence to the conduction band, and they are accelerated by the junction potential across the junction, giving a net flow of charge across the element, which can be detected by an external circuit. This mechanism is illustrated in Fig. 5. If no bias current is used, the observed current is linearly proportional to the rate of absorption of photons. Cooling is important in most materials in order to suppress thermally excited carriers. These devices are also called photodiodes. They are characterized by a very high responsivity, rising as a function of wavelength, as for photoconductors, up to the cutoff wavelength determined by the energy gap. The cutoff wavelengths and wave numbers of a selection of photovoltaic detectors are listed in Table 1.

The roughly linear increase of D^* with wavelength seen in Fig. 4 is characteristic of all photon detectors: Whereas a thermal detector has a flat response in a plot of $D^*(\lambda)$, photon detectors have a flat response in a plot of the photon response parameter $\eta(\tilde{\nu})$. Indeed, in order to judge how well a photon detector approaches its theoretical limit or compares with other detectors in the signal-photon–limited case, the quantum efficiency $\eta(\tilde{\nu})$ defined in Sec. 2.4 should be considered rather than D^*. If $\eta(\tilde{\nu})$ is determined and plotted against $\tilde{\nu}$, and thus against photon energy, for the curves shown in Fig. 6(a), one finds the curves of Fig. 6(b), which not only are flat, but the maximum values do not follow in the same sequence of materials as in Fig. 6(a) (Birk and Brault, 1988). This is because of the different amount of background radiation to which each detector can respond under BLIP conditions (Vincent, 1989, pp. 64–67). In the signal-photon–limited case, the noise is proportional to the square root of the current, or proportional to the square root of the number of carriers, and will thus follow the curve of $\eta(\tilde{\nu})$ rather than that of D^*.

3.3.4 Photoemissive Detectors When electrons are emitted from the surface of a detector element, in the classic photoelectric effect, we speak of a photoemissive detector.

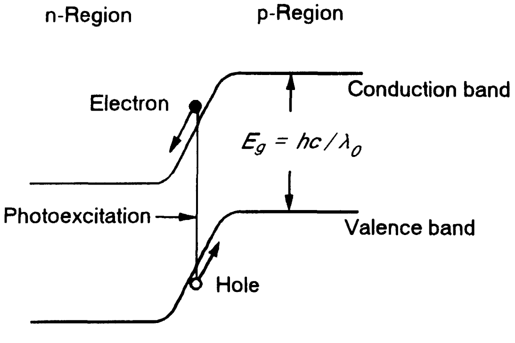

FIG. 5. Mechanism of photovoltaic detectors.

Table 1. Photovoltaic detector cutoff wavelengths λ_c and wave numbers $\tilde{\nu}_c$.

Material	λ_c/μm	$\tilde{\nu}_c$/cm^{-1}
InSb	5.4	1 850
InAs	3.5	2 900
PbS	2.9	3 500
PbSe	5.4	1 850
Ge	1.8	5 500
Si	1.1	9 100
CdSe	0.69	14 500
CdS	0.52	19 200

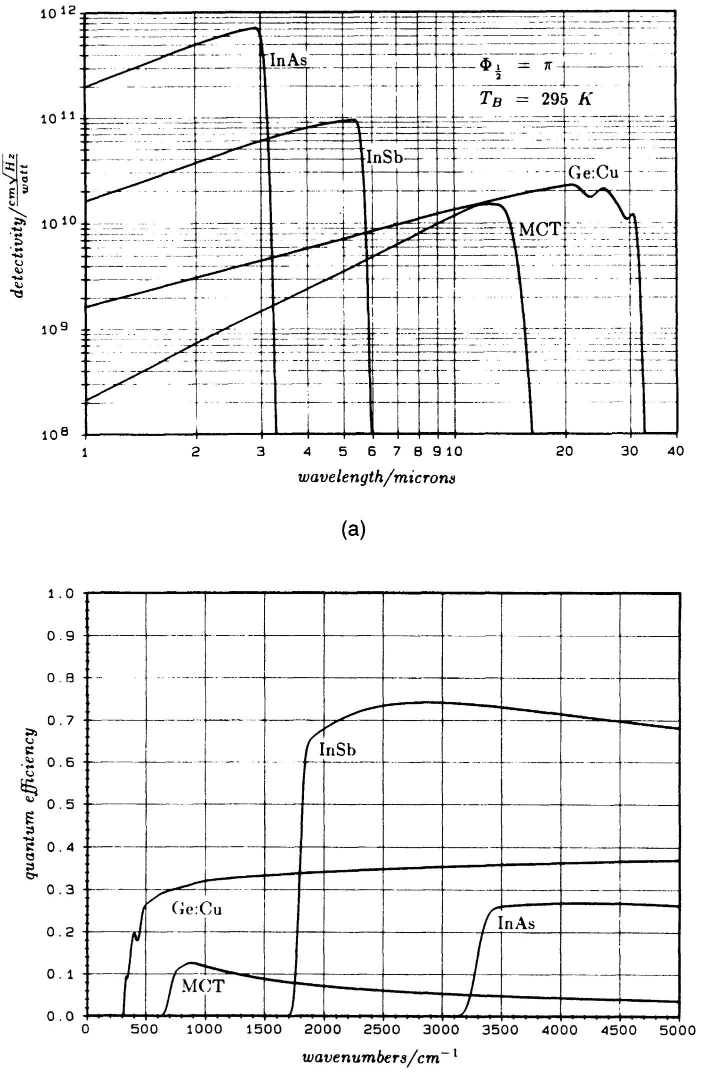

FIG. 6. (a) Spectral detectivities $D^*(\lambda)$ and (b) spectral quantum efficiencies $\eta(\tilde{\nu})$ for several photon detectors. Courtesy of Birk and Brault (1987).

These are used today for visible and shorter wavelength radiation. The electron, once emitted, is accelerated into a series of secondary electron amplifiers, generally a photomultiplier tube, giving a high responsivity. The cutoff wavelength for the use of these detectors is determined by the work function, or surface-ionization potential, of the detector materials. The photomultiplier tube is described in the article DETECTORS, SCINTILLATION.

3.3.5 Photodiodes The performance of a semiconductor as a photoconductor can be enhanced by constructing a diode junction between *n*- and *p*-doped zones within the semiconductor, creating what is called a photodiode. The doping generates a carrier-depletion zone, and thus a high impedance. Since the absorption is due to the intrinsic semiconductor, the quantum efficiency remains high. The high impedance allows good performance at room temperature. Photodiodes are made from Si, Ge, InAs, and HgCdTe and some other composite semiconductors.

Schottky diodes operate also on this principle. A barrier is created at the junction between a metal and a semiconductor, affecting the mobility of holes. Other variants of photodiodes are *pin* diodes, avalanche diodes, and multilayered quantum-well devices (Rieke, 1994, pp. 122–132).

4. DETECTOR SELECTION FOR APPLICATION TO BROAD-BANDED SPECTROSCOPY

The selection of a given detector is made not only on the basis of the performance criteria discussed in Sec. 2, but also on such factors as the basis of cost, size, need for cooling and to what temperature, incident-radiation beam geometry, thermal-resolution requirements, time-resolution requirements, mechanical stability, and required peripheral experimental equipment. In the following, for each region of the infrared spectrum, detectors with optimum properties, at the time of writing, for straight absorption spectroscopy or Fourier-transform infrared (FTIR) absorption spectroscopy against broad-banded thermal or tunable monochromatic sources are specified. For high-resolution measurements, high sensitivity is required and the bandwidth may be limited to a few hundred cm^{-1}. A narrow field of view is employed and, below 1200 cm^{-1}, a cold filter.

These choices will not be optimum for other applications. For example, for two-dimensional imaging, CCD arrays may employ a material that is not by itself optimum, but can be integrated efficiently into a CCD array. Commercially widespread yes-or-no detection systems such as motion sensors have other optimization criteria, and frequently employ thermistors or thermopiles, showing lower sensitivity but also lower cost and complexity.

4.1 Submillimeter Region

For the range 10–30 cm^{-1} there are few interferometric applications; there are no strong broadband sources and the interferometer elements have to be very large. Thus monochromatic sources (klystron harmonics, backward-wave oscillators, carcinotrons) are used for direct absorption measurements with source modulation at typically 10–40 kHz, and the detector of choice is an InSb hot-electron detector at 1.8 K. Most sources in the submillimeter region have low intensity, and a relatively high modulation frequency is needed to get well out of the $1/f$ noise. Such applications require a faster response than a bolometer can offer.

If a gas sample is at a pressure of several hundred Pa, a photoacoustic detector is competitive with an InSb.

4.2 Far Infrared

Most applications in the far infrared for straight absorption or FTIR lead to the choice of a Si or Ge bolometer. If the size of the detector and the diameter and length of the leads connecting it to the preamplifier are properly dimensioned, a bolometer can be optimized for a particular heat load, such as the weak radiation of the usual sources in the range 20–50 cm^{-1}, and achieve high detectivity if the modulation frequencies are kept low. For interferometers this means slow mirror scanning rates.

4.3 Mid-Infrared, 400–2000 cm^{-1}

The best performance is achieved in the mid-infrared with photovoltaic detectors, starting just above the far infrared with Ge:Cu or a similar doped detector; Si:B is an alternative. If the 4.2-K cooling is impractical, HgCdTe at 77 K doped for a long wavelength is suitable.

4.4 Mid-Infrared, 2000–4000 cm^{-1}

Above 1800 cm^{-1} photovoltaic InSb is the optimum detector for spectroscopy with thermal or tunable sources. In this region, signal-photon–limited performance can frequently be achieved.

4.5 Near Infrared

Here also InSb is the obvious choice. Different detector chip sizes and dimensioning for different heat loads are used for the various regions of the NIR. Above ca. 5000 cm^{-1} (below 2 μm), Ge diodes are also used.

4.6 Visible

Both Ge and, below 1000 nm, Si photodiodes and InGaAs *pin* diodes are the most efficient photovoltaic materials in the visible.

The solid-state analog of a photomultiplier tube for very narrow-banded, high-frequency (MHz) applications, such as with pulsed lasers, is provided by Ge or InGaAs avalanche diodes, which exhibit an internal amplification (Rieke, 1994, p. 123).

5. CONCLUDING REMARKS

Details of semiconductor-detector chip structure have not been discussed. The high precision, reproducibility, and reliability achieved in the technologies of semiconductor purification, doping, deposition, bonding, etching, absorbing-layer deposition, etc., have been crucial for the now predominant use of semiconductor-detector elements. Absorption, impedance matching, and heat-load matching are now well understood. As a result, many detectors now operate close to theoretical limits.

Clear-cut procedures for testing the performance of detectors and determining such parameters as the optimum load resistance, for photoconductive and bolometer detectors, have been worked out on the basis of detailed quantitative analysis of the performance of IR detectors, sketched here only qualitatively (Vincent, 1989; Rieke, 1994).

ACKNOWLEDGMENTS

The help of A. F. Krupnov, H. H. Mantsch, A. S. Pine, C. M. Walmsley, and A. Keens in locating references, J. W. Brault in discussions, and J. Preusser in preparing the figures is much appreciated.

GLOSSARY

"Background-Limited Infrared Photoconductor" Detectivity, D^*_{BLIP}: The spectral detectivity measured for monochromatic radiation at the wavelength of the peak detectivity for a given (cooled) detector, having a 2π steradian field of view of 300-K background radiation. This parameter is frequently cited, but the background conditions named are seldom relevant, and comparisons for a given application may not be useful.

Bolometer: A detector element with a temperature-dependent resistance, responding as a black absorber.

Cutoff: The wavelength or wave number at which the response of a semiconductor photon detector drops precipitously, because the energy of the photons falls below the value of the energy gap between the valence and conduction bands.

Detectivity: A parameter that normalizes information contained in the NEP and thus also in responsivity, intended to allow a comparison of detector-element performance. It is defined as $D^* = \sqrt{A_d B}/\mathrm{NEP}$ in units of cm $\mathrm{Hz}^{1/2}/\mathrm{W}$, where A_d is the area of the detector, and B is the modulation bandwidth in hertz. It may be given as a function of wavelength or wave number. The conditions under which NEP is determined must be specified.

Generation-Recombination Noise: Noise in photon detectors due to randomness in the photoelectric generation and recombination, or relaxation, of carriers. Photovoltaic detectors only produce generation noise, but photoconductors also have recombination noise.

Golay Cell: A type of thermal detector, now largely obsolete. See Sec. 3.1.4.

Hot-Carrier Photoconductor: Also called hot-electron photoconductor or bolometer. A semiconductor in which the mobility of the free electrons is large, and relaxation at low temperature between the free electrons and the lattice is slow. Incident photons with energies below the energy gap between the valence and conduction bands may be efficiently absorbed by the electrons in the conduction band, raising them to higher energy levels within the conduction band and thus increasing the conductivity.

MIM Diodes: Metal–insulator–metal diodes, used primarily for mixing radiation from the microwave up to the visible region.

Photoacoustic Effect: The generation of an electrical signal in the acoustic frequency region due to selective absorption of radiation by a sample material in contact with a microphone.

Photoconductive Device: A semiconductor element employed with a bias current in order to probe the conductivity. If an incident photon raises an electron from the valence band to the conduction band, the number of free charge carriers is increased, and the conductivity of the material increases correspondingly.

Photodiode: A photoconductor enhanced by the inclusion of a junction between *n*- and *p*-doped zones within the semiconductor. The doping generates a carrier-depletion zone, and thus a high impedance, while maintaining high quantum efficiency and allowing room-temperature application.

Photoemissive Device: A combination of a photoelectrically sensitive element, from the surface of which electrons are emitted, and a series of secondary electron amplifiers, generally a photomultiplier tube.

Photovoltaic Device: A *p-n* material in which electrons are lifted by the absorption of incident photons from the valence to the conduction band, and are accelerated by the junction potential, giving a net flow of charge.

***p-i-n* Diode:** A photodiode with an extended depletion region consisting of an intrinsic layer. This leads to a device that has a high breakdown voltage and is thus very fast.

Pyroelectric Detector: An element with an intrinsic electric polarization that can be changed by heating, yielding a signal current.

Quantum Efficiency: The fundamental performance parameter for detectors that function via the photoelectric effect. It is a function of photon energy, $\eta(\tilde{\nu})$, and varies between 0 and 1, giving the probability that an incident photon will produce a charge carrier.

Responsivity: The signal induced in a detector element per unit rms incident radiant power, given as $\mathfrak{R}$ in volts/watt or amperes/watt.

Schottky-Barrier Diode: A variety of photodiode. A barrier is created at the junction between a metal and a semiconductor, affecting the mobility of holes.

Thermistor: A bolometer consisting of a metal–oxide layer, usually on a sapphire substrate, generally used at room temperature.

Thermopile: A sequence of thermocouples, yielding as voltage signal the sum of the corresponding work functions.

INTRODUCTION

X rays and radioactivity were discovered nearly simultaneously by Röntgen in 1895, and by Becquerel in 1896, respectively. Gamma rays were found by Villard in 1900. The first radiation detectors used were photographic films and fluorescent (scintillating) screens (Röntgen), and simple "ionization chambers" consisting of an open parallel-plate condenser with a gold-leaf electroscope (Pierre and Marie Curie). Soon after the discovery of the new types of radiation, their application in different fields began: x-ray radiology, e.g., in medicine (1896), radium in radiation therapy (1901), the use of radioisotopes as tracers in chemical reactions (1913). Radiation hazards to biological material and the necessity to take protective measures were perceived soon after the first applications. In 1934 the "International Commission on Radiological Protection" (ICRP) presented its first recommendations, e.g., a "tolerance dose" of 0.2 R per day, which exceeds the actual limitations appreciably. The application of radioisotopes was speeded up when the first particle accelerators were available for the production of artificial isotopes in 1932 (Fermi, Seaborg). Finally, Hahn and Strassmann discovered nuclear fission by the bombardment of uranium with neutrons (1939); now the idea of nuclear chain reactions was born. Only three years later, in 1942 the first experimental nuclear reactor was in operation in Chicago. In the following years, military and civilian utilization of nuclear energy started to a large extent. In parallel, more and more sophisticated radiation detectors were developed mainly for protective purposes.

Radiation detection is essentially based on the creation of charged particles in gases, liquids, and solids. In gas-filled detectors, ions and electrons created by the primary radiation are separated by an electrical field, thus enabling the measurement of electrical pulses or currents. In scintillator detectors, the primary radiation creates fast electrons that excite light emission along the particle or photon path. Similarly, secondary electrons are mainly responsible for the generation of visible, microscopic particle tracks in nuclear track detectors by chemical reactions. In semiconductor detectors, electron–hole pairs are generated by particles or photons and are separated by internal electric fields of suitable homojunctions or heterojunctions. A feature of neutron detectors is the necessity of converting their kinetic energy into the creation of secondary charged particles by nuclear reactions or elastic scattering, which then produce ionization events within the detector material, because neutrons are nonionizing and therefore cannot be detected directly. (For details concerning radiation interaction with matter see INTERACTION OF SOLIDS WITH PARTICLES AND RADIATION; ELECTROMAGNETIC RADIATION.)

The Cherenkov detector is based on another physical effect than the detectors described above. The so-called Cherenkov light is generated if the velocity of a charged particle is larger than the velocity of light in the detector material.

Special and highly sophisticated detectors that are used in high-energy particle physics are not considered in this article; they are described in other sections of this *Encyclopedia* (DETECTORS, PARTICLE, CALORIMETRIC; PARTICLE DETECTORS, TRACKING). The object of this article is to give a survey on the more or less classical instrumentation used in the fields of, e.g., applied research and medicine, and in industrial nuclear facilities, not the least for radiation-protection purposes. Also, it is not intended to describe basic physics of detector operation in detail; these items are covered by a number of special articles in this *Encyclopedia*. In the following, we will describe special features of the existing vast variety of detectors with respect to the kind of radiation to be detected, the wide range of particle and photon energies, and the very different demand in scientific and commercial application.

1. GAMMA- AND X-RAY DETECTORS

Gamma radiation is everywhere present in the environment, from long-living natural radioisotopes in the Earth and from cosmic radiation. Artificial radioisotopes are distributed in the environment by nuclear fallout, and in limited areas around nuclear facilities. Gamma and x rays are produced in accelerators and in all those facilities and institutes where x-ray tubes are used. So gamma- and x-ray detectors are needed in a vast variety of civilian and noncivilian establishments. The majority of natural and artificial radioisotopes decay by emission of gamma and also x radiation in a wide energy range between a few keV and about 10 MeV. So far the measurement of radiation intensities and energies is the most important task in nuclear research and application.

1.1 Gas-Filled Detectors

Gas-filled counters (proportional and Geiger-Müller counters, ionization chambers) are used in many fields for cross detection of gamma and x radiation, because they are comparatively simple in construction and in operation, and also relatively inexpensive. On the other hand, more sophisticated instruments are widely used in precision 4π counting of isotope decay, and also in spectrometry, though their importance has decreased in the last decades as a result of the development and growing application of scintillator and semiconductor detectors. Figure 1 shows a simplified cross section of a 4π gamma ionization chamber, which is applied in a large number of versions for activity measurements in the range between 100 kBq and 10 GBq, e.g., for comparative control measurements of radiopharmaceutical samples. The chambers can be easily calibrated for nearly any gamma-emitting isotope, provided the energy is not too far below 100 keV. The chambers are filled usually with noble gases like argon at normal pressure to pressures up to about 40 bar. The lower activity limit of about 100 kBq is determined by background radiation; therefore the chambers are mostly heavy-metal shielded. The sensitivity of chambers is of the order of 1 pA of ionization current per MBq, dependent on chamber size and counting-gas pressure. An advantage of this kind of chamber is the relative insensitivity to the size of samples and to the location of samples inside the well.

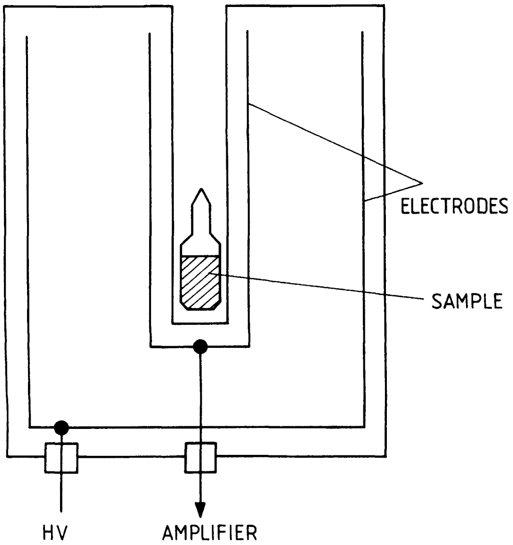

FIG. 1. Simplified cross section of a 4π well ionization chamber for precision measurement of gamma activities. The deviation from 4π geometry due to the open well is corrected by calibration procedure.

Proportional counters are suitable for energy spectrometry of low-energy gamma and x radiation. In the energy range <100 keV their energy resolution is even higher than that of scintillation counters (see Sec. 1.4). Mostly, gas-filled counters are used in radiation-protection monitoring because they are robust, handy, and comparatively inexpensive.

1.2 Detection of Low-Level Gamma- and X-Ray Activities

There is a large variety of applications in basic research and in industrial facilities, where low-level activities of gamma- and x-ray–emitting isotopes have to be measured, e.g.,

1. fallout products in the environment—in air, water, soil, and biological materials;
2. monitoring of waste water and air released from nuclear facilities;
3. nondestructive analysis of extraterrestrial material;
4. tracer techniques in nuclear medicine.

Since gamma and x rays from radioactive decay are emitted as sharp lines, and because of the good energy resolution of the available detectors, especially that of the semiconductor detectors, rapid simultaneous measurement of many isotopes in the same sample is possible, by use of multichannel analyzing techniques. Moreover, many instruments are designed to detect both gamma and beta radiation simultaneously (see also Sec. 3). Usually, NaI(Tl) scintillation detectors (for details see DETECTORS, SCINTILLATION) are used in low-level source measurements, because of their high detection efficiency (Fig. 2).

The detection efficiency is appreciably increased if specially shaped scintillator crystals are applied, which allow one to measure almost under 4π geometry. A large variety of such detectors is in use; suitable calibration procedures are necessary in each case, because the geometries of sample and scintillator, the kind of sample, and the sample–detector distance influence the detection efficiency appreciably. The most common calibration procedure is to use commercially available activity standards of the same shape as the sample, and, if necessary, to embed the standard isotope or isotope mixtures into a samplelike matrix. The efficiency curve given in Fig. 2 is the result of such a calibration, and allows prediction of the efficiency for the detection of other nuclides by interpolation of the curve.

In particular, low-level activity detectors equipped with large-sized scintillator crystals need appropriate shielding against cosmic and environmental background radiation. Large scintillators are more sensitive to the more penetrating gamma components than small ones. Electronic shielding is performed by anticoincidence techniques, physical shielding by heavy-metal plates or water tanks surrounding the detector assembly. The materials are selected with respect to low-level natural activity. Contamination due to environmental radon and its daughter products is avoided by using ventilation systems. More sophisticated systems are equipped with two NaI(Tl) scintillators, and operate in the gamma–gamma coincidence mode. Similarly, beta–gamma detector systems are built by using four detectors, two for gamma detection and two for beta detection, where plastic scintillators are used for beta detection in anticoincidence with the gamma channel (for separation of gamma and beta pulses).

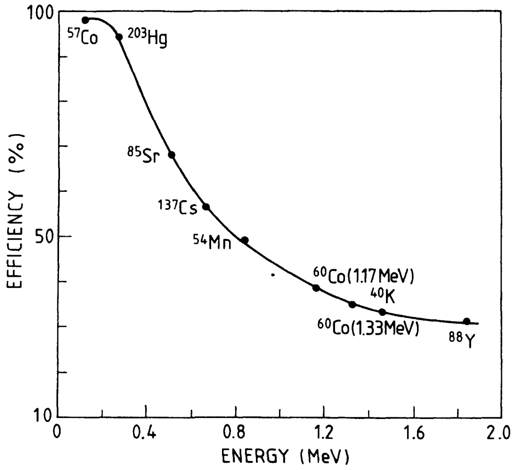

FIG. 2. Photopeak efficiency of a 4π NaI(Tl) scintillation counter system, determined by the aid of "standard" radioisotopes (Hutchinson *et al.*, 1973). Scintillator: two 8 × 8-in. well detectors, enclosing a cavity that contains the sample.

The most powerful tool, especially if low-energy gamma- and x-ray emitters in complex mixtures have to be investigated, is the semiconductor detector (for details see DETECTORS, SEMICONDUCTOR), though its detection efficiency is poorer than that of scintillation detectors, and cooling down to liquid nitrogen temperature is necessary. Today lithium-drifted and high-purity germanium crystals are in use, and advanced materials with higher *Z* are under development. Calibration, efficiency optimization, and background-suppression techniques are similar to those described above. In more sophisticated detector systems, the semiconductor detector is surrounded by a NaI(Tl) anticoincidence shield.

In the low-energy, low-level assay of gamma- and x-ray–emitting isotopes, mainly lithium-drifted silicon [Si(Li)] semiconductor detectors are applied today. A general feature of these devices is their comparatively low background sensitivity, due to the small active volumes. The detection of gammas is limited to energies of up to about 150 keV, dependent on the type of detector, because of the low *Z* and the shallow active zone of some millimeters.

Low-energy quanta are emitted by a number of isotopes in the environment, e.g., by ^{37}Ar, ^{55}Fe, ^{125}I, and ^{129}I. As an example, ^{55}Fe emits 5.9-keV x rays. For quantitative detection of this radiation, high energy resolution is necessary and care must be taken for self-absorption in the sample, absorption between sample and detector, and scattering and x-ray fluorescence in the sample and in the detector itself. In Fig. 3, two pulse-height spectra recorded with a Si(Li) detector are presented. The energy resolution is about 0.5 keV (FWHM, full width half minimum or

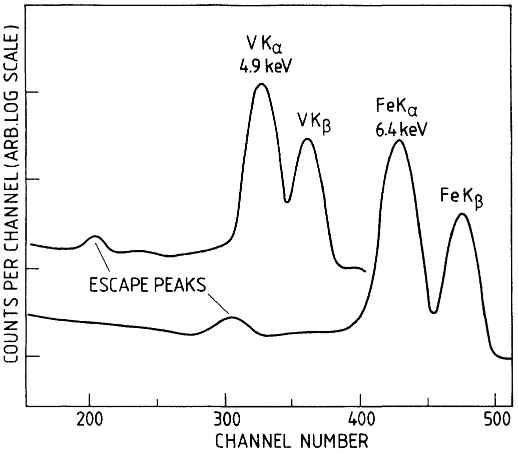

FIG. 3. *K* x-ray pulse-height spectra recorded from the electron-capture decays of ^{51}Cr → ^{51}V and ^{57}Co → ^{57}Fe (Wood *et al.*, 1971).

maximum) in this range, but can be reduced to 0.1 to 0.2 keV with state-of-the-art devices. The escape peaks are from silicon x-ray emission.

1.3 Gamma- and X-Ray Detectors Used in Radiation-Protection Dosimetry

At all sites where people are occupied with gamma- and x-ray sources, as described in the Introduction, care must be taken on radiation hazards (for health aspects of radiation see BIOLOGICAL EFFECTS OF ELECTROMAGNETIC AND PARTICLE RADIATION), and therefore monitoring of workers and working areas is decreed. The monitoring methods comprise

1. area monitoring for direct radiation from closed samples, contamination of workplaces, and airborne activities caused by open sources,
2. monitoring of waste water and air,
3. personnel monitoring with passive detectors,
4. monitoring of incorporated radioisotopes by whole- and part-body counters.

For area-monitoring purposes, mostly portable ionization chambers of various designs are used, which are calibrated in terms of Gy or Gy/h, thus giving a direct, approximate measure of the exposure of workers. The chamber walls are usually fabricated from tissue-equivalent plastics. The instruments commonly have air-filled chambers of some hundreds of cm^3 of active volume and are operated at normal pressure. The gamma-detection capability covers the range between some tens of keV to several MeV. The dose-rate range is usually 1 μGy/h to 1 Gy/h. Small "pocket chambers" are designed for personnel dosimetry. Older versions are of very simple construction and are based on capacitor discharge by ionizing events. Modern devices have sophisticated electronics for, e.g., summing up exposures over certain periods, for alarming if exposure levels are exceeded, and for self-checking of proper operation.

Special ionization chambers, so-called "flat chambers" and cylindrical "compact chambers," are constructed for dosimetry mainly in the field of gamma- and x-ray therapy (see BIOMEDICAL USE OF RADIATION). Flat chambers are used for soft radiation in the energy range between about 10 and 100 keV. They have parallel electrode plates and mostly volumes of less than 1 cm^3. The window thickness is a few mg/cm^2 in order to avoid absorption of the low-penetrating radiation. Flat chambers and compact chambers for detection of "hard" gamma and x rays have similar small volumes, but are used together with caps of about 1 cm of thickness, when the measurements are made in air, in order to ensure secondary electron equilibrium. For therapy purposes, the detection sensitivity of chambers is between 10^{-2} and 10^2 Gy, and 10^{-4} and 1 Gy/s, respectively, and the allowed error limit is some percent.

Contamination monitors, waste-air and waste-water monitors, are mostly designed to measure gamma + beta activities simultaneously. They have thin windows to avoid absorption of radiation (see Sec. 3.2). In nuclear reprocessing facilities, wastes containing numerous isotopes are handled. Detection and identification of the isotopic composition are only possible by the use of Ge semiconductor detectors. Figure 4 shows an example of the gamma spectrum of a nuclear-waste sample. The resolution of other detectors, e.g., the scintillation counter, is too poor for this purpose. A number of passive detectors are in use for personnel monitoring:

1. Film dosemeters, the blackening of which

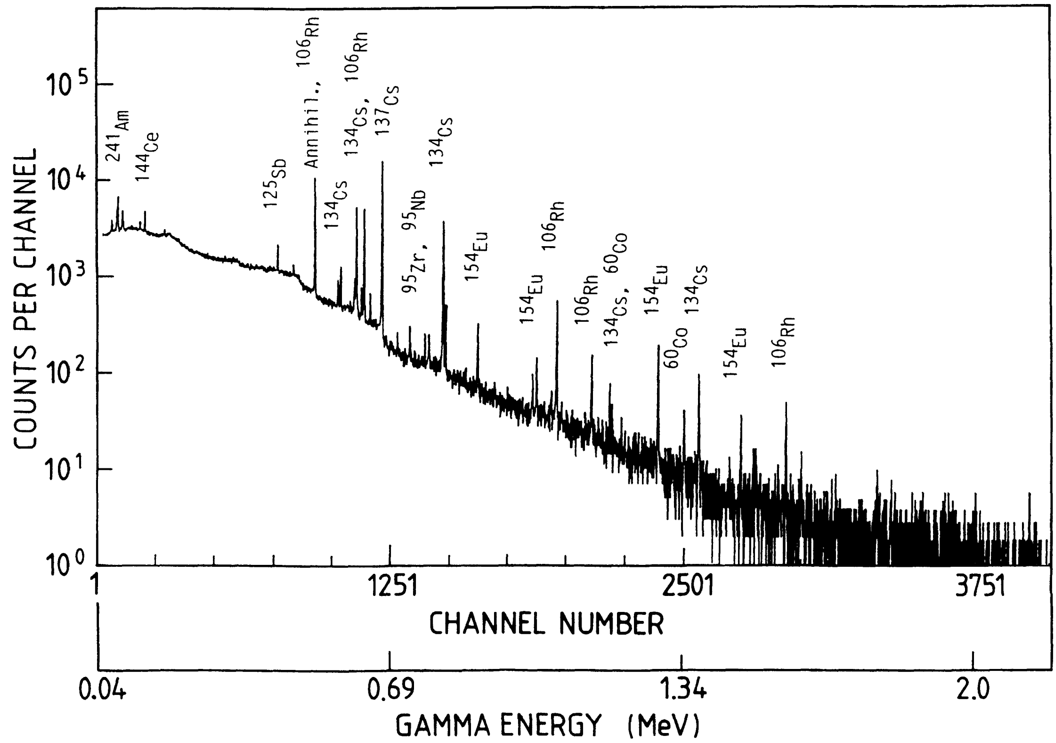

FIG. 4. Gamma spectrum recorded with a high-purity germanium spectrometer from nuclear waste produced in a reprocessing plant (Scharmann *et al.*, 1986). The record is an original one, and no corrections are made for the energy-dependent efficiency of the detector, beta-particle background, etc.

by ionization events is a measure for the exposure of workers as a result of gamma and x rays. The sensitivity of films is large at low energies and decreases with increasing energy. The lower dose-detection limit is about a tenth of a mSv at 1 MeV and some tens of μSv at 100 keV.

2. Thermoluminescence dosemeters (TLD), based on the annealing of defect centers, created by the radiation in suitable materials, mostly lithium fluoride. The annealing procedure produces a characteristic emission of light ("glow peaks"), which is related to the radiation intensity. TLDs are more sensitive to radiation than film dosemeters above a few hundred keV. Typical lower dose limits are some tens of μSv at 500 keV to some MeV.
3. Radiophotoluminescence dosemeters (RPD) are based on a similar effect: Radiation-induced defects are recovered by irradiation with light of suitable wavelength, e.g., with laser light. The induced light emission due to defect recovery is a measure for the applied dose. The sensitivity of RPD approaches that of TLD.

There are a number of other solid-state effects that are useful for passive radiation detection, e.g., exoelectron emission, lyoluminescence, electron-spin resonance, chemical reactions. Those techniques are of limited importance at the moment, and are not described in detail.

Whole- and part-body counters are constructed for detection of incorporated activities. If the activity of an isotope is concentrated in a certain organ by biological mechanisms, part-body counters are used, e.g., "lung counters" or "thyroid counters." If the activity is distributed over a number of organs or tissues, mostly whole-body counters are used. Because of absorption of radiation in tissue, especially when low-energy, low-intensity isotopes are incorporated, highly sensitive detectors have to be used, commonly scintillation detectors of the phoswich type (see Glossary). Additionally, heavy-metal and anticoincidence shielding is then necessary to suppress background radiation. Steel shields originating from old, broken-up battle ships are preferred, because these steels were fabricated in the decades before nuclear weapons were tested, and they contain low levels of activity from fallout. Nevertheless, the detection of sufficient low levels of actinides, e.g., ^{239}Pu, in a human body is extremely difficult because of low-intensity, low-energy gamma emission, and the low limits set by radiation-protection rules.

1.4 Gamma- and X-Ray Spectrometry

For gamma- and x-ray spectrometry at not too low energies, Ge(Li) or high-purity Ge semiconductor detectors and NaI(Tl) scintillation counters are nowadays the instruments of choice. When a pulse-height distribution is taken as a quantitative measure of an energy spectrum ("pulse-height analysis"), one has to be assured that all quanta are absorbed in the detector volume. Otherwise correction/calibration procedures are necessary. This is the reason why high-*Z* materials (e.g., NaI, Ge) are preferably used in solid-state gamma detectors, and the development of advanced higher-*Z* detectors is forced (e.g., HgI and CdTe).

The choice of whether to take a semiconductor detector or a scintillation detector, when the spectral analysis of a radioactive sample is to be performed, depends on the type of source: If high energy resolution is demanded, e.g., measuring a mixed isotope source like that presented in Fig. 4, a semiconductor detector should be applied. The energy resolution of scintillation detectors is about an order of magnitude poorer (Fig. 5), and there would be no chance to perceive the isotopic composition of a complex source. On the other hand, if low-level sources have to be investigated, the higher detection efficiency of the scintillation detector is of importance. In sophisticated systems, combinations of semiconductor and scintillation detectors are used to suppress background radiation. In Fig. 6, a schematic sketch of a highly sensitive spectrometer assembly is presented. The main Ge(Li) detector is surrounded by two NaI(Tl) scintillators in order to reduce the background electronically. Additional steps are taken to reduce

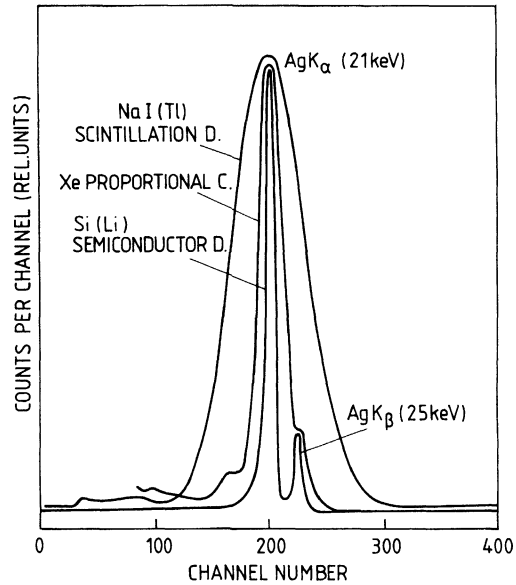

FIG. 5. Comparison of silver *K*α and *K*β x-ray spectra, recorded with different detectors (Muggleton, 1972). The two silver lines are at about 21 and 25 keV, respectively.

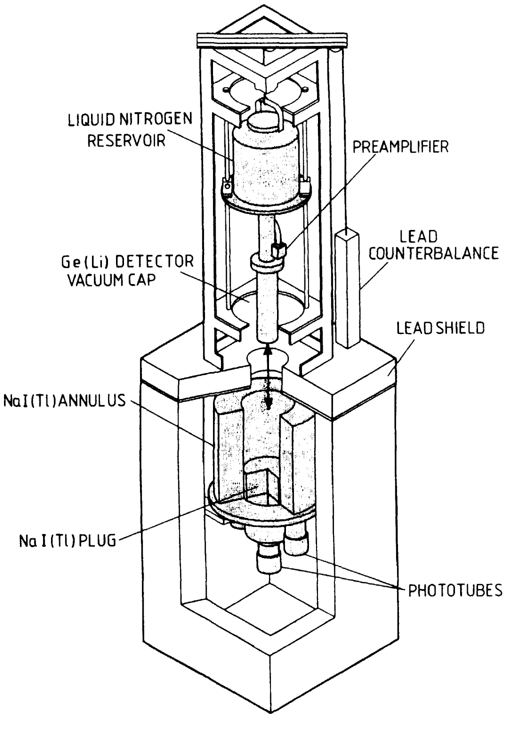

FIG. 6. Cross section of a *Ge(Li)–NaI(Tl) coincidence–anticoincidence* gamma spectrometer (Cooper and Perkins, 1971).

background pulses by means of physical shielding, as described in the preceding sections.

Spectrometry in the lowest-energy regime is nowadays mostly performed with Si(Li) detectors, which have the highest energy resolution in this range (see Fig. 3). In the intermediate-energy range, competing instrumentation is, e.g., the scintillation counter (>100 keV) or the proportional counter (<100 keV). The latter can be used down to energies below 1 keV. Under development at present is a high-resolution detector on the basis of a superconducting "Josephson junction," which exceeds even the resolution of the Si(Li) detector at low x-ray energies. It can be assumed that with advanced devices of this type, the lower-energy limit in single-photon spectrometry, which is today at about 100 eV, can be shifted to the visible region of several eV.

1.5 Detector Arrays and Imaging Systems

The oldest and most widely known imaging system is the photographic film. The films consist usually of silver bromide grains with thicknesses of up to 1 μm in a gelatin matrix. Ionizing radiation sensitizes these grains, and after subsequent processing of films, the bromide is converted to elemental silver, not only in the excited primary grain but also in a large number of grains in the vicinity of the primary one. So a macroscopic track of the quanta (or particles) is produced.

The two categories of application of films are the recording of single-particle tracks, e.g., in nuclear physics, and imaging of a large number of ionizing events in (scattered) broad beams of x or gamma radiation, the so-called radiography. The latter technique is applied, e.g., in medicine, in materials research, and also in general biological research. Figure 7 shows a principal assembly used in radiography. The different scattering and absorption of radiation in materials of different density or with different Z (e.g., tissue and bones in medical application) produce "shadows" on the processed film. By high-Z converter foils or scintillator foils, placed between the radiation source and the film emulsion, the sensitivity of the film detector can be increased by a factor of 10. When a scintillator screen is used instead of a film, an image of an object is created by the different light intensities.

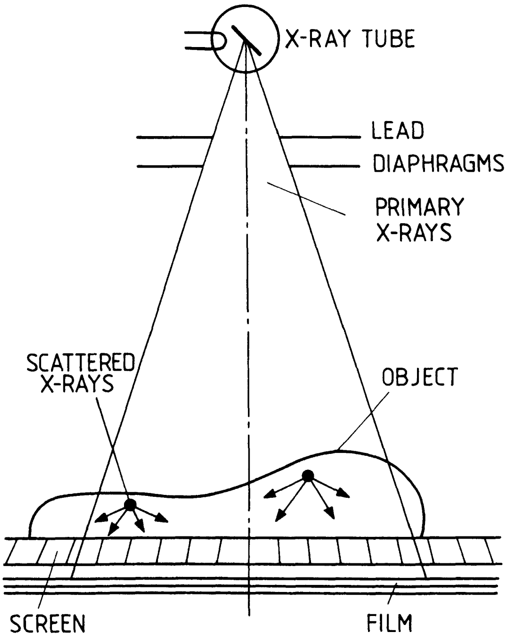

FIG. 7. Schematic sketch of an x-ray radiography assembly for diagnosis in medicine (Lang, 1979).

Another technique is the recording of coherently scattered gamma or x radiation (diffraction techniques), which allows one to observe the microscopic structure of materials.

Modern imaging systems were developed originally for use in basic research, but during the last decade there is growing interest in such systems for practical application. Whenever time-resolved ionization events are to be recorded, detectors other than film emulsion detectors are needed. In nuclear and high-energy basic research, a large number of time- and position-resolving detectors are in use, e.g., ionization chambers, proportional counters, semiconductor detectors, and scintillation counters. Figure 8 shows one of various position-sensitive semiconductor assemblies that were developed in the past (for modern devices see DETECTORS, SEMICONDUCTOR). Exemplary applications of such detectors aside from basic research are, e.g., computer tomography in medicine and the corresponding techniques in materials research.

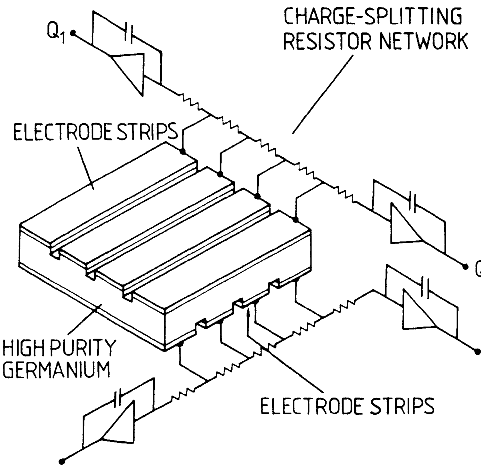

FIG. 8. Example of a position-sensitive germanium detector (Gerber *et al.*, 1977).

2. NEUTRON DETECTORS

Since neutrons are nonionizing particles, their direct detection is impossible. Therefore neutron-flux and neutron-energy measurements are always based on the detection of secondary particles, which are produced in suitable devices via nuclear reactions or elastic scattering. There are numerous techniques for the creation and detection of secondaries like alphas, protons, betas, gammas, and fission products. A need for neutron detectors aside from basic scientific interest is, e.g., in facilities of the nuclear-fuel cycle, at high-energy accelerators, and also at accelerators for medical purposes, in military nuclear facilities, and in civilian isotope-production facilities. The detectors are used, e.g., in nuclear-reaction and process control and in radiation-protection dosimetry. In nuclear and accelerator facilities and also in the cosmic-radiation environment, neutrons are produced in a large energy range (Fig. 9). Because of the complex, strongly energy-dependent interaction of neutrons with detector materials, various detection concepts are applied to cover the total range of neutron energies (e.g., Griffith *et al.*, 1990). An additional problem exists in radiation-protection dosimetry of neutron fluxes: The energy-dependent quality factor of neutrons, which is related to their biological effectiveness, has to be taken into consideration in dose-measurement techniques and instrumentation, respectively.

2.1 Detection by (n,α) Reaction

2.1.1 Boron–Fluoride Proportional Counter BF_3 gas-filled counters are the most commonly used active neutron detectors in scientific research, process control, and radiation-protection monitoring. By the reaction $^{10}B(n,\alpha)^7Li$, alpha particles are created and can be detected with high sensitivity. Because of the large specific ionization of alpha particles, it is possible to suppress a gamma background by pulse-height discrim-

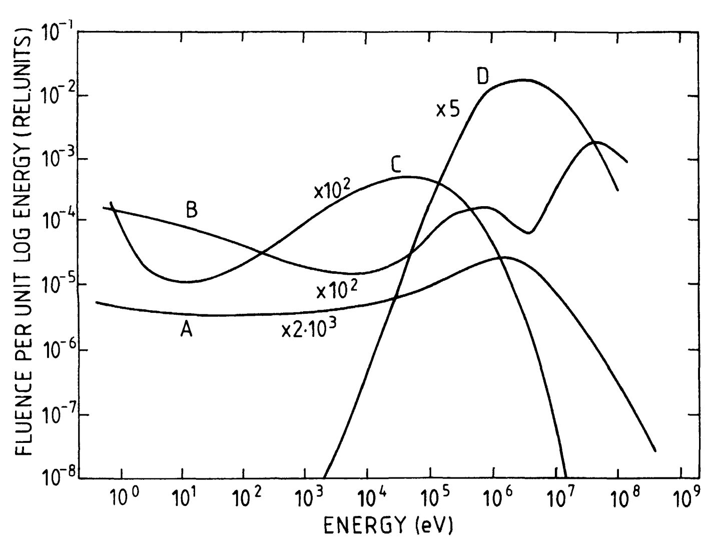

FIG. 9. Selected neutron spectra. Curve A, cosmic-ray neutron spectrum at an altitude of 12.3 km (Hewitt *et al.*, 1976). Curve B, neutron spectrum at an alternating-gradient synchrotron (location: ring top) (Distenfeld, 1976). Curve C, neutron spectrum in a commercial power water reactor (Endres *et al.*, 1981). Curve D, neutron spectrum at a Sagittaire therapy accelerator (Holeman *et al.*, 1977). Note: The given spectra are exemplary and are valid only for distinct areas at the facilities. The spectra may vary strongly dependent on the location within the facility, and in the case of cosmic radiation with geomagnetic coordinates, time, height, etc.

ination. Gamma background doses below about 1 Gy/h are then negligible. The counter dimensions are a few centimeters in diameter and 10 cm to about 1 m in length; dimensions of less than a few centimeters would result in a drastic drop of the (*n*,α) reaction yield. Usually the BF_3 pressure is around 5 × 10^4 Pa (0.5 bar). BF_3 itself shows appropriate quenching characteristics, so that the addition of a quenching-gas component is not necessary. Depending on the active counter volume and the gas pressure, the sensitivity is between 1 and 100 counts/s at a thermal neutron-flux density of 1 *n*/cm^2 s. The counter is useful up to dose rates of about 1 Gy/h (about 10^5 *n*/cm^2 s). Above this limit, gas dissociation occurs and the quenching properties diminish.

Another but more uncommon version of the boron-activated proportional counter is the "boron layer counter," where the inner counter walls are covered with boron compounds, as, e.g., BC_4 or B_2O_3. Its properties are poorer at low neutron fluxes, and therefore they are used only in the presence of high neutron fluxes.

The cross section σ of the (*n*,α) reaction is a function of the neutron energy: $\sigma \sim 1/E^{1/2}$ (Fig. 10). That is, the high sensitivity of the BF_3 counter is limited to the low-energy regime. The cross section for thermal neutrons (E = 0.025 eV) is 3.84 × 10^{-25} m^2 (3840 b). The sensitivity to neutrons of higher energies can be enlarged by the aid of surrounding moderator materials like polyethylene or paraffin. By using one or more moderator spheres (or cylinders), the detection of fast and even of energetic neutrons is possible (see Sec. 2.5).

2.1.2 Boron Ionization Chamber

Boron ionization chambers are suitable for measurement of neutron-flux densities of 10^4 up to 10^{14} *n*/cm^2 s, as they occur, e.g., in the vicinity of nuclear-reactor cores. The chambers are filled with nitrogen, argon, methane, or hydrogen; the inner walls are covered with suitable boron compounds. Gas pressures are between 10^4 and 10^5 Pa (0.1 and 1 bar), depending on chamber design. Dimensions are similar to those of boron-activated proportional counters. A further advantage of the ionization chamber is its usability at temperatures of up to 700 to 800 K, whereas the BF_3 gas-filled proportional counter or ionization chamber cannot be used at temperatures exceeding about 400 K. If one is working in the direct-current mode, more expensive compensation techniques are necessary in the presence of gamma radiation. Different methods are in use:

1. compensation by the aid of an integrated second gamma chamber that is not boron activated, and by subtracting the gamma-induced current electronically;
2. additional mechanical compensation by varying the active volume of the gamma chamber in a suitable manner, thus improving the electronic compensation mentioned before, and enlarging the measurable neutron-flux range appreciably.

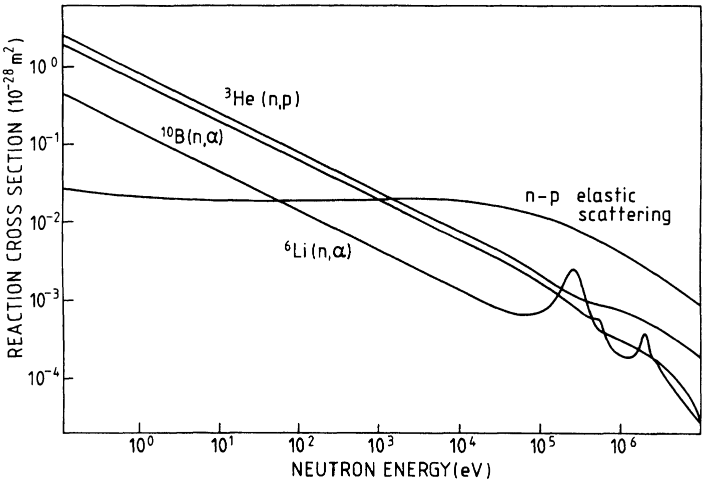

FIG. 10. Cross sections vs neutron energy for some important interactions of neutrons with detector materials.

2.1.3 Scintillation Counter

Scintillation counters (see DETECTORS, SCINTILLATION) may be used for neutron detection when charged particles like alphas or protons can be created by suitable neutron reactions within the scintillator material. Even the "normal" NaI scintillation counter is sensitive to neutrons by virtue of the reactions $^{23}Na(n,\gamma)^{24}Na$, and $^{127}I(n,\gamma)^{128}I$. Both the isotopes created by this reactions are beta–gamma emitters. Though the neutron sensitivity of the NaI counter is small, it is sometimes used for calibration purposes.

An efficient scintillator material for neutron detection is $^6LiI(Eu)$. This material is sensitive to slow neutrons because of the reaction $^6Li(n,\alpha)^3H$. The cross section σ for thermal neutrons is 9.5×10^{-26} m^2 (950 b); the energy dependence of the reaction cross section is similar to that of boron (Fig. 10). $^6LiI(Eu)$ scintillators are highly sensitive to gamma radiation, and so a gamma background must be suppressed by the aid of pulse-height and pulse-shape discrimination techniques. The usefulness of the $^6LiI(Eu)$ scintillation detector is limited to low- and medium-energy neutrons. In the MeV energy range, competing nuclear reactions occur, $^6Li(n,nd)^4He$, and $^6Li(n,p)^6He$. That is, the pulse spectrum is complex and quantification of results is hardly possible (Fig. 11). [For the response of a $^6LiI(Eu)$ counter to low- and medium-energy neutrons see Fig. 24 in Sec. 2.5.3.]

Another type of ^6Li-activated scintillator material is the "glass scintillator," containing, e.g., $^6LiO_2$, and Ce as an activator for scintillation. Those detectors can be used for thermal-neutron detection but they have poorer detection properties and are not commonly in use. Further versions of the neutron scintillation counter are based on other neutron interactions: on elastic neutron scattering (see Sec. 2.3.2), and on fission reactions. Mixtures of, e.g., ZnS(Ag) together with fissionable isotopes, as thorium, uranium, or neptunium are used as scintillators. These versions are not commonly in use.

2.1.4 Helium-3 Proportional Counter

In this type of counter, the reaction $^3He(n,p)^3H$ is applied for the detection of neutrons of energies between 10^{-2} and 10^3 eV. The reaction cross section is 5.33×10^{25} m^2 (5330 b) at thermal-neutron energies, thus larger than the corresponding one of ^{10}B. It depends on neutron energy as $1/E^{1/2}$ (Fig. 10). The ^3He proportional counter is operated at gas pressures up to 10 bar, containing pure He or He–Kr mixtures, and is more sensitive to neutrons than the BF_3 counter. The sensitivity to gamma radiation is small, and a gamma background is easy to suppress. In the presence of a broad neutron-energy distribution, some competing effects occur, e.g., He recoil nuclei from elastic n–He scattering. Also ^3H recoil nuclei, and Kr recoils in mixed-gas counters, create additional pulses. These contributions to the pulse spectrum can be well separated (Fig. 12) and suppressed by pulse-height and pulse-shape discrimination. An energy resolution of 3% between 1 eV and 1 MeV neutron energy is possible. For the response of the ^3He counter, see also Fig. 17.

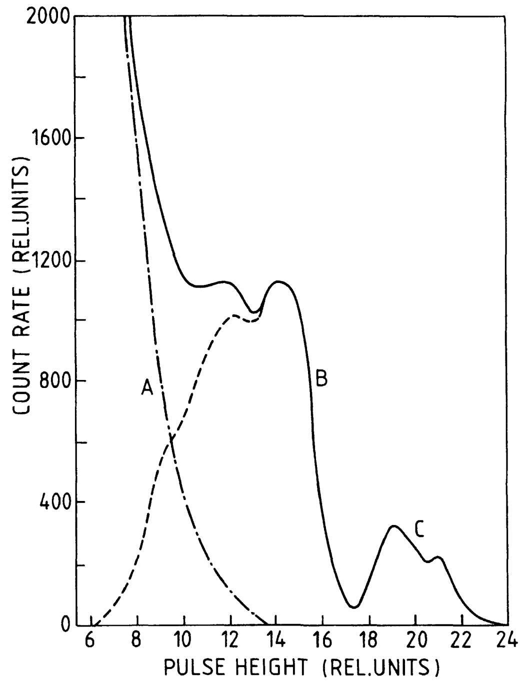

FIG. 11. Coincidence pulse spectrum due to 14-MeV neutrons measured with a LiI(Eu) scintillation detector (Neuert 1966). Curve A, gamma background; curve B, charged particles; curve C, alpha particles.

Another version of a ^3He counter consists of two semiconductor devices, between which the active gas volume is embedded. Protons and ^3H recoils are counted in coincidence, while other recoil nuclei and signals

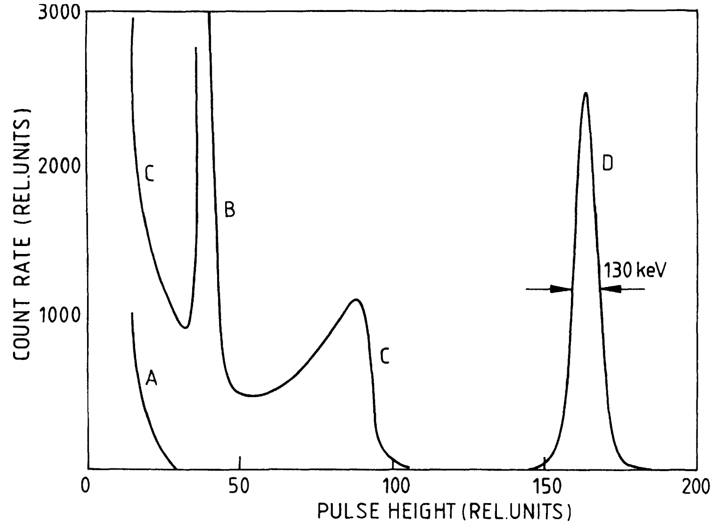

FIG. 12. Pulse spectrum due to 2.5-MeV neutrons measured with a helium-3 proportional counter; gas filling: ^{3}He + Kr + CO$_2$ (Sayres and Coppola 1964). Curve A, gamma background; curve B, epithermal neutrons; curve C, Kr and CO$_2$ recoil distribution; curve D, 2.5-MeV neutrons.

from Si(n,α) and Si(n,p) reactions are eliminated by this technique.

2.1.5 Semiconductor Detector The reaction ^{6}Li(n,α)^{3}H is also utilized by detecting neutrons with surface-barrier detectors (see DETECTORS, SEMICONDUCTOR). A pair of such detectors, one of which is covered by a thin ^{6}LiF film, is used in a sandwich structure. Because of the low range of alpha and hydrogen particles, the distance between the two detector surfaces is made as small as possible. The two particle groups can be detected separately in each device, the sum peak of both, and also a coincidence spectrum can be determined (Fig. 13). The amplitude of the sum pulses is related to the primary neutron energy. The high energy

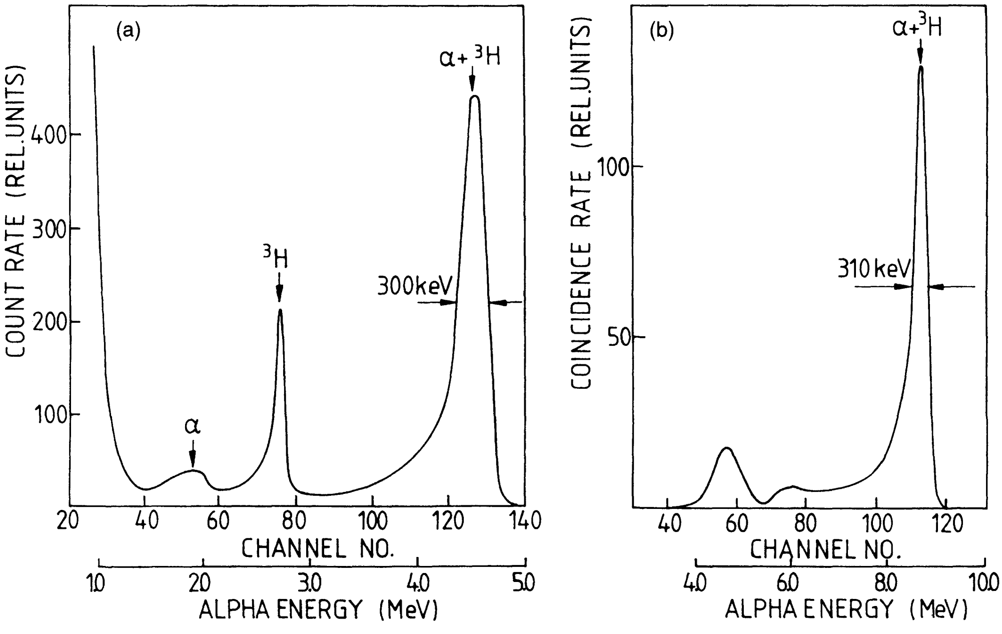

FIG. 13. Pulse spectra of secondaries from the reaction ^{6}Li(n,α)^{3}H measured with a LiF surface-barrier sandwich detector (Neuert 1966). (a) Spectrum of thermal neutron-created secondaries. (b) Coincidence spectrum of 4.15-MeV neutron-created secondaries.

resolution of the surface-barrier detectors is reduced by the LiF film thickness, which should not be too small with respect to the sensitivity of the system. Though the response of this type of detector is small (~1 count per 10^6 neutrons), they are useful for neutron spectrometry because of their good energy resolution.

2.1.6 Thermoluminescence Detector The thermoluminescence detector is a passive device that commonly contains ^{6}Li as neutron-sensitive component. If a ^{6}LiF detector is heated after neutron irradiation, thermoluminescence emission is observed, which can be separated from a gamma background by using a pair of neutron-sensitive and neutron-insensitive detectors. This type of detector is used predominantly in radiation-protection dosimetry: the so-called "albedo personnel dosemeter." The high cross section of ^{6}LiF for thermal neutrons in combination with suitable moderator materials allows the determination of "personnel doses" from the thermal- to fast-neutron range, if the neutron spectrum is well known (see Sec. 1.3).

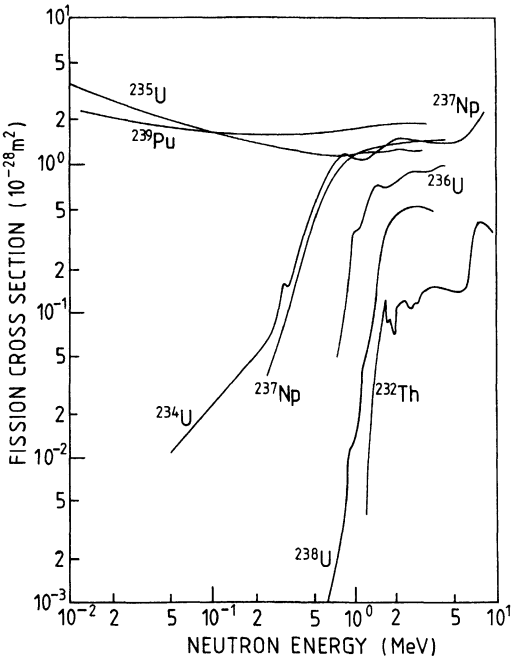

FIG. 14. Nuclear-fission cross section of isotopes used in fission detectors (Lamphere, 1960). 10^{-28} m^2 = 1 barn.

2.2 Nuclear-Fission Detector

Advantageous properties of fission detectors are the following:

1. The energies of fission particles are large (~100 MeV), and so the electronic suppression of a gamma background is easy.
2. There are a large number of suitable elements to be used in the thermal to energetic neutron range (Fig. 14).
3. A number of elements have sharp fission thresholds, so that high-energy neutrons can be detected separately from lower-energy neutrons in a comparatively easy manner.

(See NUCLEAR ENERGY, FISSION)

2.2.1 Fission Ionization Chamber The electrodes of fission chambers are covered with a thin film of a suitable fissionable element. Normally, fission chambers work in the pulse-counting mode; the current mode is used only at very high neutron fluxes. Some of the elements decay by emission of alpha particles, e.g., uranium, thorium, and plutonium. For having high sensitivity at low neutron fluxes it is necessary to suppress the alpha signals, too. This can be done electronically if the chamber is operated in the pulse-counting mode. For operation in the current mode, the chamber dimensions are made smaller than the alpha-particle ranges. The contribution of alpha-particle ionization is then small compared with the contribution of fission-fragment ionization. In Fig. 15, a miniaturized fission chamber for in-core control measurements of neutron fluxes in nuclear reactors is shown. The inner electrode is covered with ^{235}U. Those chambers can be in operation for a number of years since the fission cross section of ^{235}U is comparatively small. This is advantageous over boron ionization chambers, which would be burnt up in short times because of their large cross section for slow neutrons. The fission chamber in Fig. 15 has been constructed to withstand temperatures up to 700 K, and pressures up to 200 bar. It has a nearly linear response up to a neutron flux of 2×10^{14} *n*/cm^2 s in the presence of a gamma dose rate of 10^7 Gy/h. The outer diameter of such a chamber is only about 5 mm in order to en-

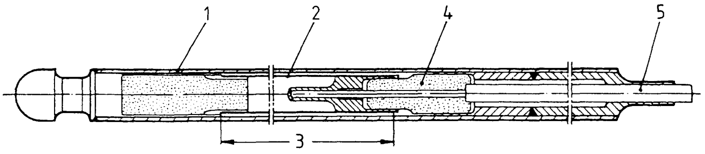

FIG. 15. Cross section of a miniaturized fission ionization chamber for use as in-core flux detector in a nuclear reactor; see text (manufacturer: AEG, Germany). 1, Chamber wall and outer electrode; 2, hollow, uranium-covered inner electrode; 3, sensitive length of the chamber; 4, metal–ceramic seal; 5, ceramic cable.

able installation within the fuel elements of a reactor.

2.2.2 Fission Track Detector Fission recoil nuclei create tracks in solid materials as a result of structural damage along their path, from elastic collisions and primary and secondary ionization events. Dependent on the detector material and the mass of the recoil fragment, the tracks are roughly of the order of nanometers in diameter and up to some tens of microns in length. Fission-track detectors are passive devices consisting mostly of a foil of fissionable material (Fig. 14) in contact with a suitable track-recording sheet. This sandwich configuration has advantages over another version of fission track detectors, where the fissionable material is incorporated in the detector material, since the detection starts with combining the two foils. Otherwise a background from time before start of measurement has to be considered. Numerous glasses and plastics are in use as detectors. Counting of tracks can be performed in different ways:

1. By electron microscopy.
2. By visual (automatic) counting, after the track dimensions have been enlarged by chemical or electrochemical etching.
3. By spark counting, applying high voltage across the (etched) detector film. The tracks across the film lead to single electrical breakthroughs.

Fission track detectors can be used over the total neutron-energy range by taking suitable fissionable materials (Fig. 14), and also for neutron spectrometry, at a large range of neutron fluxes/doses. The technique is comparatively simple, as no expensive electronic equipment is needed. The detectors are insensitive to beta and gamma radiation. The tracks are stable over long periods. As an extreme example, fission track dating is used in geochronological research, e.g., tracks from fission of natural uranium in mica allow dating of material that is up to about 10^8 years old. The detectors also enable the three-dimensional observation of fragment tracks in high-energy and cosmic-ray research.

2.3 Proton Recoil Detector

Proton recoil detectors are based on elastic collisions of fast neutrons with protons in gaseous or solid detector materials. The cross section of this non-nuclear reaction is large because of the equal masses of the two particles (Fig. 10). In hydrogen-containing gases or plastics, protons are kicked out of the molecular binding structure by fast neutrons, and act as fast ionizing particles.

2.3.1 Proton Recoil Proportional Counter Proton recoil proportional counters are filled with hydrogen–argon or methane–argon gas mixtures or the inner walls of the chamber are lined with hydrogen-containing plastics; in many devices both hydrogen gas and plastic lining are combined. Dependent on the gas filling, the gas pressure, and the dimensions of the active counter volume, neutrons with energies between about 10 keV and about 10 MeV can be detected. In Fig. 16, a cross section of a methane–argon-filled proportional counter is shown. The shaded areas represent hydrogen-containing plastic material covering the inner wall of

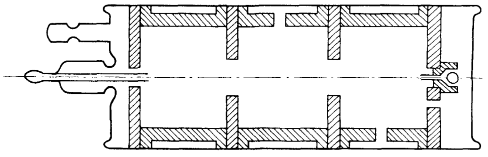

FIG. 16. Cross section of a methane–argon-filled proton recoil counter. The shaded areas represent hydrogen-containing plastic.

the detector. Because of the high specific ionization of fast secondary protons, a suppression of a gamma background by pulse-height discrimination is easy to realize. If the counter is equipped with suitable electronics, and if the counter volume is large enough to stop all secondary protons, neutron spectra can be determined by this type of counter. One disadvantage of the proton recoil proportional counter is the relatively low sensitivity (<0.1 count per *n*/cm² s) as compared with, e.g., (moderated) BF_3, He, and LiI detectors. On the other hand, neutron dose rates up to about 1 Gy/h (10^5 *n*/cm² s) can be detected.

2.3.2 Proton Recoil Scintillation Counter In this type of counter, hydrogen-containing organic scintillators are used as neutron converters, e.g., plastic scintillators, stilbene and anthracene crystals, and also liquid scintillators. Since it is possible to use large scintillator dimensions (especially with liquid scintillators), the detection probability can be made very high even at neutron energies up to about 100 MeV. With liquid scintillators, the detection efficiency at moderate energies approaches 100%. The sensitivity of organic scintillators to gamma radiation and also to competing processes within the scintillator, e.g., carbon recoil nuclei and carbon (*n*,*α*) reactions, is high (Fig. 17). Contributions from those interfering signals must be suppressed by using pulse-height and pulse-shape discrimination techniques. The lower energy limit of this detector type is about 0.5 MeV on account of nontrivial discrimination problems. For quantitative neutron-flux measurements using large scintillators, multiple scattering of neutrons within the scintillator, resulting in pulse summation, has to be considered. Using suitable electronics, neutron-energy spectra between about 0.5 and 100 MeV can be measured with the proton recoil scintillation detector.

Proton recoil scintillation counters are also built using scintillators that are covered with thin inorganic films as, e.g., ZnS(Ag) together with polyethylene, paraffin, or Plexiglas. Also, powdery mixtures of ZnS(Ag) with plastic scintillators are built, but those counters are rarely in use.

2.3.3 Proton Recoil Semiconductor Detector In this version of the proton recoil detector, the *n*-*p* converter is placed onto a silicon surface-barrier detector in a manner that 50% of the active surface is covered by the converter. Since the undesired background reactions are equal in both parts of the barrier detector, the differential pulse spectrum gives the pure proton recoil spectrum. The device is suitable for measurement at higher neutron fluxes.

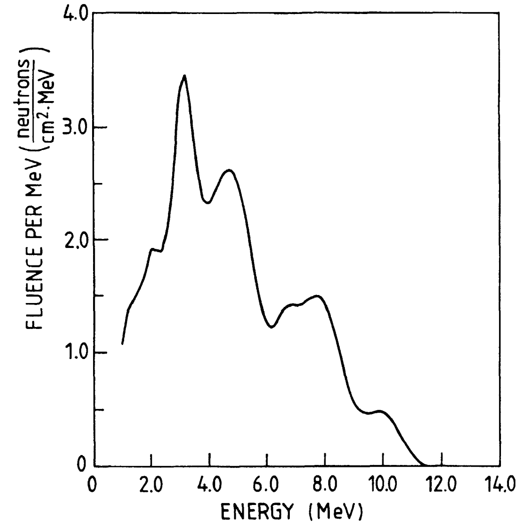

FIG. 17. Neutron spectrum from a ^{239}Pu–Be source measured with a liquid scintillation detector (Ing *et al.*, 1985).

2.3.4 Nuclear Track Detector Proton recoil track detectors are passive devices and are used predominantly in radiation-protection dosimetry. CR 39, an organic carbonate, is a very proton-sensitive material within a limited energy range. The *n*-*p* scattering cross section of CR 39 is large and varies smoothly with neutron energy. The ranges of protons in the detector are large compared with that of heavy ionizing particles, and so CR 39 is more sensitive to neutrons than other materials. Proton-induced tracks are counted after chemical or electrochemical etching of the sheets; also spark-counting techniques are applied. 1- to 10-MeV neutrons can be detected. Because of its sensitivity to *α* particles, e.g., from environmental radon, background tracks must be taken into consideration. For enlarging the response to fast and energetic neutrons, the detector can be combined with a hydrogeneous radiator sheet. The response of CR 39 devices is about 10^3 tracks/cm^2 per mSv dose of fast neutrons.

Besides the n-p scattering, (n,α) and (n,p) radiator sheets are applied with track detectors. Because of the smaller cross sections (see Fig. 10) and the lower recoil ranges within the detector, the response of these devices is poor.

2.4 Activation and Threshold Detectors

Activation detectors are passive devices, which are used to measure neutron fluxes by the aid of various nuclear reactions. Dependent on the slope of reaction cross sections (Fig. 18) with neutron energy, the detectors are classified as thermal, resonance, and threshold detectors.

2.4.1 Activation Detector Activation detectors in a narrower sense are thermal- and low-energy neutron detectors based on (n,γ) reactions (Table 1), though fast and energetic neutrons can also be detected by the use of moderators. The neutron flux can be calculated from gamma- and/or beta-emission intensities of the activated materials, and from the time of exposure to the neutron flux. It is necessary to take into consideration the self-absorption, especially of betas, within the detectors and also the decay of the reaction products. For the determination of gamma and beta activities, various monitors may be used: large-area gas counters, scintillation counters, and semiconductor counters. Because of the self-absorption effects—especially when measuring beta activities—the materials are mostly used as thin films or plates.

Table 1. Slow-neutron detectors

Reaction	Half-life of product	Energy of gamma ray (MeV)	Resonance energy (eV)
$^{23}\mathrm{Na}(n,\gamma)^{24}\mathrm{Na}$	15.0 h	1.37, 2.75	2850
$^{55}\mathrm{Mn}(n,\gamma)^{56}\mathrm{Mn}$	2.58 h	0.85, 1.81	337
$^{59}\mathrm{Co}(n,\gamma)^{60}\mathrm{Co}$	5.26 a	1.17, 1.33	132
$^{63}\mathrm{Cu}(n,\gamma)^{64}\mathrm{Cu}$	12.8 h	0.51	580
$^{115}\mathrm{In}(n,\gamma)^{116}\mathrm{In}^{m}$	54 min	1.09, 1.29	1.46
$^{181}\mathrm{Ta}(n,\gamma)^{182}\mathrm{Ta}$	115 d	1.12, 1.22	4.3
$^{186}\mathrm{W}(n,\gamma)^{187}\mathrm{W}$	23.9 h	0.48, 0.69	18.8
$^{197}\mathrm{Au}(n,\gamma)^{198}\mathrm{Au}$	2.70 d	0.41	4.9

In Fig. 18, cross sections of some activation detector materials are presented. A number of materials have cross sections $\sigma \sim 1/E^{1/2}$ over larger neutron-energy ranges (e.g., Mn), others have strong resonances at certain energies (e.g., In and Rh at about 1 eV). The spectral distribution of low-energy neutrons can be determined if a number of detectors are used simultaneously.

2.4.2 Threshold Detector Neutrons of higher energies can be detected by threshold detectors utilizing, instead of activation detectors, (n,p), $(n,2n)$, or (n,f) reactions, which are induced by neutrons above a certain threshold of the neutron energy (Fig. 19 and Table 2). Threshold detectors have low cross sections compared with activation de-

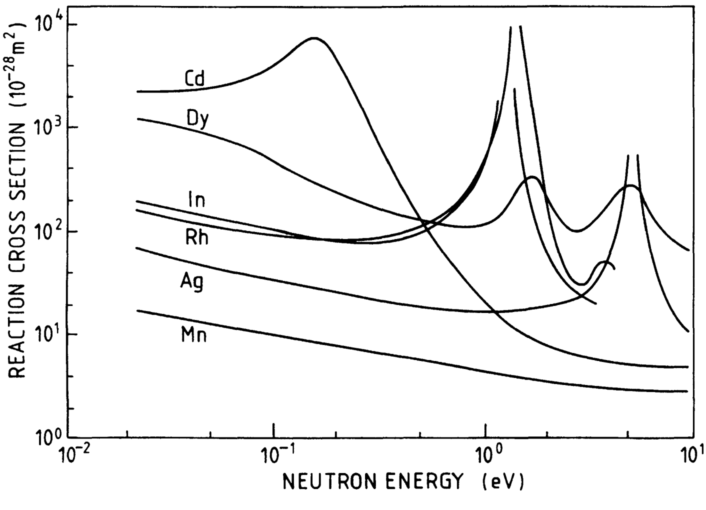

FIG. 18. Nuclear cross sections of common activation and resonance detector elements vs neutron energy (Wirtz and Beckurts, 1958); 10^{-28} m^2 = 1 barn.

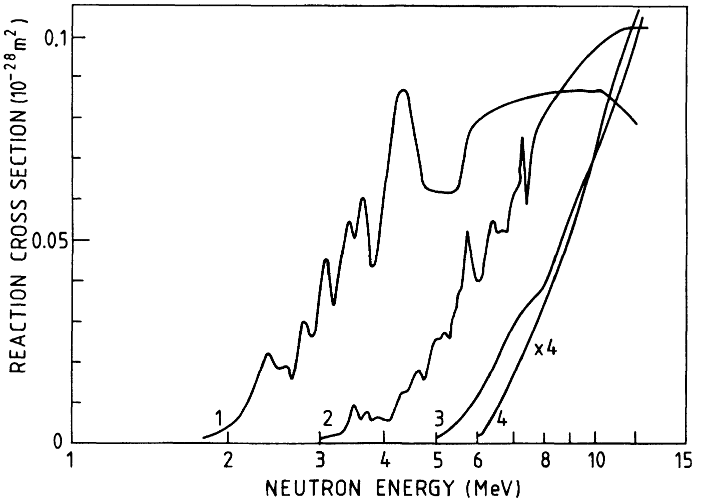

FIG. 19. Nuclear cross sections of some threshold detector elements vs neutron energy (Bresisti, 1963); 10^{-28} m^2 = 1 barn. Curve 1, ^{32}S(n,p)^{32}P; curve 2, ^{27}Al(n,p)^{27}Mg; curve 3, ^{56}Fe(n,p)^{56}Mn; curve 4, ^{27}Al(n,α)^{24}Na.

tectors. The beta and gamma emitters produced by the reactions within the detector material are normally measured with large-area gas counters, scintillation counters, or semiconductor counters. A less common method is the use of scintillator counters where the threshold material is part of the scintillator material. Together with activation detectors they are used in the presence of broad neutron spectra as, e.g., in nuclear facilities or at high-energy accelerators.

2.5 Moderated Detectors

The measurement of fast and energetic neutrons by the aid of active devices is mostly carried out with low-energy neutron detectors surrounded by suitable moderators, because of the large cross sections of low- and thermal-energy neutron detector materials, e.g., with BF_3 proportional counters and LiI scintillation counters (see above).

Table 2. Threshold detectors

Reaction	Half-life of product	Energy of gamma ray (MeV)	Approximate threshold energy (MeV)
^{12}C(n,2n)^{11}C	20.3 min	0.51	20
^{12}C(n,spall)^{7}Be	53.6 d	0.48	30
^{24}Mg(n,p)^{24}Na	15.0 h	1.37, 2.75	7.5
^{27}Al(n,p)^{27}Mg	9.5 min	0.84, 1.01	3.8
^{27}Al(n,α)^{24}Na	15.0 h	1.37, 2.75	4.9
^{27}Al(n,spall)^{22}Na	262 a	0.51, 1.28	25
^{32}S(n,p)^{32}P	14.3 d	1.71 (β)	3.3
^{56}Fe(n,p)^{56}Mn	2.58 h	0.85	5.0
^{58}Ni(n,p)^{58}Co	71.3 d	0.51, 0.81	1.3

2.5.1 Long Counter Long counters are used for precise measurements of neutron-flux densities in the energy range from 10^{-2} to 10^{7} eV. A sketch of a long counter is presented in Fig. 20: A BF_3 proportional counter is surrounded by a suitably designed polyethylene or paraffin moderator, which enables the detection of neutrons with nearly energy-independent sensitivity. The cadmium shield prevents the penetration of low-energy stray neutrons from outside, because cadmium is a strong low-energy neutron absorber. The detection efficiency of such devices is about 0.1 to 1%, i.e., one count per 10^2 to 10^3 neu-

trons. It is also anisotropic with a strong maximum in the forward direction. The cadmium cap at the front side of the instrument can be used to separate thermal- and low-energy neutrons from the faster ones.

2.5.2 Rem Counter Rem counters are dose-equivalent survey meters, constructed for area monitoring in radiation protection. Their sensitivity to neutrons of different energies between 10^{-2} eV and 10^{7} eV should approach the dose equivalent per unit neutron-flux function as far as possible. The latter accounts for the biological effectiveness of neutrons as a function of their energy, and is defined by the International Commission on Radiological Protection. The Rem counter consists of a BF_3 proportional counter or more rarely of a LiF scintillation or a helium-3 counter, surrounded by a spherical or a cylindrical polyethylene moderator of suitable dimensions. In Fig. 21, one device from a variety of commercial products is presented. The proportional counter is surrounded by an inner polyethylene sphere and by a spherical perforated cadmium layer, in order to give a reduced response for lower-energy neutrons. This is because lower-energy neutrons have a smaller biological effectiveness than fast ones. Nevertheless, in the presence of a broad neutron-energy distribution the results are not exact; therefore instruments are available that have two or three replaceable moderator shells of different thickness, thus allowing more accurate dose measurements. The indicating instrument gives the result of measurement directly in equivalent dose-rate units Sv/h. The dose-rate range covered by Rem counters is commonly 0.1 μSv/h to 0.1 Sv/h. Though an isotropic response of the instruments would be very desirable for area monitoring, the response is a more or less strong function of the angle of neutron incidence. Figure 22 gives the response of Rem counters with respect to neutron energy in a unidirectional neutron field.

2.5.3 Multisphere Detection ("Bonner" Spheres) In order to overcome inaccuracy of single-sphere moderated counters in broad-energy neutron fields, precision measurements of neutron fluxes are carried out

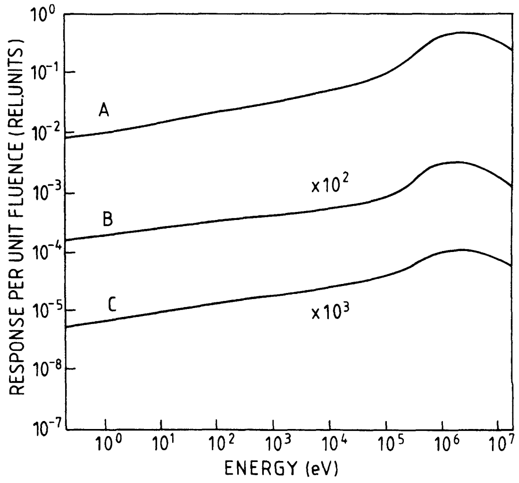

FIG. 22. Responses of Rem counters from different manufacturers. Curve A, "Snoopy" cylindrical moderator/BF_3 detector Rem counter (Hankins, 1977); curve B, Leake 95/0075 spherical moderator/helium-3 detector Rem counter (Harrison, 1979); curve C, PNR-4 spherical moderator/BF_3 detector Rem counter (Hankins, 1977).

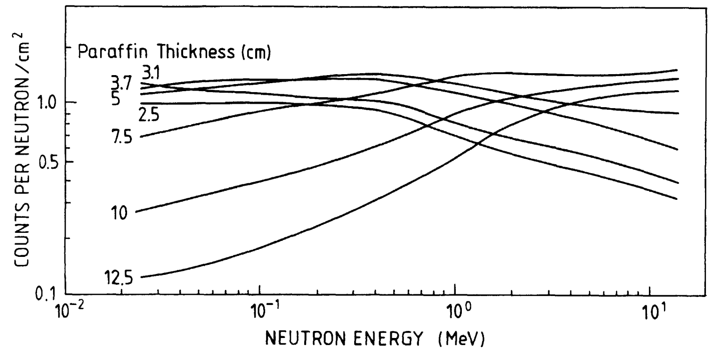

FIG. 23. Count rate of a paraffin-moderated BF_3 proportional counter vs neutron energy at different moderator thicknesses (Wallace, 1960).

with up to ten or even more replaceable moderator spheres of different diameters. The count rate C_i of each counter–moderator assembly is given by

$$C_i = \int \varphi_E(E) \times R_i(E)dE,$$

where $\varphi_E(E)$ is the spectral neutron-flux density, $R_i(E)$ the energy-dependent response, and E the neutron energy. By the aid of mathematical unfolding techniques, the spectral neutron-flux distribution $\varphi_E(E)$ can then be calculated if the functions $R_i(E)$ are well known. Responses of multisphere assemblies are given in Figs. 23 to 25. Similar measurement procedures are applied using passive low-energy detectors, e.g., activation foils. The energy resolution of multisphere detectors is poor as compared with, e.g., semiconductor or helium-3 detectors, but in many applications the covering of a wide neutron-energy spectrum is of over-riding interest.

2.6 Current Developments

2.6.1 Bubble and Drop Detectors The basic principle of this technique is well known from conventional bubble chambers. The boiling of a superheated liquid is initiated by neutrons via recoil nuclei, which deposit their kinetic energy by ionization along their track in the superheated liquid. Small devices are under development for radiation-protection purposes that are much less expensive than conventional bubble chambers. By embedding the liquid, preferably freon 12, in a gel, a large number of isolated very small drops are homogeneously dispersed

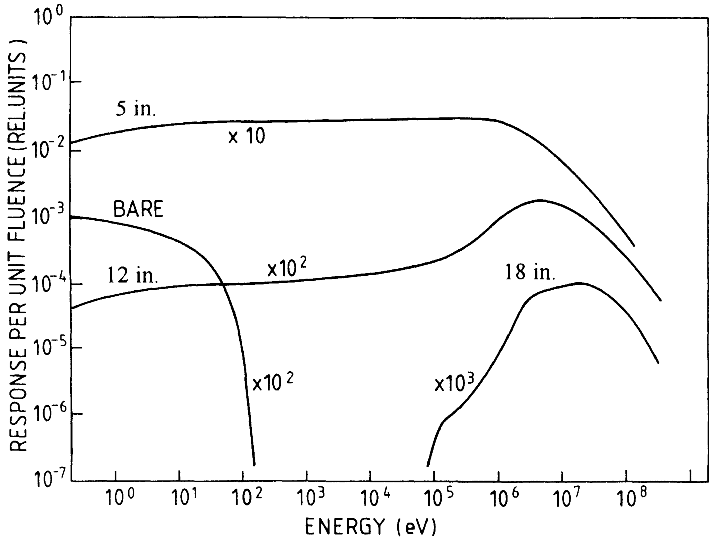

FIG. 24. Response of polyethylene-moderated LiI(Eu) scintillation detector vs neutron energy at different moderator thicknesses (Nachtigall and Burger, 1972).

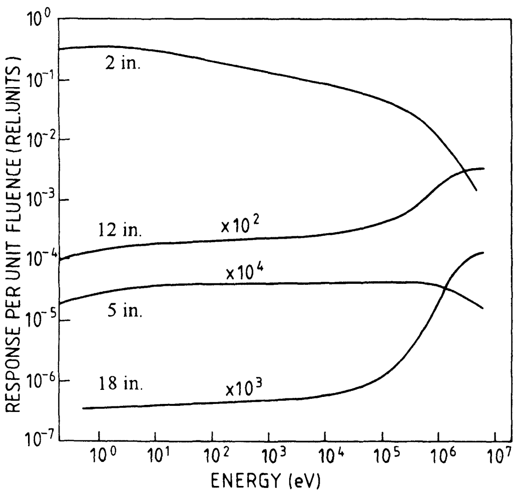

FIG. 25. Response of a polyethylene-moderated helium-3 detector vs neutron energy at different moderator thicknesses (Caizergues and Poullot, 1977).

within the gel matrix. Vaporization of drops due to neutron-induced events is detected by the aid of a piezoelectric transducer, which records the small-pressure pulses. The device enables the detection of neutrons of thermal to very high energies (Apfel and Roy, 1985).

Another approach to the use of superheated liquids for neutron detection has been utilized by Ing and Birnboim (1984): They use a solid polymer as a matrix for the small superheated drops. After vaporization by neutron-induced events, tiny immobile bubbles are formed in the polymer matrix. The bubbles can be observed visually and can be counted by simple optical instrumentation.

2.6.2 Tissue-Equivalent Proportional Counter Tissue-equivalent proportional counters (TEPC) are under development for radiation-protection monitoring in mixed-radiation fields. The TEPC chamber is constructed from tissue-equivalent wall material and is filled with tissue-equivalent gas at very low pressure. If suitably designed, the microprocessor-based TEPC gives a direct measure of absorbed radiation dose. It is possible to measure neutron, gamma, and charged-particle dose simultaneously, and to separate their contribution to dose by sophisticated electronics and mathematics. Equivalent doses and radiation quality factors can be determined numerically, too (Brackenbush *et al.*, 1985). The instruments are reasonably accurate at neutron energies between 100 keV and 14 MeV, which covers most occupational neutron exposure. TEPCs are constructed for area monitoring, and as miniaturized devices for personnel monitoring.

2.7 Neutron Spectrometry

Most of the detectors described above allow neutron-intensity measurements if the neutron spectrum is well known, but not the determination of energies in an unknown neutron field. In many applications, only rough knowledge of the neutron-energy distribution is necessary. Then, a suitable set of passive activation and threshold detectors offers a relatively simple and inexpensive chance of measurement. The application of multisphere techniques with active or passive detectors is also feasible over the total neutron-energy range, but the mathematical expenditure of unfolding procedures is large. Spectrometry in limited energy ranges is possible by the aid of BF_3, helium-3, or scintillation counters, and semiconductor detectors using discrimination and coincidence techniques. More expensive are techniques in which preselection of neutrons with respect to their energy is achieved by mechanical energy or velocity analysis, neutron diffraction, or time-of-flight analysis. With a suitable detector or if necessary with a set of detectors and if necessary with suitable moderators, the range between thermal and about 100 MeV energy can be covered spectrometrically.

In "neutron telescopes," recoil protons are produced in a thin hydrogen-containing foil (Fig. 26). Only protons that are scattered straight forward are energy-analyzed by the

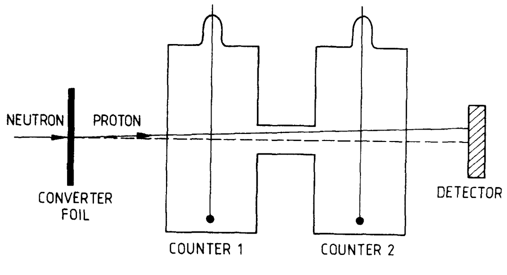

FIG. 26. Cross section of a simple neutron telescope for neutron-energy spectrometry.

detector, because they receive the total neutron energy through elastic collisions. The counting of only forward-scattered protons is enabled by operating counters 1 and 2 and also the proton detector in coincidence. Through the use of two counters, the background from stray neutrons can be appreciably reduced, compared with systems operating with only one counter + detector. A variety of counting and detecting devices is used in different types of neutron telescopes.

3. BETA-PARTICLE DETECTORS

The range of beta particles (electrons and positrons) in matter is generally much smaller than that of gamma quanta and neutrons. So self-absorption in a beta source and absorption in the detector wall must be considered. In addition, beta particles from radioisotopes have always a broad energy distribution. That is, if (self-)absorption occurs, measured beta spectra will not be identical with the original emission spectra. In Fig. 27(a) a typical beta spectrum and in Fig. 27(b) the transmission of beta particles through counter windows are shown.

Most of the artificial radioisotopes are beta emitters, and most of them emit simultaneously gamma radiation. So the activity of an isotope or an isotope mixture may in most cases be determined by the aid of a gamma detector in a simpler manner. But there are also pure beta emitters, e.g., ^{3}H, ^{14}C, ^{32}P, ^{35}S, ^{204}Tl, which are important in some applications. On the other hand, the assay of low-level beta–gamma sources is sometimes carried out by the aid of beta counters, because most of these detectors have higher efficiencies than gamma detectors. In most cases, sensitive detection of beta emission needs shielding against gamma and cosmic background radiation. Additional anticoincidence shielding leads to further reduction of background radiation.

Aside from basic scientific research, beta detectors are used in fuel-cycle facilities as well as in isotope-production facilities and in nuclear medicine departments, e.g., for process control and activity determination. In all those facilities, control of personnel exposure mainly by incorporation, and control of the release of isotopes to the environment via waste water and air is necessary.

3.1 Detectors for Activity Measurements

The activity of a source is defined as the number of nuclear disintegrations per second. This must not be confused with "beta activity" of a source, since there are isotopes that emit more than one beta particle per decay and in most cases there is simultaneous emission of one or more gamma quanta. Moreover, exact measurement is complicated if the daughter product is a beta emitter, too. Then the total activity is a function of time until equilibrium is reached (see RADIOACTIVITY). If precision is necessary, all emitted particles must be detected under 2π or 4π geometry. Otherwise the response of an instrument to betas of different energy must be well known by calibration, and also the nature of the source must be well known.

3.1.1 Liquid and Solid Scintillation Counters The liquid scintillation counter (see DETECTORS, SCINTILLATION) is in general a useful tool in activity measurement, but it is of particular importance for the assay of low-level sources, and in the presence of low-energy pure beta emitters such as ^{3}H and ^{14}C, which have maximum beta energies of only 18 and 156 keV, respectively. As a result of the homogeneous solution of the isotopic compound in the scintillator liquid, there is no primary loss of beta ionization energy. But by mixing of the two liquids quenching effects occur, and so the measurable activity is generally limited to small quantities. Background events have to be considered especially in liquid scintillation detectors, since undesired light production is possible that may even exceed that resulting from the sample decay, e.g., phosphorescence or chemiluminescence from reactions of the mixed liquids or by impurity contents. Since precision measurements are carried out by comparison with standard solutions of the isotopes of concern, the chemical identity of both samples is of importance, otherwise different background events may lead to wrong results, especially with low-energy emitters. Careful calibration is always necessary. A large number of labeled compounds are commercially available for comparative assay of nearly all isotopes of general interest. The detection probability for ^{3}H is up to 65%, and it reaches nearly 100% at higher beta energies. Though the energy res-

olution of the liquid scintillation counter is relatively poor, simultaneous measurement of isotope mixtures is possible under certain conditions (dual-label assay of two-component beta–beta or beta–alpha mixtures). By use of multichannel analyzers, suitable energy-window setting, and additional computer-supported fitting of the slope of measured spectra, the activity components of mixed isotopic compounds can be determined with reasonable success in many cases. Gaseous isotopes can also be measured with the liquid scintillation counter either by introducing the gas directly into the scintillator, or by trapping the gas in suitable liquid media, which then are mixed with the scintillator.

In solid scintillation counters for beta-particle detection, generally plastic scintillators and also organic crystals such as anthracene or stilbene are used. Those counters are well suited for beta spectrometry. By the application of large specially shaped scintillators, the sensitivity to betas but also to background gamma radiation is high. By the aid of heavy-metal and anticoincidence shielding, the background can be reduced to below 0.01 counts/s. In Fig. 28, the cross section of such an instrument is presented. By combination of two counters, a scintillator and an additional Geiger-Müller device, the gamma background is suppressed electronically.

3.1.2 Proportional and Geiger-Müller Counters Gas-multiplication detectors can be applied in solid and gaseous beta-source assay. An example of a vast variety of counter designs to be used with solid sources is shown in Fig. 29. Those counters have very thin plastic or metal foil windows with thicknesses of 0.1 to 10 mg/cm^2 in order to allow the passage of beta particles. Usually the counting gases are methane or argon–methane mixtures (proportional counter), and helium–butane mixtures (Geiger-Müller counter) at atmospheric pressure. For low-level activity assays, those devices are operated in the anticoincidence mode and are heavily shielded. On account of self-absorption in the beta source, absorption in the window, and backscattering, expensive calibration procedures are necessary. Internal counters are used for measurement of gaseous isotopes such as ^{3}H, ^{14}C, and ^{85}Kr. In most cases, the isotopes are mixed with a normal counting gas; more rarely, only the isotope acts as counting gas. Those counters exist in a large variety of designs. In low-level applications they consist usually of a

long metal or quartz cylinder with axial anode wire; their counting volumes range from some milliliters to several liters. Effective shielding as described above is necessary.

3.1.3 Ionization Chamber Like the proportional counter, the closed ionization chamber is disadvantageous if solid sources, especially low-energy beta emitters, are to be investigated. Nevertheless if suitable thin-film sources of not too low beta energies are used, the ionization chamber operated in the current mode is less sensitive to sample self-absorption than a pulse counter: Each high-energy beta particle creates thousands of ion pairs that contribute to the ionization current, but it creates only one pulse in the counter-type detector. The low-energy betas, which mainly undergo self-absorption, produce fewer ion pairs compared with the high-energy ones, but each represents one lost pulse in the counter. In Fig. 30, the construction of a combined beta–gamma reference ionization chamber is shown. It consists of a parallel-plate beta chamber and a cylindrical gamma chamber. Both solid and liquid sources can be introduced into the chamber below the beta chamber. Those chambers are available with fixed calibration factors for a large number of nuclides. Ionization chambers of this type are widely used as secondary standard instruments for the calibration of beta and gamma sources, because of their ease of operation with excellent reproducibility.

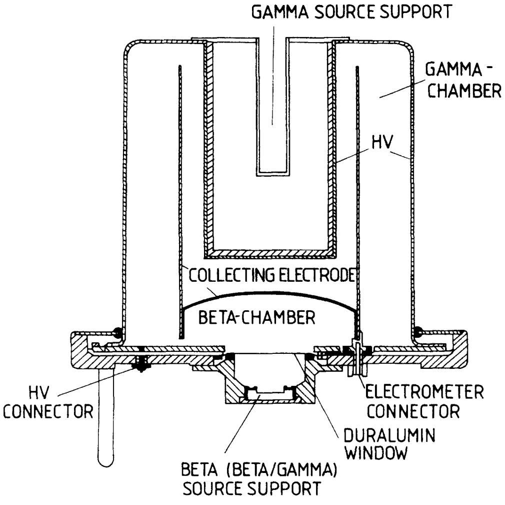

FIG. 30. Cross section of a beta–gamma ionization chamber (Robinson, 1960).

Internal ionization chambers can be used for the assay of radioactive gases such as ^{3}H, ^{14}C, and ^{85}Kr. A well-known amount of gas is filled into the chamber, and the measured ionization current is a direct measure of the gas activity. Mostly, comparative measurements are carried out by using gaseous standards.

3.1.4 Cherenkov Counter Beta particles in aqueous solutions can be detected by the aid of Cherenkov counters, if the beta energy is greater than 0.26 MeV (see ELECTROMAGNETIC RADIATION). The measurement technique is similar to liquid scintillation counting and in laboratory practice generally such equipment is applied. In practice, mostly water is used as light-producing medium. The advantage of this technique is the relative ease of sample preparation: The solid or liquid beta source is placed in a small water-filled glass or plastic vial, and the activity is counted in analogy to scintillation counting. A further advantage over liquid scintillation counting is the absence of chemical quenching effects, due to the different light-creation process. Since the Cherenkov radiation is emitted at short wavelength and anisotropically in the forward direction, a wavelength shifter is applied when using liquid scintillation coincidence counting equipment. The wavelength shifter effects a better adaption of the wavelength of light to the phototube spectral sensitivity, and it also reduces the light anisotropy due to the isotropic emission of the secondary light. The latter effect enhances the sensitivity of the equipment, because the phototubes are usually arranged diametrically opposed in liquid scintillation counters. Though the number of detectable isotopes is limited by the detection threshold, and furthermore the detection efficiency is lower than in scintillation counting, the technique is often used because of the ease of operation. Table 3 gives some examples of detection efficiencies, which strongly depend on beta energies of isotopes.

3.1.5 Beta-Particle Spectrometry Precision beta spectrometry is carried out mainly by the aid of spectrometers based on the deflection of particles in electric and

Table 3. Cherenkov-counting efficiencies for various beta-emitting nuclides (Francois, 1973). The efficiencies were measured using a liquid-scintillation counting system, with two diametrically opposed phototubes in coincidence.

Isotope	E_{mean} (MeV)	E_{max} (MeV)	Detection efficiency (%)
^{204}Tl	0.240	0.764	3
^{198}Au	0.312	0.961	6.7
^{24}Na	0.554	1.390	32.5
^{40}K	0.561	1.312	38.4
^{89}Sr	0.583	1.488	28.3
^{32}P	0.695	1.710	35.1
^{90}Y	0.935	2.284	50.6
^{76}As	1.064	1.75 (16%) 2.41 (31%) 2.97 (50%)	59
^{42}K	1.430	1.996 (17.5%) 3.521 (82.1%)	70.3

magnetic fields, having an energy resolution of about 10^{-4}. Those expensive techniques are applied only in basic scientific research. In practical application, the task is mainly to identify a beta emitter or mixtures of beta emitters by gross energy-distribution measurement.

The measurement of beta absorption in thin sheets of different thickness is a very simple method. When the counting rates are plotted vs sheet thickness on a logarithmic scale, an extrapolation of the curve to zero counting rate gives the maximum beta energy of the unknown isotope. The technique is time consuming and not very exact, especially in the presence of a gamma background and/or a mixed beta source.

The method of choice in gross beta spectrometry is scintillation counting supported by multichannel analysis. Suitable scintillators are plastics and organic crystals like anthracene or stilbene. The thickness of scintillators should be 1 to 2 cm, because total absorption of beta particles within the material is necessary. An advantage of organic scintillators over inorganic ones is the low Z, which causes low backscattering rates. A further reduction of backscatter is possible by using specially shaped scintillators (see, e.g., Fig. 28). Because of the high sensitivity of scintillation detectors to gamma radiation (anti-)coincidence techniques should be applied. In principle, also silicon surface-barrier or diffused-junction semiconductor detectors (see DETECTORS, SEMICONDUCTOR) are suitable for beta spectrometry, but their detection efficiency is lower than that of scintillation detectors, and their high energy resolution is hardly needed because of the broad beta-energy distributions [see Fig. 27(a)]. Therefore these detectors are rarely used in beta spectrometry. Thin-window proportional counters are well suited for low-energy beta spectrometry; below 100 keV their energy resolution exceeds even that of scintillation detectors. Because of the range of beta particles in gases (some meters at 1 MeV), they are not stopped totally within the counter volume at higher energies, and the measured spectra would be distorted. The upper energy limit is enhanced by using high-pressure counters.

3.2 Detectors for Area and Environmental Control

In all workplaces where beta and beta–gamma sources are handled, and the possibility exists that gases, vapors, liquids, or dusts are released from open radioactive sources or even from normally closed sources in hazardous amounts, area monitoring, personnel monitoring, and room-air and waste-water and -air monitoring are necessary. Various equipment is needed depending on the monitoring purpose and the kind of radioactive sources. Equipment of workplaces, tools, and work clothes can be controlled by portable contamination monitors. At the exit of a controlled area, personnel often are checked by large-area lock monitors. In many facilities, ventilation systems are installed and the room air is controlled by suitable monitors. Waste water and air are even analyzed spectrometrically if complex isotopic mixtures may be released under normal or accidental conditions.

3.2.1 Beta–Gamma Contamination Monitors Portable contamination monitors are usually equipped with flat, xenon-filled proportional counters. The windows are made from typically several-mg/cm^2-thick aluminum or titanium foils, and the active areas are about 100 cm^2. Mostly they give an acoustical alarm if certain isotope-related threshold pulse rates are exceeded. In Table 4, typical sensitivities for some isotopes are exemplarily given. It can be seen from the table that the monitor well meets the specifications given by concentration limits (3.7

Table 4. Isotope-related counting rates of a portable beta–gamma contamination monitor (Lab. Berthold, 1984)

Isotope	Specific counting rate ($\mathrm{Bq \cdot cm^{-2}/count \cdot s^{-1}}$)	Counting rate at the limit of 3.7 Bq $\mathrm{cm^{-2}}$ ($\mathrm{s^{-1}}$)
^{14}C	0.2	20
^{60}Co	0.07	50
^{99m}Tc	0.3	13
^{125}I	0.3	13
^{131}I	0.04	100
^{241}Am	0.3	13

Bq/cm^2) in radiation-protection regulations. ^{3}H cannot be detected by this class of monitors because of its low beta energy. If isotopes or isotope mixtures with larger gamma energies are present, these monitors detect also incorporated radioactivity. At many workplaces, the composition of isotopic mixtures is well known and constant. Then, only the control of one well-detectable "leading isotope" is necessary.

Larger counters of the type described above are used with hand or hand–foot monitors, usually with active-window areas of about 1000 cm^2. In large lock monitors, where the whole person is controlled, several counters with some square meters of active-window area are combined.

3.2.2 Room- and Waste-Air Monitors

Room-air monitors installed in ventilated areas are designed for permanent operation. Modern systems have sophisticated electronics including, e.g., permanent recording of data, self-control of important functions, automatic alarming when the concentration of isotopes exceeds certain levels, and long-term stability. Because the kind of isotope or isotope mixture differs appreciably in the various nuclear facilities, and may also differ from workplace to workplace in even one facility, a large variety of room-air monitors has been developed. There are monitors for detection of special nuclides only, and those which detect isotope mixtures, either in separate measuring channels or as sum concentrations. In many cases, it is again possible to detect only "leading isotopes" from a mixture of, e.g., beta–gamma sources. In many facilities where only beta or beta–gamma gases with not too low energies are handled, large-area, thin-window proportional counters (see Sec. 3.1) have sufficient detection sensitivity. It is important that the contaminated air pass the counter window in a continuous and well-defined flow. When radioactive aerosols are present, it is necessary to sample them by the aid of filters, and to measure the filter activity in suitable time intervals. In either case, covering of the counter window by inactive or active dust or aerosols can lead to false results. This must be measured and suppressed automatically by system electronics.

Low-energy beta emitters such as ^{3}H and ^{14}C cannot be detected by these methods, in particular not at low concentration levels as is necessary with waste-air control. The techniques of choice are real-time detection with flow-through counters, and sampling of isotopes by adsorbers and measuring in suitable time intervals with open counters. The latter technique is applied mainly in beta–alpha monitors, and is described in Sec. 4. A main problem with low-energy beta emitters is to perceive quickly a sudden, e.g., accidental, concentration increase in the room air. This needs high flow rates in the counter and also computer-supported automatic action of the system. Mostly, internal methane or methane–argon proportional counters are applied for control of low-energy beta activity in room air. In Fig. 31, the configuration of such a system, designed for independent measurement of ^{3}H and ^{14}C, is shown. The methane–air mixture flows through four flat counters—two screening counters and two measuring counters—which are not separated mechanically but by grounded grids. The two outer "screening counters" are applied for background suppression. By means of the coincidence–anticoincidence system, pulses from the two isotopes can be separated from each other and from background radiation. Additionally, the counter is heavy-metal shielded. The concentrations are not measured continuously but during successive intervals, within which the pulses are summed up. The methane–air volume ratio is 2:1. Each single detector has a volume of 1.2 L. The lower detection limit depends on the integration time. Of course, other gaseous pure beta emitters such as ^{85}Kr or ^{133}Xe can be detected by the aid of this concept. More rarely applied are other sensitive detectors, the lower detection limits of which meet the requirements described above: liq-

uid scintillation detectors, internal plastic scintillation detectors, and compensated ionization chambers.

3.2.3 Waste-Water Monitors In nuclear facilities, large amounts of waste water are produced, which have to be controlled. Generally, the same detection principles as described above are applied: thin-window proportional counters, plastic scintillation counters, and liquid scintillation counters for monitoring of very low-energy isotopes such as tritium. The simplest technique for monitoring waste water at not too low activity levels and beta energies is the use of diving counters. The detectors are preferably thin-walled, methane- or methane–argon-filled proportional counters. They can be used in streaming water and of course for activity measurements in containers. But their walls must be thicker than those of air detectors, because they must withstand larger pressures, especially dynamic pressure variations in pipes. Therefore wall thicknesses below 30 to 60 mg/cm^2 are not possible, and beta particles with energies of less than about 500 keV cannot be detected. There are also problems with active or inactive films that may be deposited after some time of use at the outer walls, and may lead to false results.

In the presence of lower-energy betas, large-area, thin-window proportional counters and more rarely plastic scintillation counters are applied, which are placed directly above water surfaces. In many cases, when the sensitivity of this method is too low, physical or chemical concentration techniques are applied before measurement. This is especially necessary if ^{3}H has to be monitored in aqueous media. Those measurements are performed using liquid scintillation counters as described in Sec. 3.1.1. A continuous, direct, and sensitive monitoring of ^{3}H in streaming water is impossible.

3.2.4 Beta Monitors for Radiation Dosimetry One task of beta measurement in radiation-protection dosimetry is to monitor the risk of man to direct beta irradiation. Because of the low penetration depth of beta radiation in tissue, this risk is small compared with the risks of incorporation from air or liquids. Therefore it is limited to those persons who deal occupationally with high-energy beta emitters such as ^{90}Sr/^{90}Y, ^{32}P, or ^{234}U or with, e.g., therapy electron accelerators. In these cases, there is a need for area and personnel monitoring at workplaces. On the other hand, high sensitivity of detectors is not necessary in this field.

For area monitoring, there is a demand for robust and handy instruments. The monitors (so-called "survey monitors") are usually air-filled ionization chambers and are operated at normal pressure. They have thin walls (several mg/cm^2) that preferably consist of tissue-equivalent materials like plastics. Chamber dimensions are between about 200 and 500 cm^3. The devices are normally not of special design for beta measurements, and the results should be taken with care, unless the response of the chamber is calibrated in a well-known reference field.

More exact beta monitors are developed in order to allow measurements in beta fields of unknown energy distribution, e.g., using a tissue-equivalent plastic scintillator combined with a multichannel analyzer for beta-spectrum determination. Beta dose rates can so be measured with an accuracy of about 25% if the gamma background is not excessive.

The "extrapolation chamber" is an instrument for precise and absolute determination of the absorbed dose rate in tissue-equivalent material. It is a special ionization chamber with parallel electrodes (Fig. 32). The volume of the filling gas can be varied by the aid of a movable piston thus making it possible to extrapolate the dose rate to zero thickness. When used in a tissue-equivalent phantom at different depths, the strongly depth-dependent absorbed dose by betas of different energy can be measured. For beta emitters with maximum energy >800 keV, the relative uncertainty of results is better than ±2%. Measurement is possible down to 50 keV but with increased uncertainty.

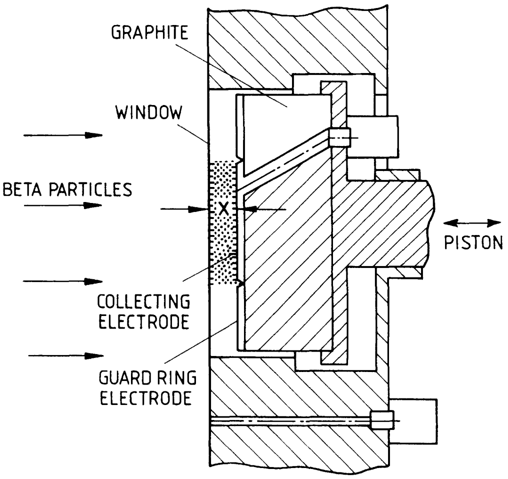

FIG. 32. Beta-particle "extrapolation chamber" for precision measurements of beta dose rates. The dotted area represents the active detector volume (Böhm, 1984).

3.3 Passive Beta Detectors

Passive beta particle detectors are mainly used in personnel monitoring for direct beta irradiation. On account of the small penetration depth of betas in tissue, the International Commission of Radiological Protection had prescribed measuring the absorbed beta dose in a corresponding tissue depth of 0.07 and eventually 3 mm. There are a number of detection techniques applied in personnel monitoring:

1. Film dosemeters, which have a lower detection limit of about 500 keV, because photographic films must be worn in a light-tight pack that absorbs lower-energy betas. But even 70-keV betas can be hazardous for human skin.
2. Thermoluminescence dosemeters (TLD), in which mostly thin lithium–fluoride films act as detector material. Their response decreases below about 200 keV, but is not zero.

3. Exoelectron dosemeters, in which the thermally stimulated emission of "exoelectrons" from beryllium-oxide thin films is applied for beta detection. These dosemeters are the most sensitive devices known up to now. Their response is appropriate even at the lowest relevant beta energies, because of their sensitive depth of about a tenth of a millimeter.

Independent of the type of dosemeter, personnel beta monitoring suffers from absorption of beta particles in air, i.e., the dose is recorded at the location where the dosemeter is worn. Therefore, recording of beta doses with personnel dosemeters is only a rough estimate of individual beta dose, and the results should be interpreted very carefully.

4. ALPHA-PARTICLE DETECTORS

Because of their mass, which is about 8000 times greater than that of beta particles, alpha particles have much lower penetration depths in matter than beta particles. The ranges of alpha particles from radioactive sources in solids and liquids are lower than about 0.01 cm, and in air about 5 cm. This means that self-absorption in sources and absorption in counter windows is a more severe problem than with beta sources, as described in the preceding section. Indeed, there is the possibility to detect alpha emitters by the aid of their gamma emission, but in most cases this gamma emission is of very low energy, and especially in mixtures of radioisotopes this method may be unsuitable. On the other hand, the ionization density of alpha particles in matter is more than two orders of magnitude higher than that of betas and gammas. In contrast to beta emission, alpha particles are emitted monoenergetically, i.e., the identification of alpha emitters in mixed sources by spectrometry is generally easier than beta spectrometry. Table 5 gives data of some selected alpha emitters. Aside from basic scientific research, alpha detectors are in use in facilities of the military and civilian nuclear-fuel cycle, including uranium mining, and in isotope-production facilities. An additional field is the environmental natural radon, especially in conventional mining.

Table 5. Data on Selected Alpha-Particle Emitters

Radioisotope	Alpha-particle energy (MeV)	Relative intensity (%)	Half-life
^{212}Po	8.7842	64.1	3×10^{-7} s
^{220}Rn	6.288	99.9	55.6 s
^{222}Rn	5.4895	99.9	3.8 d
^{232}Th	3.830	0.2	
	3.954	23	1.4×10^{10} a
	4.013	77	
^{235}U	4.368	12.3	
	4.374	6.1	7×10^{8} a
	4.400	57	
^{239}Pu	5.105	11.5	
	5.1438	15.1	2.4×10^{4} a
	5.1566	73.3	
^{241}Am	5.388	1.4	
	5.443	12.8	
	5.4486	85.2	432.6 a
	5.512	0.2	
	5.5443	0.34	
^{252}Cf	6.0757	15.5	2.64 a
	6.1181	84.5	

Concerning radiation protection, alpha emitters are the most hazardous isotopes with respect to incorporation. Therefore the allowed air concentrations of alpha emitters at workplaces are as low as, e.g., 6×10^{-1} Bq/m^3 for uranium ($^{235}UO_2$, $^{235}U_3O_8$), or 2×10^{-1} Bq/m^3 for plutonium ($^{239}PuO_2$). The detection of alpha-in-air concentrations below those limits is extremely difficult. The task is rendered more difficult by the larger concentrations of the natural alpha emitter radon and its daughters in room air, which is much less hazardous than the isotopes mentioned above.

4.1 Detectors for Activity Measurements

4.1.1 Liquid and Solid Scintillation Counters Because of the very short alpha-particle ranges, the amount of matter between detector and source should be a minimum. As with beta-particle detection described in the preceding section, scintillation counting is a suitable tool for alpha-activity measurement. But the relative large background counting rates of liquid scintillation counters (see Sec. 3.1.1) restrict the usability of this technique to low-level sources. In mixed-isotope sources, the separation of alpha energies is difficult. Using a multichannel analyzer and pulse-shape discrimination, an energy resolution of about

10% at nearly 100% detection efficiency is achievable with liquid scintillation counters if suitable alpha sources are investigated (Fig. 33). But generally this is not the method of choice in alpha spectrometry.

In solid scintillation detectors, uncoated scintillators have to be used because of the short alpha-particle ranges. Inorganic materials such as $CaF_2(Eu)$, ZnS(Ag), and CsI(Tl) are applied, which are more or less insensible to air humidity. With regard to alpha self-absorption the source should not be thicker than the range of alpha particles, when gross alpha measurements are performed. For precise spectrometry, the source thickness should be less than 1% of the particle range of about 10^{-4} cm to provide maximum energy resolution below 5%.

Gaseous alpha emitters such as the natural radon isotopes and their daughter products can be assayed with both liquid and solid scintillation detectors. A number of detectors are in use, one of which is shown in Fig. 34. The charged radon recoil particles are sampled on the ZnS(Ag)-coated anode by the aid of an electrical field.

Both liquid and solid scintillation counters should be constructed of materials that contain extremely low concentrations of natural alpha emitters, to reduce spurious background counts. Furthermore, initially clean devices may be contaminated by exposure to air, as a result of alpha-emitting daughter products of natural radon isotopes that "plate out" on surfaces.

4.1.2 Alpha-Particle Spectrometry Although scintillation detectors may be of use in this field, high-resolution spectrometry is carried out mainly with silicon surface-barrier detectors (see DETECTORS, SEMICONDUCTOR), and more rarely with pulse-ionization chambers. In Fig. 35, an alpha spectrum from ^{241}Am is presented where the different alpha-particle groups emitted by this isotope are well resolved, thus demonstrating the superior performance of this detector type (see Fig. 33). In this alpha-energy range, energy resolution is about 0.2% (FWHM), being somewhat poorer at lower alpha energies because of electronic noise.

After long-term use, the detector performance degrades as a result of radiation damage in the active detector volume, leading to increased leakage current and loss of resolution. A rough number for the occurrence of serious defects from alpha particles is 10^{11} particles/cm^2.

Pulse-ionization chambers are also used in alpha spectrometry though semiconductor detectors are in advance during the last two decades. With very large-area chambers (up

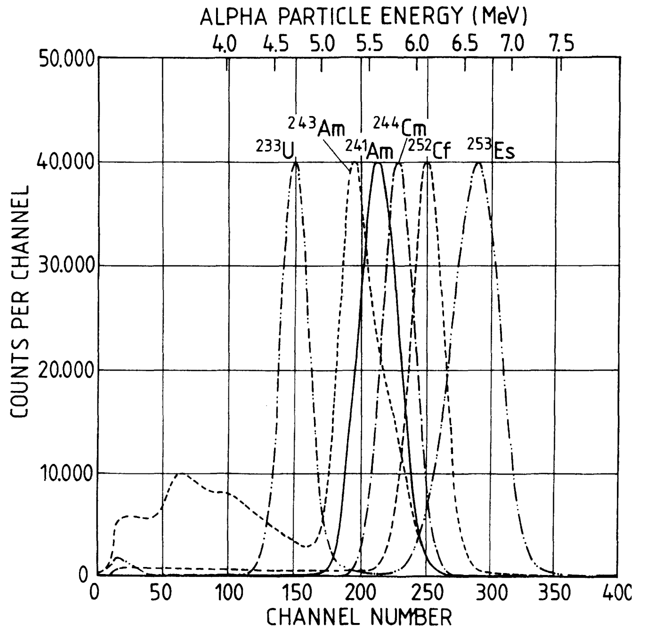

FIG. 33. Alpha spectra of selected actinides recorded with a liquid-scintillation detector (McDowell, 1971). Note: The spectra are not from a mixture of the actinides.

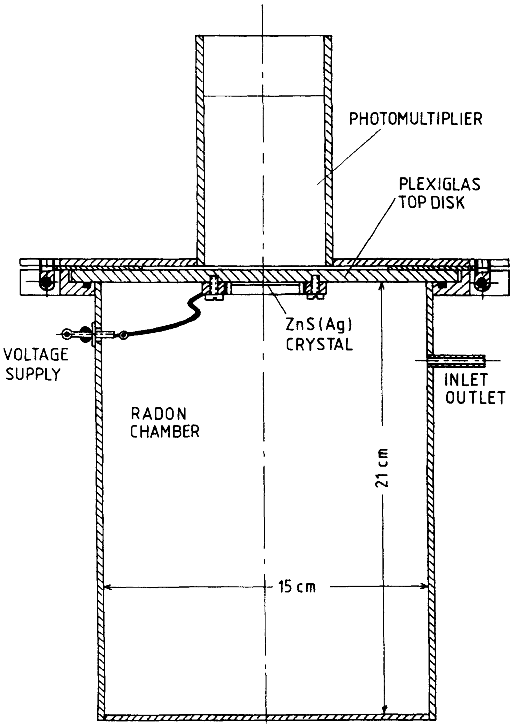

FIG. 34. Cross section of a scintillation counter for detection of radioactive gases (Mann and Seeliger, 1958).

to 1.5 m^2), a resolution of about 1% can be obtained. Further techniques applied on a small scale are mass spectrometry and calorimetry.

4.2 Detectors for Area and Environmental Control

As mentioned above, the detection of alpha-particle concentrations in room and waste air and also in waste water is very difficult because of the low concentration limits that are decreed for many alpha emitters; e.g., much less than one decaying ^{239}Pu atom/s in 1 cm^3 of air has to be detected. With the exception of radon gas, all alpha emitters are present as aerosols or dusts. A variety of sophisticated systems has been developed, the most sensitive based on aerosol and dust-sampling techniques. The control of liquid wastes is mostly carried out after physical or chemical concentration of samples. Most monitoring systems detect alpha and beta activities simultaneously.

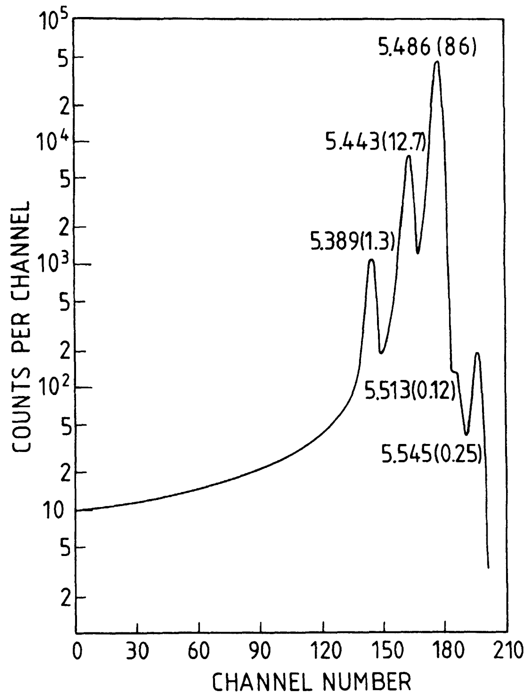

FIG. 35. Alpha spectrum of ^{241}Am recorded with a silicon surface-barrier detector (Chanda and Deal, 1970).

4.2.1 Alpha-Contamination Monitors

Alpha-contamination monitors operate mostly with very thin-window, large-area proportional counters. Windows are made from plastics, metals, and metallized plastics, 0.5 to 1 mg/cm^2 in thickness. Gas fillings are methane, butane, propane, and also noble-gas mixtures. The active counter area of portable devices is usually 100 cm^2. Most of the instruments in use detect both beta (+gamma) and alpha radiation by applying two different high-voltage levels. Because of the higher ionization density of alpha particles in the counter gas, the so-called "alpha plateau" is at lower voltages than the beta + gamma plateau. Typical alpha and beta + gamma plateau voltages are 2.3 and 3.4 kV, respectively, when working with methane, and 1.5 and 2.2 kV, respectively, when working with an argon–methane mixture. The detection efficiency of alpha monitors for, e.g., ^{241}Am is up to about 20%. The figures given vary widely depending on the type of product, i.e., the design of the instrument.
]

4.2.2 Room-Air, Waste-Air, and Waste-Water Monitors Except from some gaseous alpha emitters of comparatively low hazard potential, which can be controlled by flow-through and thin-window counters (see Sec. 3.2.2), efficient room- and waste-air control is not possible without sampling techniques. When actinide aerosols or dusts are present in room air, as is possible in nuclear reprocessing plants (limiting isotope: ^{239}Pu) or in nuclear-fuel–element production facilities (limiting isotope: ^{238}U) sampling times of up to 24 h may be necessary in order to secure that limits of isotope-in-air concentrations are not exceeded. Aerosols and dusts in room air are usually sampled by pumping 1 to 50 m^3/h of air through suitable filters. For detection of sampled activities, open scintillation counters or thin-window gas-multiplication counters are used. In many facilities, counting systems detect both alpha and beta activities simultaneously in two channels. This is realized by using two different detectors, by operating a gas counter at two high-voltage plateaus, or by using a ZnS(Ag)-coated plastic scintillator where the ZnS(Ag) coating is for alpha detection and the plastic scintillator for beta detection. One main problem of detection of low-level actinide activities is the suppression of higher-level alpha activities of natural radon and its daughter products. This can be carried out by

1. filtering the fresh air supplied from outside, so lowering the radon daughter activity concentrations;
2. applying pulse-height discrimination, since all the radon and radon daughter products have higher alpha energies than, e.g., plutonium or uranium;
3. comparing prompt and delayed count rates, and determining the decay of sampled activity. Radon and radon daughter products possess much smaller half-lives than, e.g., the relevant actinides.

Whereas room-air control is mostly performed with detection systems in which single filters are exchanged and controlled after a certain sampling period, waste-air monitors are equipped mostly with running filter belts, whereby the belts are run continuously or stepwise after certain sampling intervals. There are various commercial systems available; an example is shown in Fig. 36. The system has two alpha–beta detectors. The first one measures the prompt activity sampled on the filter, the second one measures the decayed activity after a delay of, e.g., 12 or 24 h. The highest detection sensitivity is obtained with filter belts running stepwise, since the amount of sampled activity is increased with sampling time at each belt sector. When highly resolved alpha spectrometry is necessary, e.g., in nuclear reprocessing plants, silicon surface-barrier detectors are installed.

Concerning waste-water control, especially if low-level actinide concentrations have to be detected, additional physical and chemical concentration techniques have to be applied before measurement. Often, the activity is determined by pure chemical means. This technique is also be used for independent control of activity-covered air filters.

4.2.3 Passive Alpha-Particle Detectors Nuclear track techniques are applied in many fields, e.g., in indoor and environmental radon monitoring, in uranium ore prospecting, and in geophysical research. Alpha particles produce tracks in photographic emulsions, glasses, plastics, and many natural materials. By chemical or electrochemical etching the track diameters can be enlarged and the track density can be determined by optical methods. Another technique is spark counting.

Widespread use is made of track detectors in a large number of national programs in

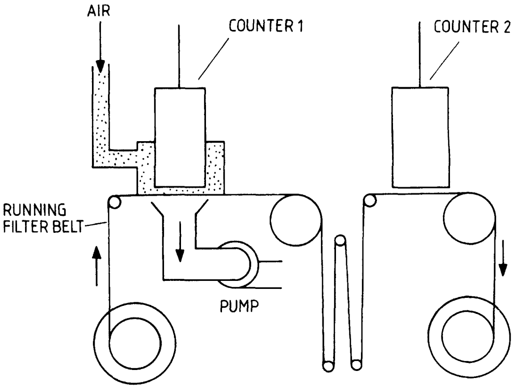

FIG. 36. Schematic drawing of a waste-air monitoring system (Schröck-Vietor, 1962).

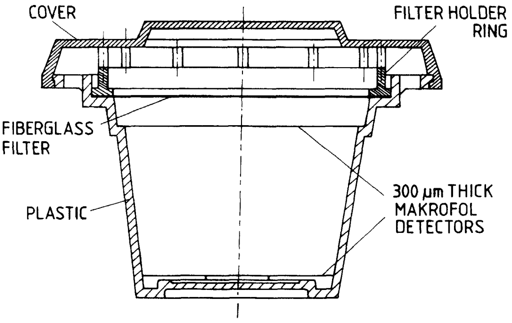

FIG. 37. Nuclear track-detector device for determination of radon gas concentration in air (Urban and Piesch, 1981).

many countries, aiming to detect natural radon and its daughter products in buildings on a large scale. Figure 37 shows a cross section of a track-detector device applied in such studies. The device is a simple diffusion chamber. A fiberglass filter holds back dusts, aerosols, and radon daughter products, so that only radon isotopes diffuse into the chamber. The upper detector is perforated. Only radon and its daughter products that are produced within the chamber and plate out on the foils are detected. The technique of filtering the daughter products present in room air allows a sufficiently accurate correlation of track density and radon concentration. This is not possible by using bare foils. The lower detection limit of the device is some Bq/m^3 of radon after an exposure period of three months.

GLOSSARY

Activity: The activity A of a radioisotope is defined as $A = -dN(t)/dt$ where dN is the number of radioactive transitions in the time interval dt. The unit is 1 Bq (1 Bequerel) = 1 transition/s irrespective of the number of particles or photons emitted per transition.

Coincidence, Anticoincidence Techniques: A coincidence unit determines if two or more detected events are coincident in time. It generates a logic signal only if they occur simultaneously, no signal if not. An anticoincidence unit rejects events that are coincident in time.

Dosimetric Units: The absorbed dose or energy dose is the energy that is absorbed per kilogram of tissue. The unit is 1 Gy (Gray) = 1 J/kg. The dose equivalent is the absorbed dose multiplied with a dimensionless quality factor Q (also called radiation-weighting factor w_R), which is related to the relative biological effectiveness of radiation. Q is 1 for photons and beta particles, 20 for alpha particles, and dependent on energy between 5 and 20 for neutrons. The unit of the dose equivalent is 1 Sv (Sievert) = 1 J/kg. Dose rates are doses per time interval; the units are 1 Sv/h and 1 Gy/h. A formerly used dose unit is the ion dose 1 R (Röntgen), which is defined in terms of the charge produced in air by photons: 1 R = 2.58 C/kg = 0.0087 Gy.

Electronvolt (eV): 1 electronvolt is the energy that a singly charged particle receives if it is accelerated by a voltage of 1 V. The unit eV is used as a measure of energy of, e.g., charged and uncharged particles or quanta in nuclear physics. 1 MeV = 1 Megaelectronvolt, 1 eV = 1.6022×10^{-19} J.

FWHM (Full Width Half Maximum or Minimum): Full width of a peak or a dip in, e.g., a measured energy distribution of particles or quanta determined at half maximum or minimum.

Moderation: The slowing down of fast neutrons by elastic collisions in matter. This process is most effective with light nuclei. Therefore, hydrogen-containing materials such as plastics are widely used as moderators.

Nuclear-Reaction Symbols: For classifying nuclear reactions generally symbols are used, e.g., (n,α), $(n,2n)$, (n,f). This means that a neutron is absorbed in the nucleus, and an alpha particle and two neutrons are emitted from the nucleus, respectively. In the third case, a neutron induces the fission of a nucleus into mostly two new nuclei.

Phoswich Detector: A phosphor sandwich detector where two scintillators with different light-decay times are coupled to one photomultiplier. The pulse-shape difference of the two scintillators can be used to discriminate low-range particles (beta and alpha particles) that are stopped in the first scintillator, and penetrating radiation (neutrons, gammas) that penetrates both scintillators.

Photopeak: The photopeak in gamma- or x-ray energy spectra is due to the photoeffect where the quanta lose their total energy to an electron of the detector material. The photopeak gives the primary energy of the quanta and enables the identification of isotopes also in mixed-radiation fields.

Pulse-Height Discrimination: Radiation of different energies or different kinds generates pulses of different height in a suitable detector. If only one radiation component should be measured, a single-channel analyzer may be applied, which has adjustable lower and upper thresholds thus defining a pulse-height acceptance window. Pulses of lower or larger heights are rejected. For pulse-height spectroscopy over a broad range of energies or radiation components, it is convenient to use a multichannel analyzer, which sorts pulses of different heights into corresponding channels.

Pulse-Shape Discrimination: The rise and decay times of detector pulses from a mixed-radiation field can deliver information on the kind of exciting particles or photons due to different ionization densities or powers in the detector. By determining the detector pulse-decay times electronically, components of the radiation can be discriminated. The technique is commonly applied in fast-neutron detection, since there is mostly a strong gamma component present.

INTRODUCTION

A radio telescope is a remote-sensing device that measures the equivalent temperature of a distant object by means of its radio-frequency radiation. Basically, a radio telescope has two parts: (1) an antenna for collecting the object's radiation and (2) a receiver for detecting, processing, and displaying the information, as illustrated in Fig. 1. A radio telescope is analogous to an optical telescope, except that it functions at much longer wavelengths from millimeters to hundreds of meters. The antenna is analogous to the lens or reflector of an optical telescope while the receiver-processor corresponds to a photographic plate or other optical-sensing device.

Radio telescopes are used for exploring the heavens and mapping the sky. The appearance of the radio sky is very different from the way it appears to the eye.

1. GENERAL PRINCIPLES AND BRIEF HISTORY

1.1 Radio Telescopes and the Radio Sky

Observations of the sky from the ground by either optical or radio telescopes are limited to two principal windows of the Earth's atmosphere and ionosphere:

1. in the optical region (400 to 700 nm) and
2. in the radio region (nominally 1 mm to 100 m) restricted at short wavelengths (1 mm) by molecular absorption in the atmosphere and at long wavelengths by ionospheric reflection.

Radio telescopes carried into space and directed at the earth are used to map the Earth's surface temperatures for studies of the Earth's resources and environment. In mapping the sky or the Earth, the radio telescope is a *passive* remote-sensing device. If the telescope is equipped with a radio transmitter, it can also function as an *active* remote-sensing device or *radar* telescope, providing more information. Since the echo power of a radar telescope decreases as the fourth power of the distance, astronomical radar telescopes are restricted to studies of solar-system objects.

1.2 History and Discoveries

In 1933, Karl J. Jansky, a radio engineer at the Bell Telephone Laboratories, Holmdel, New Jersey, built a rotating radio antenna to study the direction of arrival of thunderstorm static at 14.6-m wavelength. In the ab-

digital Encyclopedia of Applied Physics

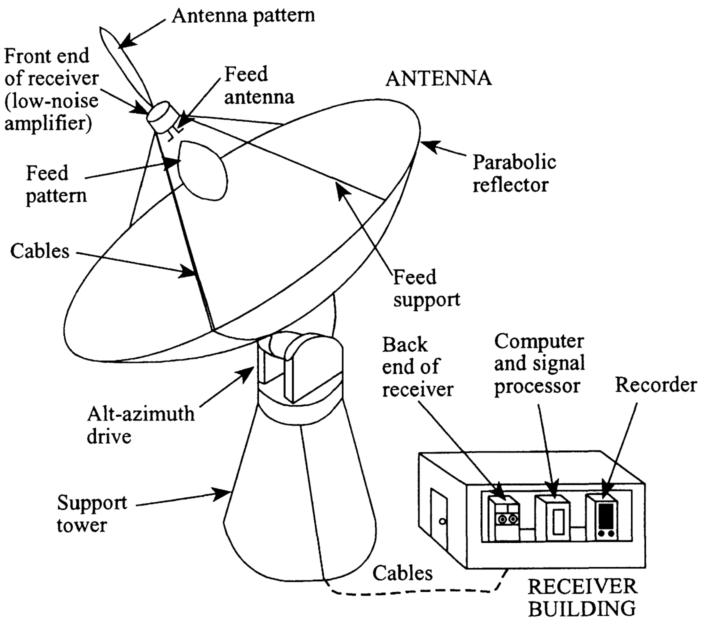

FIG. 1. Radio telescope with low-noise amplifier (LNA) at prime focus and back end of receiver, signal processor, and recorder in receiver building.

sence of any static, he noted a weak but persistent noise signal that he traced to radiation from our galaxy or Milky Way (Jansky, 1933). Prior to Jansky, all of our astronomical knowledge came from optical observations. Jansky broke the "optical barrier" and forever changed the course of astronomy.

Jansky's serendipitous discovery was followed up by another radio engineer, Grote Reber, who made the first maps of the radio sky at a wavelength of 1.9 m using a 9.5-m-diam dish antenna he constructed in the backyard of his home in Wheaton, Illinois (Reber, 1940, 1983). Reber established that the galactic radiation was nonthermal or non-Planckian in nature (stronger at longer wavelengths). It was subsequently determined (20 years later) to be synchrotron radiation from fast electrons spiraling in interstellar magnetic fields.

For almost a decade, Reber was the world's only active radio astronomer, but after WW II, with the advent of new radio devices, radio astronomy developed rapidly.

Radio telescopes have found quasars (compact radio galaxies) so distant that they are receding at over 90% of the velocity of light; radio objects traveling at apparently superluminal velocities (faster than light); neutral hydrogen clouds throughout the galaxy, giving the first picture of our galaxy's spiral structure; giant interstellar molecular clouds of hundreds of different molecules ranging from ammonia and ethyl alcohol to sulfur dioxide and water; and pulsars, rapidly rotating neutron stars, some of which spin 1000 times per second and provide long-term timekeeping comparable to the most accurate atomic clocks. Such long-term measurements of the rate of decay of the orbital period of a binary pulsar (PSR 1913 + 16) were found to agree closely with that expected from damping by gravitational radiation. Even though indirect, this constitutes observational evidence of the existence of gravitational waves, as postulated by Einstein (Taylor, 1981).

Another radio discovery is the 3-K cosmic radiation that sets a minimum background temperature for the sky. From measurements over a wide range of wavelengths, this relic radiation from the primordial fireball or "Big Bang" has been established as having the Planckian (or black body) curve of a 2.7-K object (Penzias and Wilson, 1965). This implies that all but a few hundredths of one percent of the background radiation was released within a year of the Big Bang.

2. RADIO-TELESCOPE ANTENNAS

2.1 Antenna Patterns

The antenna of a radio telescope acts as a collector of radio waves, converting radio photons to radio-frequency currents. The response of the antenna as a function of angle is given by the antenna pattern. By reciprocity, this is the same pattern measured when the antenna is transmitting. The pattern is independent of distance if measured sufficiently far from the antenna. The pattern may be expressed in field intensity E (V/m) or power flux P (W/m^2), where $P = E^2/Z$ and Z is the intrinsic impedance of space = 377 ohms/square.

A symmetrical pencil beam pattern may be described in terms of a single power flux pattern (Fig. 2) where $P(\theta)$ represents the power flux as a function of the angle θ. The half-power beam width (HPBW) and the beam width between first nulls (BWFN) are indicated. Dividing $P(\theta)$ by its maximum value, $P(\theta)_{\max}$, we obtain a normalized power pattern, which is dimensionless. In the general case, a pattern is described as a function of the angles θ and ϕ in two orthogonal planes as in Fig. 3. The normalized power pattern for this case is then

$$P_n(\theta,\phi) = P(\theta,\phi)/P(\theta,\phi)_{\max}. \tag{1}$$

FIG. 2. Antenna pattern in polar coordinates and linear power scale.

2.2 Antenna Parameters

Three important characteristics of a radio telescope antenna (or of any antenna) are its *directivity* D (dimensionless), *beam area* Ω_A (steradians), and *effective aperture* A_e (m^2). By reciprocity they are the same for both reception and transmission. They are related as follows:

$$D = 4\pi/\Omega_A = 4\pi A_e/\lambda^2, \tag{2}$$

where λ = wavelength (m). For example, if the beam area is 1 square degree ($=3 \times 10^{-4}$ steradians), the directivity is 41253 (or $10 \log_{10} 41253 = 46$ dB), and at a wavelength of 1 m, the effective aperture $A_e = 41253/4\pi = 3283$ m^2. Note that the solid angle in a sphere is 4π steradians or 41253 square degrees.

The beam area is given by the integral of the normalized power pattern (maximum value = unity) over a sphere (4π steradians). Thus,

$$\Omega_A = \iint_{4\pi} P(\theta,\phi) d\Omega \tag{3}$$

(dimensionless), where $P(\theta,\phi)$ = power pattern as a function of the coordinates (θ,ϕ), and $d\Omega = \sin\theta d\theta d\phi$ = element of solid angle (steradians). For a symmetrical pencil beam (Fig. 2), Eq. (3) reduces to

$$\Omega_A = 2\pi \int P(\theta) \sin\theta d\theta. \tag{4}$$

For the pencil beam, the beam area is approximately equal to the half-power beam width (HPBW) squared or $\Omega_A \cong \mathrm{HPBW}^2$. Thus, a pencil beam with HPBW = 1° has from Eq. (2) a directivity $D = 41253$. On the other hand, if the antenna is omnidirectional (same power in all directions), $P_n(\theta,\phi) = 1$, $\Omega_A = 4\pi$, and $D = 1$. This is the smallest directivity an antenna can have.

A directivity $D = 41253$ for the 1° pencil

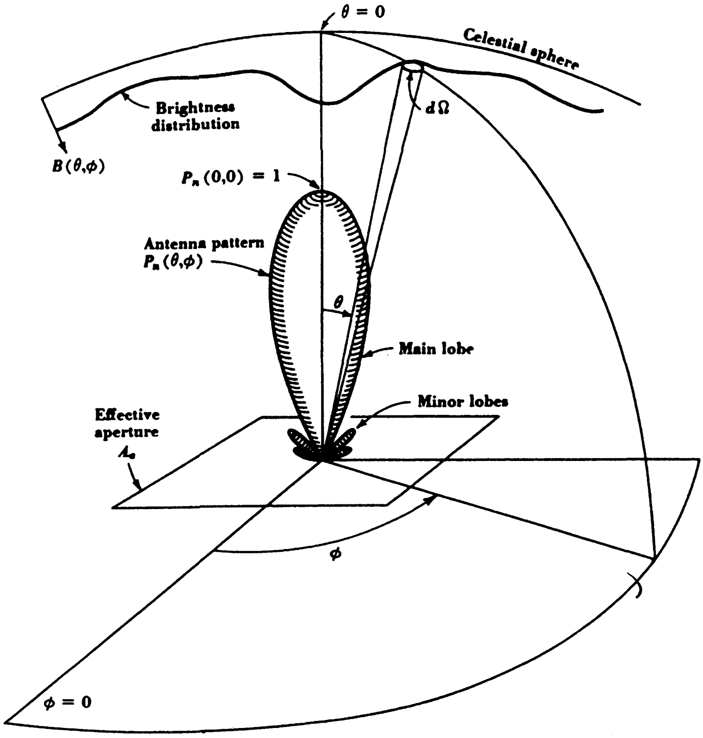

FIG. 3. Relation of antenna pattern to celestial sphere with associated coordinates.

beam means that a 1-W transmitter connected to the antenna produces a power flux in the direction of the beam equal to that from a 41253-W transmitter connected to an isotropic or omnidirectional antenna.

Directivity also has significance as a measure of the number of sources in the sky that a radio telescope antenna can resolve. The resolution of a pencil beam antenna is given *approximately* by its HPBW. A more accurate measure is the *Rayleigh resolution* (= BWFN/2) which is 12% more than the HPBW. Thus, the antenna can resolve *approximately* a number of sources $N = D$ over 4π steradians of sky where $D = 4\pi/\Omega_A = 4\pi/\text{HPBW}^2$. If, for example HPBW = 1°, the antenna can resolve of the order of 40 000 sources, assuming a uniform distribution over the sky.

The ratio k_1 of the power radiated by an antenna to its power input is unity if the antenna is lossless but less if losses are present. The gain G of an antenna is equal to its directivity multiplied by k_1. Thus $G = k_1 D$. Since k_1 is nearly unity for most antennas, the antenna gain and directivity are used almost interchangeably.

In addition to the Ohmic power loss factor k_1, other factors affecting the efficiency of large reflector antennas are the aperture utilization factor k_2, the surface accuracy factor k_3, and other factors we may combine as k_4, which include the feed efficiency, the effects of aperture blocking by the feed and feed supports, feed displacement normal to the axis (squint), feed displacement parallel to the axis (astigmatism), surface leakage, etc.

For a uniform field distribution across the aperture the aperture utilization factor k_2 is unity. However, to reduce minor lobes, the field is usually tapered to a low value at the edges. For in-phase fields $k_2 = E^2_{av}/(E^2)_{av}$ where E_{av} = average field E over aperture, $(E^2)_{av}$ = average of E^2 over aperture, and E = field at any point in the aperture. Thus, for a uniform field distribution $k_2 = 1$ while for a cosine distribution ($E = 0$ at edges), $k_2 = 0.81$.

Surface error is the deviation of the actual surface from the paraboloid of best fit. The surface accuracy or error factor k_3 may be close to unity at long wavelengths but decreases for shorter wavelengths at which the surface deviation becomes a significant fraction of the wavelength. Thus, for an rms surface deviation or error $\delta = \lambda/16$, the factor $k_3 = 0.5$ (or -3 dB) as given for small δ by the relation* (Christiansen and Högbom, 1985),

$$k_3 = \cos^2(720^\circ\ \delta/\lambda). \qquad (5)$$

The effect of surface accuracy on the gain of two large radio telescopes is shown in Fig. 4. The $k_3 = 0.5$ (or -3 dB) point occurs at a wavelength of about 8 mm on the 100-m Bonn, Germany, telescope of the Max Planck Institute (Wohlleben and Sieber, 1968) (Fig. 5), and at a wavelength of about 2.5 mm on the Nobeyama Radio Observatory 45-m telescope on Honshu Island, Japan (Fig. 6) (Akabane *et al.*, 1983).

The other factors may yield a k_4 value of 0.8 to 0.9. Combining all factors the gain G is given by

$$G = 4\pi k_1 A_e/\lambda^2, \qquad (6)$$

where k_1 = Ohmic or power loss factor, A_e = effective aperture = $k_2k_3k_4A_p = \epsilon_{ap}A_p$, m^2, λ = wavelength, m, A_p = physical aperture, m^2, ϵ_{ap} = aperture efficiency = A_e/A_p = $k_2k_3k_4$, k_2 = field distribution or utilization factor, k_3 = surface accuracy factor, and k_4 = product of other factors. All factors are dimensionless with values between 0 and 1.

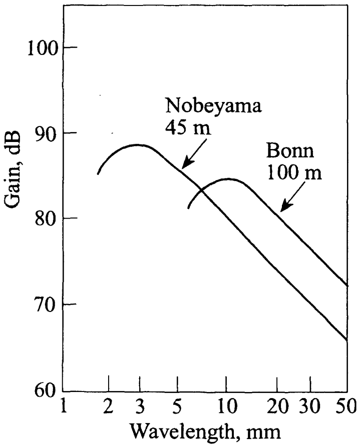

FIG. 4. Gain peaking and rolloff with decreasing wavelength for Bonn 100-m and Nobeyama 45-m radio telescopes (as given by the factor k_3).

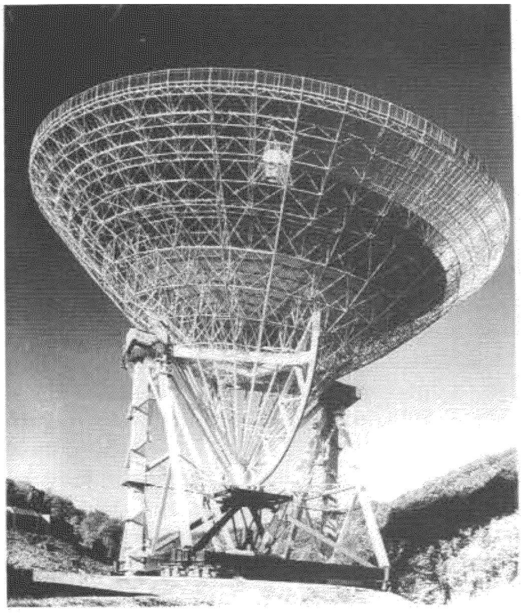

FIG. 5. The 100-m-diam fully steerable radio telescope in a mountain valley near Bonn, Germany. It stands nearly 40 stories tall. Note the massive backup structure for providing rigidity to the dish. Moving parts weigh 3200 tonnes. (Courtesy Dr. R. Wielebinski, Max-Planck-Institut für Radioastronomie.)

Useful observations with a radio telescope may be made even if the aperture efficiency is as small as 0.2. The 25-m dishes of the

---

*Equation (5) is appropriate only for small δ ($<\lambda/12$). A more universal relation sets $k_3 = \exp-(4\pi\delta/\lambda)^2$ (Ruze, 1966).

VLA (Very Large Array) (Fig. 7) operate with aperture efficiencies of 52% at 1.5 GHz, 65% at 5 GHz, and 48% at 20 GHz (Napier *et al.*, 1983).

2.3 Antenna Designs and Examples

The main or primary reflector of a large radio telescope is constructed of many individual panels. If the panels have an rms surface accuracy of 50 μm and are set into a backup structure with an rms accuracy of 50 μm, a total error of 71 μm accrues ($71 = \sqrt{50^2 + 50^2}$) resulting in a value of $k_3 = 0.81$ at a wavelength of 2 mm. To set the panels accurately, a holographic technique may be used in which the amplitude *and* phase of a satellite beacon signal are measured over an angular extent much larger than the main beam of the antenna. The amplitude and phase of the antenna aperture field distribution are then obtained by a two-dimensional Fourier transform yielding a phase map of the reflector showing where the panels need to be adjusted to reduce the phase variation (Goldsmith and Erickson, 1986).

Radio telescopes must maintain an accurate reflector surface in spite of wind loads, temperature gradients, and gravitational deformation. For a 45-m-diam reflector, such as the one at Nobeyama, an overall rms surface deviation of 150 μm and a pointing accuracy of 1 arcsec are required. The Nobeyama telescope is on a mountain site to reduce the atmospheric attenuation at millimeter wavelengths.

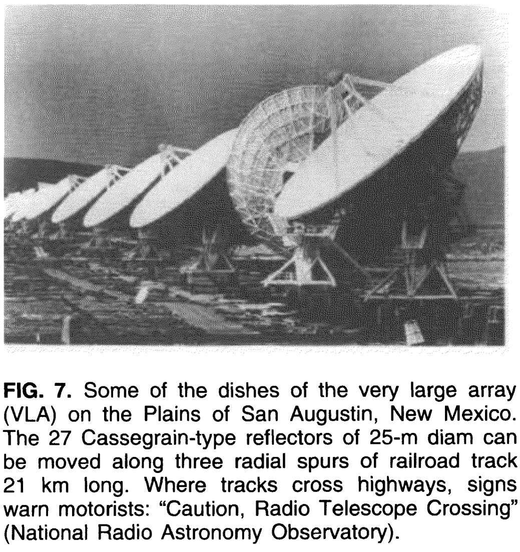

FIG. 7. Some of the dishes of the very large array (VLA) on the Plains of San Augustin, New Mexico. The 27 Cassegrain-type reflectors of 25-m diam can be moved along three radial spurs of railroad track 21 km long. Where tracks cross highways, signs warn motorists: "Caution, Radio Telescope Crossing" (National Radio Astronomy Observatory).

All ground-based steerable parabolic reflectors deform under gravity as the reflector is tilted so that for a given wavelength there is a maximum diameter limit which cannot be exceeded by adding more metal to the backup structure. However, this limit can be exceeded by a *homologous* design in which one paraboloid deforms into another as the reflector is tilted (Von Hoerner, 1977). The next limit is imposed by thermal deformation.

In the Nobeyama 45-m telescope, thermal insulation and ventilation are used to reduce thermal deformation. In the IRAM (Institut de Radio Astronomie Millimètrique) 30-m telescope at Pico Veleta, Spain (Fig. 8), insulation, ventilation, and temperature control are employed. The IRAM/SEST 15-m telescope [Swedish ESO (European Southern

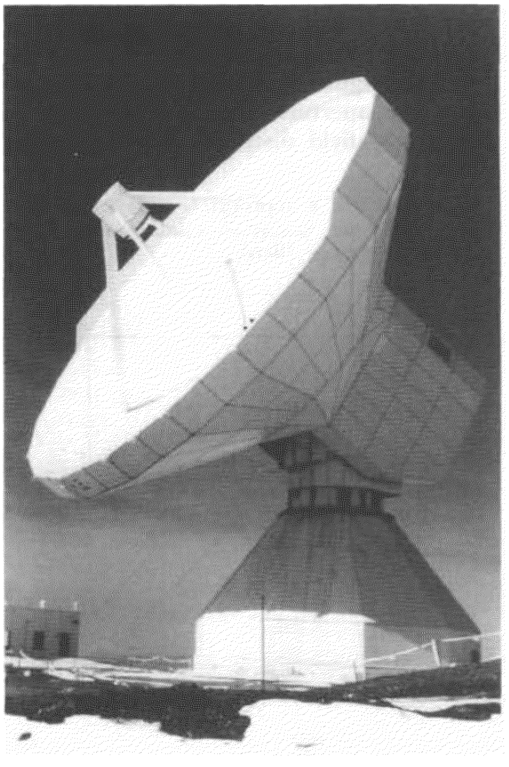

FIG. 8. 30-m telescope for millimeter wavelengths of the Institut de Radioastronomie Millimètrique (IRAM) at Pico Veleta, Spain. Note cladding to reduce thermal deformation (IRAM photo).

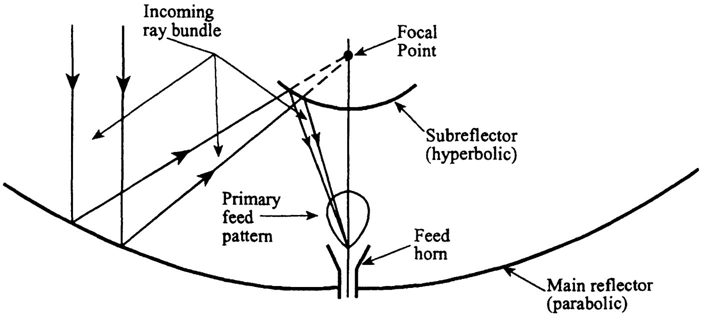

FIG. 9. Geometry for Cassegrain or shaped subreflector telescope designs.

Observatory) Submillimeter Telescope] at La Serena, Chile, has panels, feed legs, and much of the backstructure made of low-expansion carbon fiber material. Insulation, ventilation, and thermal control are also used. Panel accuracy is about 10 μm with equivalent panel positioning accuracy achieved by holographic measurements (Greve *et al.*, 1992).

Although some radio-telescope antennas have the feed antenna and receiver front end at the prime focus point as in Fig. 1, the Cassegrain design is widely used, especially in millimeter-wavelength telescopes. As shown in Fig. 9, a subreflector surrounds the prime focus of the main reflector. In the classical design, the subreflector is hyperbolic in shape. Higher aperture efficiency may be realized by shaping or modifying the hyperbolic contour of the subreflector to correct the pattern of the feed antenna and produce a more uniform field distribution across the parabolic reflector aperture.

An advantage of the Cassegrain design is its compactness, with the feed antenna (usually a horn) and associated front-end receiver components located near the vertex of the parabola (instead of far above the main reflector at the prime focus). A disadvantage is that the subreflector may increase aperture blocking and create side lobes. A constraint is that to minimize blocking the subreflector should be small compared to the main reflector but large compared to the wavelength.

The Bonn 100-m telescope can operate in either Cassegrain or prime-focus modes. The 15- and 30-m IRAM telescopes are Cassegrain types. The Nobeyama 45-m telescope has a Gregorian feed which is similar to the Cassegrain except that the subreflector is concave instead of convex.

The Bonn 100-m telescope is the world's largest fully steerable instrument. Until it was constructed in 1972, the 76-m telescope at the University of Manchester, England, was the largest of this type (Lovell, 1968).

The stationary 305-m-diam spherical reflector of the National Astronomy and Ionospheric Center (Cornell University) is suspended on cables in a mountain valley at Arecibo, Puerto Rico (Fig. 10) (Findlay, 1964). By moving the feed antenna, sup-

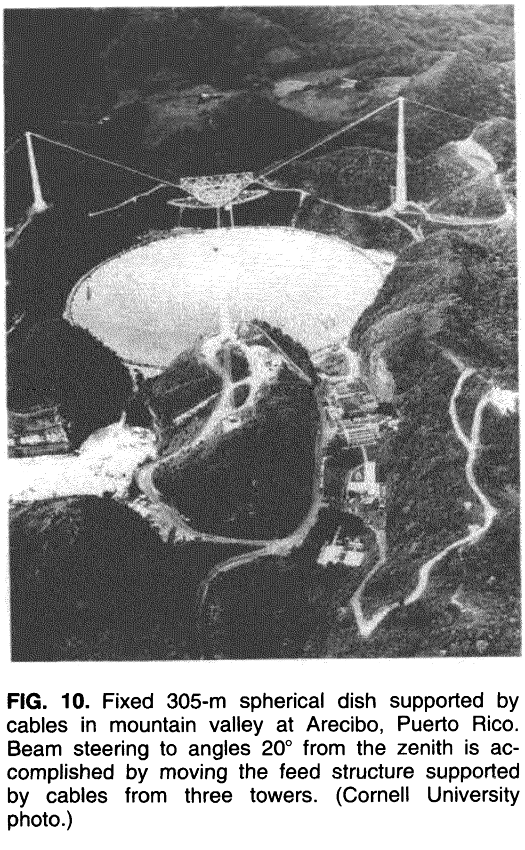

FIG. 10. Fixed 305-m spherical dish supported by cables in mountain valley at Arecibo, Puerto Rico. Beam steering to angles 20° from the zenith is accomplished by moving the feed structure supported by cables from three towers. (Cornell University photo.)

ported above the spherical reflector by cables from three towers, the antenna beam can be steered 20° in any direction from the zenith. Operation is possible to centimeter wavelengths.

A Mills-cross antenna of the University of Sydney, Australia (Mills *et al.*, 1963) is a meridian transit instrument with cylindrical parabolic reflectors 12 m wide by 1.6 km long in the form of an east–west, north–south cross. The beam is steered in declination by a combination of mechanical tilting of the east–west element on its long axis and an electrical phase shifting of the feeds of the mechanically fixed north–south element. At 408 MHz the beam width is about 3 arcmin.

The Ohio State University Radio Telescope has a 110 × 21-m^2 standing curved reflector and a 104 × 31-m^2 tiltable flat reflector with the two joined by a 15 000 m^2 aluminum-covered ground plane (Fig. 11) (Kraus, 1986, pp. 6–86, 6–90). The design provides a maximum aperture per unit cost. Also it has less than $\frac{1}{2}$% aperture blocking and reduced susceptibility to terrestrial interference because of the low profile, with feed horns at ground level and shielding by the large reflectors. It also has a spacious underground laboratory directly below the prime focus for the electronics equipment.

A similar but larger antenna of this general design is situated at Nancay, France (Fig. 12) (Blum *et al.*, 1963; Findlay, 1964). Its curved reflector measures 300 × 35 m^2.

The RATAN-600 Radio Astronomy Telescope at Zelenchukskaya, Russia, has both tiltable flat and curved reflectors (Fig. 13). The curved reflector consists of 895 automatically adjustable aluminum panels forming a ring 600 m in diameter. Operation is possible to millimeter wavelengths (Golubin, 1982; Parijskij, 1993).

A 100-m fully steerable telescope with offset feed (to avoid aperture blocking) is under construction at the National Radio Astronomy Observatory, Green Bank, West Virginia (Fig. 14). It is replacing a 91-m meridian transit telescope that collapsed there on November 15, 1988. The new telescope, being built at a cost of $75 million, is scheduled for completion in 1995. It is designed to operate efficiently at wavelengths as short as 1 cm.

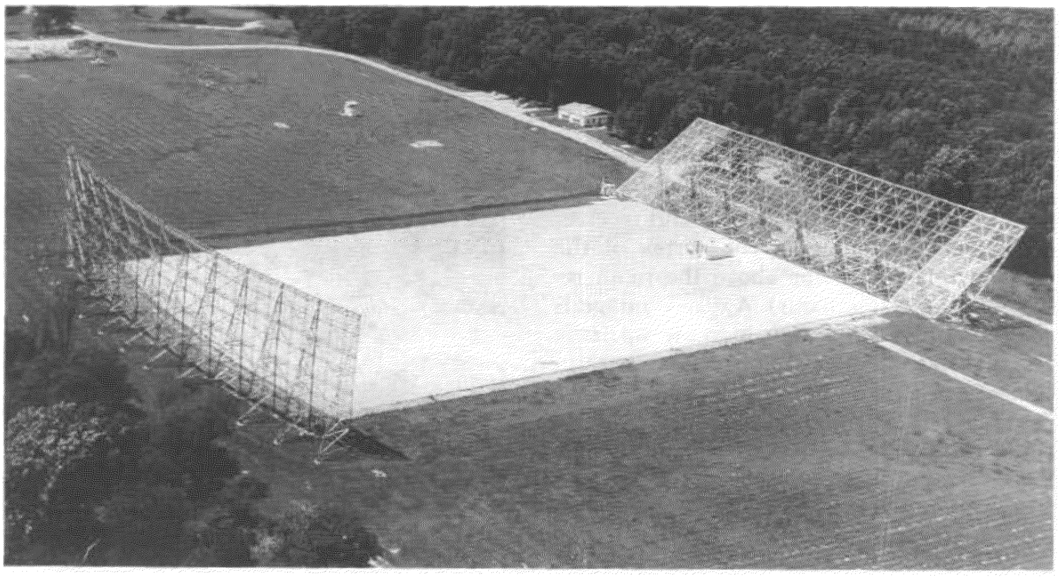

FIG. 11. 110-m standing curved reflector with tiltable flat reflector at the Ohio State University Radio Observatory. The reflectors are connected by a conducting ground plane larger than three football fields. The telescope was used to make maps of the sky at 21-cm wavelength and compile a catalog of 20 000 radio sources including the first ones found to have red shifts greater than 3.

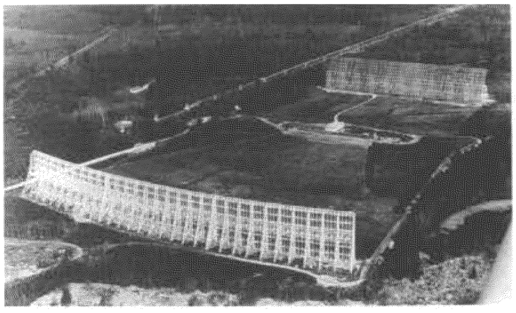

FIG. 12. Radio telescope at Nancay, France, with 300-m standing curved reflector and tiltable flat reflector. The curved reflector is spherical, which facilitates tracking sources for 2 h or more by moving the feed system. (Observatoire de Paris photo.)

2.4 Aperture Distribution and Pattern

The field distribution $E(x_\lambda)$ across the aperture of an antenna and its far-field pattern $E(\theta)$ are reciprocal Fourier transforms where $x_\lambda = x/\lambda$. The field distributions for three one-dimensional apertures of width $L_\lambda = L/\lambda$ and of uniform, Gaussian, and edge distributions are shown in Fig. 15. The latter distribution may be regarded as two spaced narrow apertures in the same configuration as in an interferometer (Sec. 2.6). The field pattern for the uniform aperture distribution has a main lobe with side lobes. Its BWFN $= 2\lambda/L$ rad $= 114.6\ \lambda/L$ deg and the HPBW $= 0.44$ BWFN. The field pattern of the Gaussian aperture distribution is also Gaussian. It has no side lobes but a larger HPBW. The field pattern of the edge distribution has many lobes of equal size but with smaller beam widths. As the separation L increases, the beam widths of the lobes decrease. This distribution is discussed further in connection with interferometers in Sec. 2.6.

2.5 Brightness and Flux Density

When the *brightness* of the sky (W m^{-2} Hz^{-1} rad^{-2}) as measured at the Earth is integrated over the area of a celestial source (Fig. 3), we obtain the *flux density* S of the source. Thus,

$$S = \iint_{\text{Source}} B(\theta,\phi)d\Omega \quad (\text{W m}^{-2}\,\text{Hz}^{-1}), \qquad (7)$$

where $B(\theta,\phi)$ = brightness of the sky as a function of position and $d\Omega$ = element of solid angle (rad^2). The unit of flux density is the jansky (Jy) = 10^{-26} W m^{-2} Hz^{-1}.

When the source is observed with a radio-telescope antenna with normalized power pattern $P(\theta,\phi)$, a flux density S_0 is obtained as given by

$$S_0 = \iint_{\text{Source}} B(\theta,\phi)P_n(\theta,\phi)d\Omega \quad (\text{Jy}). \qquad (8)$$

If the source extent is small so that $P(\theta,\phi) \cong 1$ over the source, the observed flux density S_0 will be nearly equal to the true value.

The power received from the source by an antenna of effective aperture A_e (m^2) is then

$$W = S_0 A_e \Delta f \quad (\text{W}), \qquad (9)$$

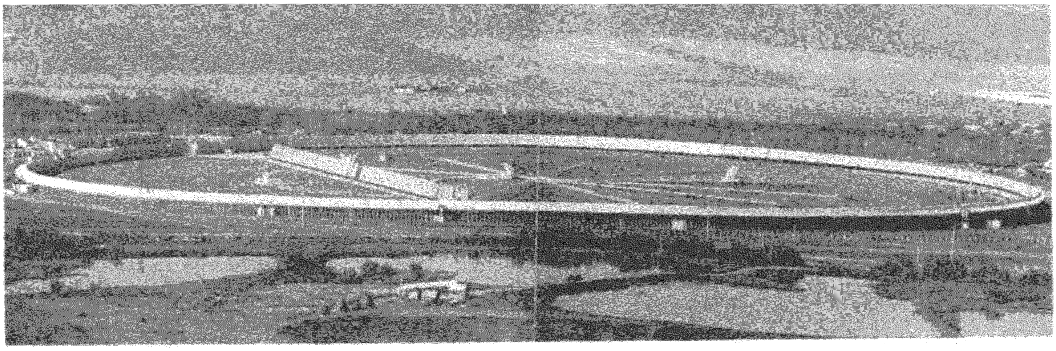

FIG. 13. The 600-m-diam RATAN-600 radio telescope near Zelenchukskaya, Russia, with tiltable flat and curved reflectors. Although the ring reflector is large enough to hold four Arecibo dishes, the collecting area is less. (Photo courtesy, Dr. Y. Parijskij.)

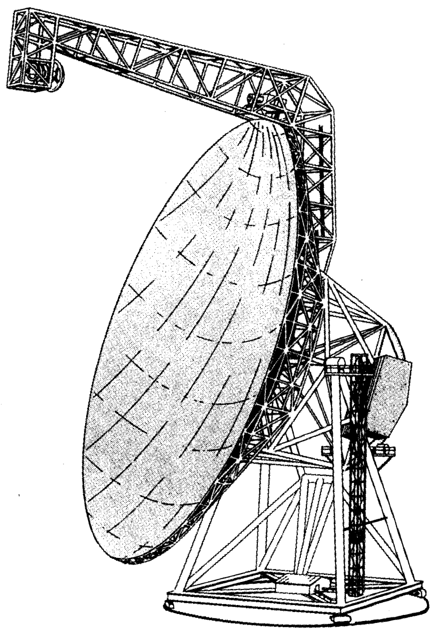

FIG. 14. Sketch of 100-m (GBT) radio telescope at the National Radio Astronomy Observatory, Green Bank, West Virginia, to be completed in 1995. It features an offset feed to provide a clear, unobstructed aperture. (N.R.A.O.-A.U.I.)

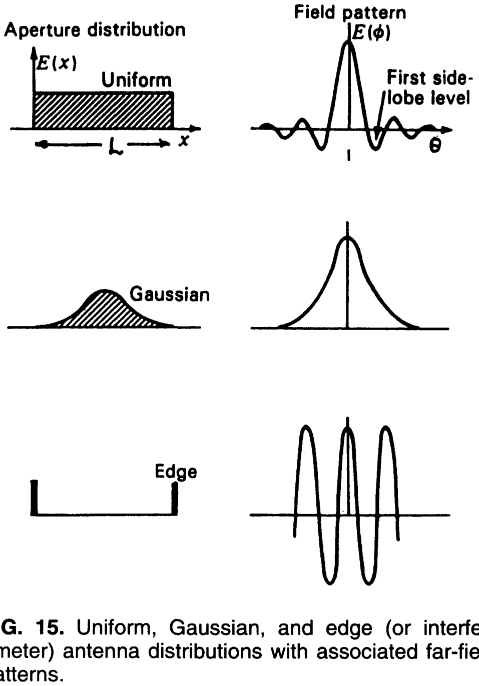

FIG. 15. Uniform, Gaussian, and edge (or interferometer) antenna distributions with associated far-field patterns.

where Δf = bandwidth (Hz). This assumes that the antenna polarization matches that of the source radiation. In general they are not matched because most celestial radio sources are unpolarized whereas an antenna is polarized (linearly, circularly, or elliptically). For this case the antenna receives one-half of the available wave power. Thus, W is one-half that of Eq. (9) for the general case.

2.6 Interferometers and Aperture Synthesis

The edge distribution of Fig. 15 in which two apertures are separated by many wavelengths constitutes a simple interferometer. Thus, if two antennas, each with a uniform distribution of 100 wavelengths in width, replace the two narrow edges and the spacing between the antennas is 1000 wavelengths, the lobes of this interferometer have a BWFN = 115°λ/L = 115°/1000 = 0.12° within the envelope of a larger lobe with BWFN = 115°/100 = 1.2° (Fig. 16). We have assumed that the angular extent of the celestial source is small compared to the width of the narrow lobes. If the interferometer antennas are separated by the Earth's diameter the resolution at 10 cm wavelength is *one millionth of a degree* (a few milliarcseconds).

A typical two-element interferometer has two steerable antennas of aperture a connected by equal-length cables to a receiver R as in Fig. 17. The antenna separation normal to the source direction is s. Whereas a single antenna has a resolution of $57.3/a_\lambda$ degrees where $a = a/\lambda$, the resolution of the interferometer is equal to $57.3/(s_\lambda + a_\lambda)$ degrees, or, if $s_\lambda \gg a_\lambda$, by $57.3/s_\lambda$ degrees. This resolution is the Rayleigh resolution (=BWFN/2). Any observed structure smaller than this angle will not be resolved.

When $d = n\lambda$ in Fig. 17, the response is maximum, and when $d = n\lambda/2$ the response is minimum (n = integer).

In Fig. 18, the interferometer response is shown as a function of source angle ϕ for three cases. In Fig. 18(a) the source extent is very small compared to the resolution angle (lobe spacing), in Fig. 18(b) it is comparable to but less than the resolution angle, and in Fig. 18(c) it is equal to the resolution angle. The amplitude $V(s_\lambda)$ of the lobe pattern as a function of the spacing s_λ is called the fringe

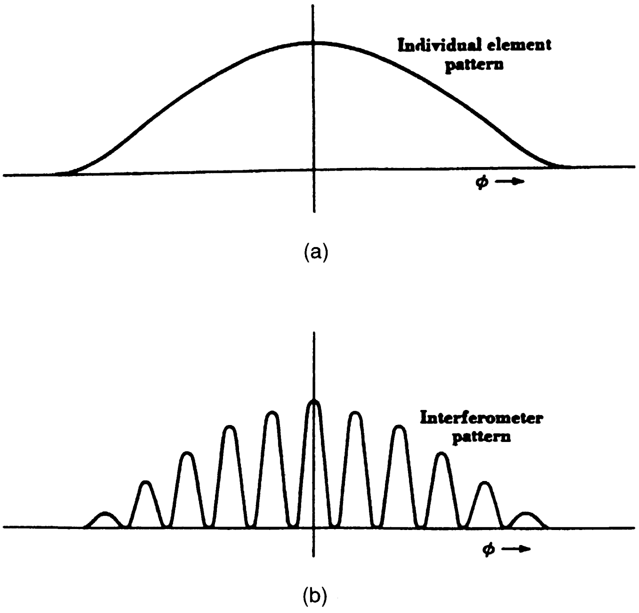

FIG. 16. Interferometer patterns (as a function of source angle ϕ) showing (a) the individual antenna pattern and (b) the actual interferometer pattern with narrow lobes within the envelope of the individual antenna pattern.

amplitude, fringe visibility, or simply the visibility as given by

$$V(s_\lambda) = \frac{S_{\max} - S_{\min}}{S_{\max} + S_{\min}}. \tag{10}$$

By moving the antennas over a full range of spacings up to L and observing $V(s_\lambda)$ at each spacing, a visibility function is obtained. Taking its Fourier transform yields the source brightness distribution. In principle this is equivalent to the distribution obtained by observations with a continuous filled aperture of length L. This process is called *aperture synthesis* (Ryle and Hewish, 1960).

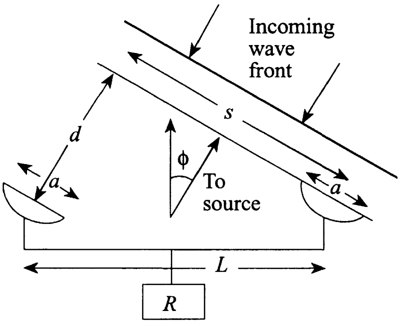

FIG. 17. Two-element interferometer with individual dish antenna diameters *a*, both antennas connected by equal-length cables to receiver *R*.

In two-dimensional aperture synthesis with many antennas (instead of just two) a celestial object is tracked by the system as the Earth rotates, with each antenna-pair combination producing a complex visibility (both amplitude and phase). A map or image of the object or region is then constructed from the visibility function. Using this technique the Very Large Array (VLA) of the National Radio Astronomy Observatory near Socorro, New Mexico (Fig. 7) (with 27 dish-reflector antennas of 25 m diam deployed at stations having a Y-shaped configuration with each arm 21 km long), is capable of resolutions at centimeter wavelengths of less than 1 arcsec providing synthesized images of 10^7 pixels (picture elements).

The spectacular radio picture of Cygnus A in Fig. 19 was obtained with this array (Perley *et al.*, 1984). The picture demonstrates the power of aperture synthesis combined, in this case, with image enhancement using "phase closure." This data-processing technique is applied following the observations and rids the image of spurious responses (Ekers, 1983; Thompson *et al.*, 1986; Kraus, 1986, pp. 6–49, 6–50).

The two bright lobes represent radio hot spots or emitting regions with relativistic jets streaming in opposite directions from a central engine midway between the bright lobes. This radio picture reveals complex filamen-

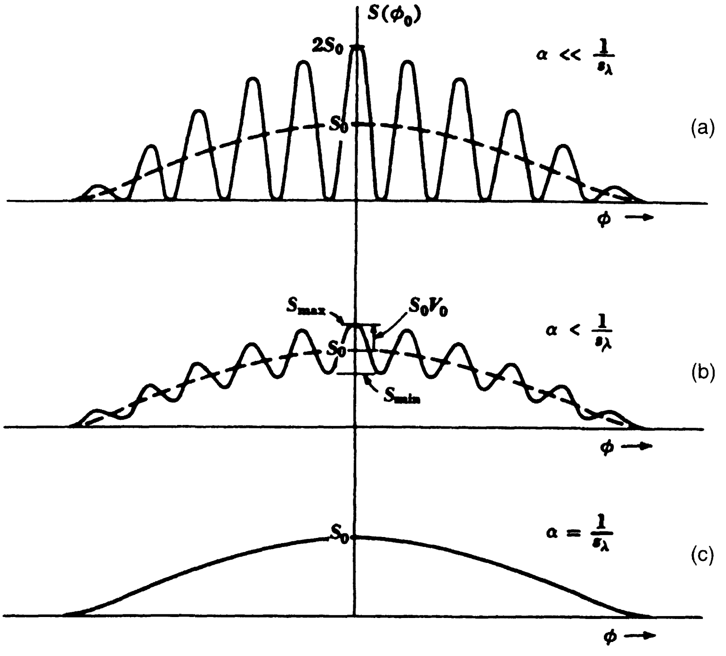

FIG. 18. Interferometer patterns (as a function of source angle ϕ) (a) for a point source, (b) for a uniform extended source of angle $\alpha < 1/s_\lambda$ and (c) for a uniform extended source of angle $\alpha = 1/s_\lambda$.

tary structure in both lobes. The overall extent of the emitting regions is about 400 000 light years or about four times our galaxy's diameter. The overall angular extent is about 115 arcsec and the resolution is 0.4 arcsec. Cygnus A is one of the strongest objects in the radio sky. Long-exposure optical photographs with the largest optical telescopes show only a small faint galaxy where the radio engine is located. There is little hint optically of the violent events that have transpired in Cygnus A.

With an actual full aperture, such as a large parabolic reflector, the incoming waves falling on each aperture area are added in phase at a focal point. In aperture synthesis, many measurements are made with different spacings of the small elemental apertures and the results summed by a computer, which may also introduce suitable weighting and phasing for controlling the synthesized antenna pattern.

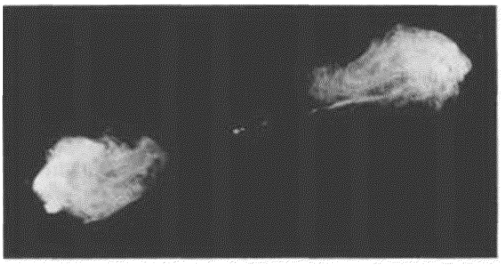

FIG. 19. The Cygnus-A double-lobe radio galaxy with filamentary structure ejected by relativistic jets from a central engine. The double structure is 400-000 light-years across. Obtained with the VLA at 5 GHz. (Photo courtesy N.R.A.O.)

The VLA is capable of antenna separations up to 36 km using physical (waveguide) radio-frequency connections. However, such connections are not feasible for separations of thousands of kilometers. Nevertheless, with antennas separated by 10 000 km it is possible to obtain milliarcsecond resolution with the following technique. In this very long-baseline interferometry (VLBI) the observed signals at widely spaced observatories are down-converted to a lower or intermediate frequency and these signals along with precise time signals are taped and sent to a central location. By synchronizing the tapes using atomic time standards, a real-time comparison can be simulated to create a radio image. Such observations require a high degree of coordination between the participating observatories and, being time-consuming, have only been performed on an intermittent basis. To avoid these problems a dedicated very long-baseline array (VLBA) has been constructed that has 10 antennas with locations coast to coast in the contiguous states of the US and in Hawaii and St. Croix (Kellermann, 1991). This array is capable of milliarcsecond resolution at centimeter wavelengths. Adding an orbiting radio telescope can increase the baselines and improve the resolution even more. The feasibility of combining ground- and space-based telescope data has already been demonstrated and plans are being made for more routine use of this technique.

To exploit the opportunities of millimeter-wave astronomy (see Sec. 3.3 and Fig. 22) a millimeter array (MMA) is planned by US astronomers. It will consist of a ring of 40 8-m dish antennas that can be deployed in a variety of configurations such as in a ring 250 m in diameter.

2.7 Radar Telescopes

By adding a transmitter to a radio telescope it can be made into a radar telescope, or active remote-sensing device, the antenna being alternately connected to the transmitter that sends pulses and then to the receiver for reception of the echoes. By reciprocity the pattern of the antenna is the same for both receiving and transmitting. According to the radar equation the echo power received, P_r, is related to the power transmitted, P_t, by

$$P_r = \frac{P_t A^2 \sigma}{4\pi r^4 \lambda^2} \quad \text{(W)}, \tag{11}$$

where A = effective aperture of antenna, m^2, σ = radar cross section of reflecting object, m^2, r = distance to object, m, and λ = wavelength, m.

The fact that the received power falls off as the fourth power of the distance places a constraint on the range of radar telescopes. Nevertheless powerful Earth-based telescopes have probed the sun, moon, Venus, Mercury, Mars, and Jupiter. Distances (or ranges) have been measured with unprecedented precision and reflectivities determined. From the Doppler spread in frequency of an echo the object's rotation can be observed. The rotation rates of Mercury (59 days) and Venus (250 days, retrograde) were first determined by radar telescopes on the Earth (Pettengill and Dyce, 1965; Goldstein and Carpenter, 1963; Goldstein, 1964). Echoes from areas on the object that are receding are downshifted in frequency and those from areas that are approaching are shifted up in frequency. From these Doppler shifts the rotation rates of Mercury and Venus were determined.

These interplanetary radar observations have resulted in improved values of planetary orbits, masses, and radii, disclosing errors in the ephemerides of the Earth and planets. The astronomical unit (Earth-sun distance) has been significantly improved. With radar, distances can be measured directly whereas optically they are inferred by indirect means.

A spectacular radar-astronomy achievement is the mapping of the surface of Venus through its opaque atmosphere by the spacecrafts Magellan and Pioneer Venus orbiting above it with data telemetered to the Earth (Fig. 20). This map covers about 85% of the surface of Venus and reveals two highlands: Ishtar Terra, as large as the continental US, and Aphrodite Terra, of comparable size. Maxwell Montes has an elevation of 8 km. The highest and lowest elevations differ by 15 km. Maat Mons is an 8-km-high volcanic peak. The radars operated at about 2.5 GHz with horizontal surface resolution of about 100 m.

3. RADIO-TELESCOPE RECEIVERS

3.1 Total-Power and Dicke Types

In the simplest, or total-power, receiver, the antenna is connected to a low-noise amplifier (LNA) and then to a mixer in which the signal is combined with that from a local oscillator to down-convert the signal to a lower or intermediate frequency (IF). This signal is then amplified, detected, integrated, and recorded [Fig. 21(a)].

In the popular Dicke receiver, the LNA is alternately switched from the antenna to a reference resistor at temperature T [Fig. 21(b)]. If T is the same as the equivalent temperature of the sky being observed, the effect of gain fluctuations in the receiver is minimized. To reduce the temperature of the resistor to sky values requires refrigeration of the resistor on ground-based telescopes. These refrigerated resistors, called "cold

loads," can be used to calibrate the telescope for accurate measurements of the sky temperature. It was by precise measurements of the sky temperature that the 3-K background was discovered (Penzias and Wilson, 1965).

3.2 Low-Noise Amplifiers

The front-end amplifier may be a GaAs FET (gallium arsenide field effect transistor) which can provide a gain of over 1000 (or over 30 dB gain) at 1.5 GHz with a noise temperature of only 60 K at ambient temperature (296 K) and 10 K when refrigerated to liquid nitrogen temperature (77 K). The high gain also reduces the effect of noise from the rest of the receiver. Thus, if the next section has a noise temperature of 1000 K, its contribution to the overall or system temperature is only 1 K [=(1000 K)/1000].

For millimeter-wavelength receivers the HEMT (high-electron mobility transistor) is popular because of its higher frequency of operation (over 100 GHz) and lower noise temperature. The SIS (superconductor-insulator-superconductor) quasiparticle mixer has a very low noise temperature set by the quantum limit.* Thus, when refrigerated to 4 K or less its noise temperature is about 7 K at 100 GHz (λ = 3 mm) (Tiuri and Räisänen, 1986). It is used without a radio-frequency amplifier (or front end) ahead of it, no low-noise amplifier being available at millimeter wavelengths.

3.3 Multichannel Receivers

There are over 100 interstellar and circumstellar molecular species that have been observed in the radio microwave region of the spectrum. For such observations receivers with multichannel spectrum analyzers are used with individual channel bandwidths appropriate to the observations. Molecular spectra obtained in a single observation toward the Orion-KL cloud are shown in Fig. 22 as observed between 88 and 90 GHz (3.4 mm) with the Nobeyama 45-m telescope using a receiver with 16 000 channels, each with a bandwidth of 125 kHz. Nearly 20 molecular lines are in evidence of which 15 are identified (Kaifu, 1985).

In some millimeter-wavelength telescopes an *x-y* array or cluster of feed horns is placed at the focus with each horn connected to its own receiver. This creates a radio camera giving a two-dimensional display of a molecular cloud or other region *n* times as fast as by scanning with a single feed horn, where *n* is the number of horns in the array (Erickson *et al.*, 1992).

In the search for extraterrestrial intelligence (SETI), receivers with spectral analyzers of over 1 million channels are in use with ones of a billion channels coming on

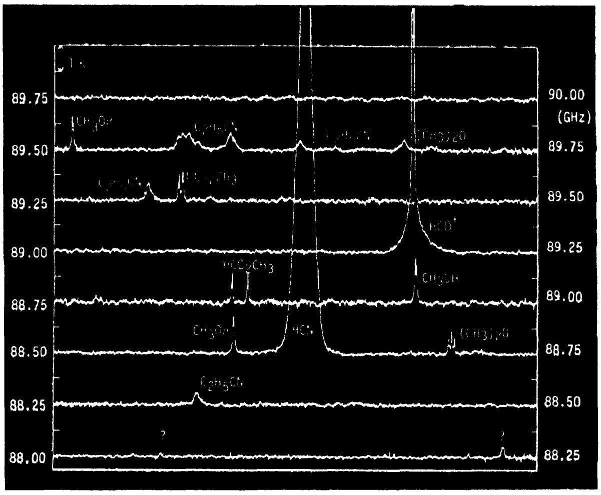

FIG. 22. Molecular spectra observed between 88 and 90 GHz in the Orion-KL cloud with the Nobeyama 45-m radio telescope. There are 15 identified molecular lines in the spectrum with HCN (hydrogen cyanide) and HCO^+ (formylium) being the strongest. (Courtesy N. H. Kaifu.)

---

*T(quantum) = $(h/k \ln 2)f$(Hz) = $0.07f$ (GHz)K and for f = 100 GHz, T(quantum) = 7 K where h = 6.63×10^{-34} J s (Planck's constant) and k = 1.38×10^{-23} J K^{-1} (Boltzmann's constant).

line. At the Harvard-Smithsonian Observatory (Horowitz and Sagan, 1993), a receiver with 8 million channels has been operating in which the incoming signal (a function of time) is fast Fourier transformed by a bank of computers into the frequency domain for spectral analysis (Fig. 23).

In the Argus concept (Dixon, 1996), an array of many simple antennas covering a large flat area is connected to a powerful computer providing multiple beams for simultaneous observation and surveillance of nearly a hemisphere of sky. Each antenna has its own receiver and digital converter. Such digital-beam-forming (DBF) arrays have great potential for the future (Kraus, 1988).

3.4 Antenna Temperature and Sensitivity (Remote Sensing)

A resistor of resistance R and temperature T matched to a receiver delivers a power $P = kT\Delta f$ watts where k = Boltzmann's constant (1.38×10^{-23} J K^{-1}), T = absolute temperature of the resistor (K), and Δf = bandwidth (Hz). If the resistor is replaced by an antenna of radiation resistance R, the radiation resistance is not at the physical temperature of the antenna but at the effective temperature of regions at which the antenna is directed (antenna assumed lossless). Thus, the radio telescope is a remote-sensing device that may be regarded as a bolometer (or heat-measuring device) for determining the

(Courtesy Prof. P. Horowitz, Harvard University.)

effective temperature of regions within the antenna beam coupled to the system through the radiation resistance of the antenna.

The power received by a radio telescope from a celestial source is $P = SA_e\Delta f$ (W) where S = source flux density, A_e = effective aperture of telescope antenna, and Δf = bandwidth. If this power equals that of a matched (calibration) resistor at temperature T connected to the receiver in place of the antenna, the flux density of the source is given by $S = kT/A_e$. But if the source is unpolarized, as most celestial sources are, the flux density is twice this value.

Sensitivity is a function of the antenna aperture and also the *system temperature.* Thus, the sensitivity, or minimum detectable flux density, is given by

$$S_{\min} = 2kT_{\min}/A_e,$$

where $T_{\min} = K_s T_{\text{sys}}/\sqrt{\Delta f\, t}$ where K_s = receiver sensitivity constant (order of unity) (dimensionless) and t = output time constant (s). The system temperature depends principally on the effective temperature of the sky and the receiver noise temperature, especially that of the front-end amplifier.

The signals received by a radio telescope have the characteristics of thermal noise. Their magnitude is measured by comparing it with the noise signal of a resistor at a known temperature. The receiver also contributes noise in its system temperature. Thus, it is aptly said that radio astronomers use their telescopes to "measure noise, with noise, in noise."

3.5 Remote Sensing of the Earth

Radio telescopes in orbit around the Earth with antennas pointed to the ground are used in environmental studies of our planet, providing information on surface temperature and reflectivity. For example, the microwave brightness of the Antarctic continent has been measured with an orbiting radio telescope, the geostationary environmental satellite (GOES). This satellite spins on an axis parallel to the Earth's, providing an east–west scan. At the end of an east–west scan the beam is stepped to the north or south and the process repeated—resulting in a temperature map of the earth's surface. The scanning is similar to the raster scanning of the spot of a TV tube.

GLOSSARY

Aperture Efficiency: Ratio of the effective aperture area of an antenna and its physical area.

Aperture Synthesis: Method of obtaining the equivalent of a large aperture with two or more small apertures.

Beam Area: Solid angle in square radians or square degrees subtended by an antenna beam.

Brightness: A measure of the power received per unit area per unit solid angle per unit bandwidth from a radiating object such as the sky. It is expressed in watts per square meter per hertz per square radian.

BWFN: Beamwidth between the first nulls of an antenna pattern.

Dicke Receiver: Radio receiver with switched input for improving receiver stability.

Directivity: Ratio of the power radiated per unit solid angle in the direction of the main beam of an antenna to that in all directions from an isotropic or nondirectional antenna. It may also be expressed as 4π divided by the beam area, both in steradians (or square radians).

Effective Aperture: If a plane wave is incident on a lossless antenna, the effective aperture is the ratio of the power received to the incident power flux density. Thus, if the incident flux density is 1 watt per square meter and the power received is 2 watts, the effective aperture is 2 square meters.

Field Intensity: Usually the electric field intensity or strength expressed in volts per meter.

Flux Density: Power flux of an electromagnetic wave per unit area per unit bandwidth (W m^{-2} Hz^{-1}).

HEMT Amplifier: High–electron-mobility transistor low-noise amplifier.

Holographic Technique: Measurement of the amplitude *and* phase of a beacon signal for mapping the surface of a parabolic reflector.

Homologous Design: Structural design of a reflector antenna in which the parabolic reflector deforms into another as the reflector is tilted.

HPBW: Half-power beamwidth of an antenna pattern. The angular width of the pattern at the half-power level.

Interferometer: In radio astronomy, two or more spaced antennas used to obtain narrower beamwidths. See **Aperture Synthesis.**

Jansky: Unit of flux density equal to 10^{-26} W m^{-2} Hz^{-1}.

LNA: Low-noise amplifier.

Minimum Detectable Flux Density: The minimum flux density of a radio source that can be measured by a telescope in the presence of its noise.

Normalized Power Pattern: The antenna pattern divided by its maximum value so that the maximum normalized power in the direction of the main beam is unity.

Pattern: Variation of power flux (or field intensity) of an antenna as a function of angle.

Physical Aperture: Actual physical cross section of antenna. See also **Effective Aperture.**

Power Flux Density: Amount of power flow through unit area, usually expressed in watts per square meter.

Rayleigh Resolution: One half the beamwidth between first nulls of an antenna pattern. Thus, the Rayleigh resolution equals BWFN/2. It is 12% more than the half-power beamwidth or 1.12 HPBW. Two point sources separated by this angle will just be resolved.

SIS Mixer: Superconductor-insulator-superconductor quasiparticle low-noise mixer.

System Temperature: The system temperature is a factor in determining the sensitivity of a radio telescope. It depends on the noise temperature of the sky, the receiver noise temperature, and other factors. The smaller the system temperature the more sensitive the radio telescope. Front-end amplifiers of radio telescopes are often refrigerated to reduce this temperature.

Visibility: Amplitude of the lobe pattern as a function of the spacing of interferometer antennas. Also called the fringe visibility.

11.1
Introduction

Nuclear chemistry and physics originated with the study of natural radioactivity. Many important insights into the properties of nuclear matter have been obtained through the study of radioactive decay. The study of radioactivity continues to play a significant role in nuclear science research even today.

As important as these fundamental studies of radioactivity have been and continue to be, most users of radioactivity are not nuclear physicists or chemists, but those who work in a wide variety of endeavors where radioactivity is simply a tool. This tool is no more special than any other laboratory instrument such as an infrared spectrometer, a computer, and so on. This review is meant for such users.

Any number of standard nuclear chemistry and physics textbooks contain excellent, thorough, in-depth discussions of radioactivity, its measurement, and its applications (see the section Further Reading at the end of this chapter for examples) The aim of this chapter is to provide a terse account of the most important features of radioactivity with the hope of piquing the reader's interest and serving as a source of information for further inquiries.

We begin by discussing what causes radioactive decay, and which nuclei are radioactive. In the second section, we discuss the equations that describe radioactive decay and dating. The next three sections are devoted to a more detailed discussion of the three main types of radioactive decay; α-, β-, and electromagnetic decay. In each of these sections, we seek to describe the basic decay mode, its energetics, and its occurrence and to provide a simplified summary of the decay mechanism and any appropriate selection rules. A final section on radioactive decay describes other, more exotic decay modes. Following these discussions of the physical principles behind radioactive decay, there are brief sections dealing with the detection and measurement of radioactivity and some sample applications. The section on detectors and measurements is brief because this book contains several full-length articles on individual detector types and their use.

11.2
Nature of Radioactivity

11.2.1
Which Nuclei Decay?

Radioactivity is the spontaneous disintegration of an atomic nucleus by emission

Encyclopedia of Applied High Energy and Particle Physics. Edited by Reinhard Stock
Copyright © 2009 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-40691-3

of some form of matter and/or energy. Nuclei that undergo radioactive decay and the decay process itself are referred to collectively as *radioactivity*. The types of radioactive decay include α-decay, β-decay, electromagnetic decay, and so on. (see Sections 11.4–11.6 for definitions and details). All nuclei will disintegrate if raised to a high enough excitation energy, but the term radioactivity is usually reserved for nuclei with little or no excitation energy. Radioactive decay is thus an exoergic process.

The release of energy in decay processes can be caused by a variety of circumstances. For example, the stable nuclei have relatively well-defined neutron-to-proton ratios (Figure 11.1). For the lighter nuclei, the n/p ratio is about 1, while this ratio approaches a value of 1.5 for the heavier nuclei. (The change in this ratio reflects the changing balance between the strong and electromagnetic forces as the nuclear composition changes.) Nuclei with n/p ratios greater than those of stable nuclei decay by β^- decay while those with n/p ratios less than those of stable nuclei decay by β^+ or electron capture (EC) decay.

Another way to represent this concept is to plot the mass of the nuclei versus the number of neutrons (N) and the number of protons (Z) in the nucleus (Figure 11.2). The stable nuclei lie at the bottom of the "valley of stability" while the radioactive nuclei lie at higher elevations and decay by dropping down into the valley of stability. For the heaviest nuclei (not shown in Figure 11.2), there is a headwall in the valley such that these nuclei decay by

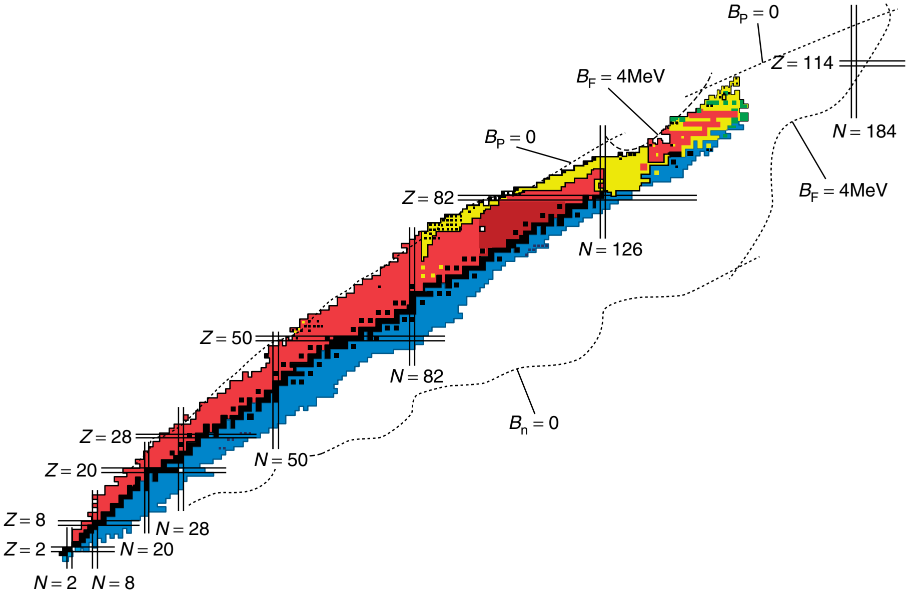

Fig. 11.1 Plot of all the known stable or radioactive nuclei, arranged by atomic number Z and neutron number N. The dashed contour shows the possible range of all bound nuclei. The black squares indicate the stable nuclei, the blue areas represent β^- emitters, the red areas represent nuclei decaying by β^+ decay or EC, the yellow regions represent the α-emitters, while the green regions indicate the nuclei decaying primarily by spontaneous fission. The "magic" numbers are shown by pairs of horizontal or vertical lines.

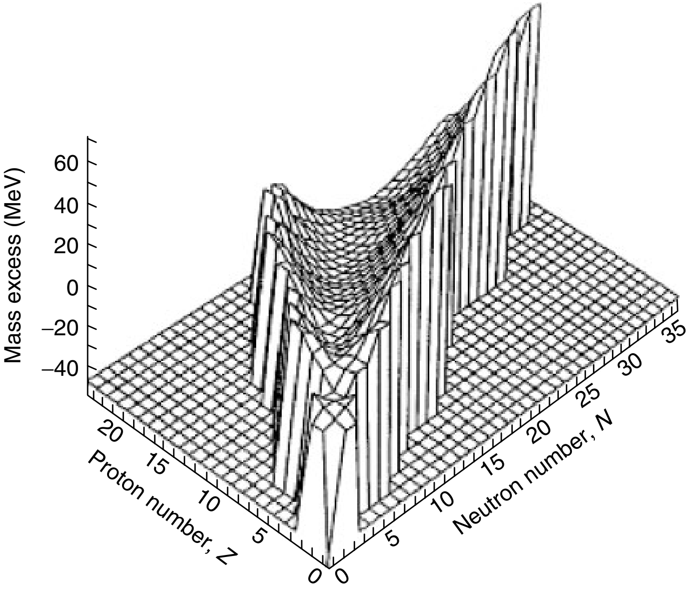

Fig. 11.2 A portion of the nuclear mass surface, showing the valley of β-stability. (From Halliday, Resnick, and Krane 2001; reproduced by permission of John Wiley & Sons, Inc.)

emitting heavy particles such as He nuclei (α-particles) or spontaneously fissioning.

11.2.2
Natural Radioactivity

One might inquire as to how a nucleus is created such that it is unstable, that is, has an unfavorable n/p ratio. All nuclides, stable and radioactive, except hydrogen, helium, and lithium-7, were made in nuclear reactions in the interior of stars or in explosive supernovas. Our solar system is composed primarily of nuclides that were formed about 4.5×10^9 years ago. If the half-life of a radioactive nuclide is greater than 4.5×10^9 years, then such original nuclei will still exist and their decay can be observed. Examples of these naturally radioactive nuclei include the heavy-element decay series, that is, the uranium, thorium, and actinium series (Figure 11.3). Each of these series consists of a long-lived parent nuclide that decays to a daughter nuclide that decays to a granddaughter, and so on, ending in a stable isotope of lead.

The thorium, uranium, and actinium series begin with long-lived primordial parents. These series are found in nature, mostly in rocks or minerals. The parent of another artificial decay series, the neptunium series, is extinct (because its half-life is less than the age of the solar system) and so this series is found only in the laboratory. The thorium, uranium, and actinium series are also known as the $4n, 4n + 2$, and $4n + 3$ series because the mass number of each member of a given series is numerically equal to $4n$ or $4n + 2$ or $4n + 3$ where n is an integer. In addition to the normal way of representing a nuclide as $^{A}_{Z}$ (Chemical

Fig. 11.3 The uranium, thorium, and actinium decay series.

Symbol)$_N$ shown in Figure 11.3, one also sees an archaic representation for each member of the series such as UI, RaC, and so on. These archaic symbols date from the original work by chemists who isolated each member of the series from ores. Some of these symbols, including ThC, ThC′, RaD, RaE, and RaF, are still used. Note that the heavy-element decay series involve isotopes of radon, which is a gas. Natural decays in rocks that occur near the surface of the earth or that occur in uranium-containing materials, such as concrete, can release this gas to the environment. The hazards associated with environmental levels of radon are a subject of current research.

Other naturally occurring radionuclides exist, such as ^{40}K, ^{87}Rb, ^{113}Cd, ^{115}In, ^{138}La, ^{176}Lu, and ^{187}Re. There are also important naturally occurring cosmogenic radionuclides that are continuously produced by the interaction of cosmic rays (mostly high-energy protons) with the earth's atmosphere. Examples of these include radiocarbon (^{14}C) and tritium (^{3}H) (Lal and Suess, 1968). Another component of environmental radioactivity is those radionuclides released to the environment as a result of the activities of man, primarily through fallout from nuclear weapons testing. Prominent among these nuclides are ^{239}Pu, ^{3}H, and some long-lived fission products such as ^{90}Sr and ^{137}Cs. For example, 5.6 tons of plutonium has been injected into the environment by weapons testing. Over 99% of this material is now in the soil and sediments. Pu concentrations in water are low, being

$\sim 10^{-18}$ M. Approximately 0.1% of the plutonium released to the environment ends up in the biota (Seaborg and Loveland, 1990).

11.2.3
Artificial Radioactivity

In addition to the naturally occurring radionuclides, one can make a large number of shorter-lived radionuclides in the laboratory. Stable nuclei are transmuted into radioactive nuclei through nuclear reactions. This process was first demonstrated by Joliot and Curie (1934). Since then, the growth in the number of artificial radionuclides has been phenomenal. In Figure 11.1, one notes that the shaded areas corresponding to artificial radionuclides include over 1500 species ranging in half-life from microseconds to millions of years. One also notes the large blank areas corresponding to the 5000 or more possible radionuclides, most of which are waiting to be discovered.

11.2.4
The Elements beyond Uranium

The most important examples of artificial radioactivity are the elements beyond uranium, that is, those elements with $Z > 92$. At present, there are 25 such man-made elements, ranging in Z from 93 to 118. In Table 11.1, we list the names of these elements and the nuclear reactions used to synthesize them.

In total, there are about 260 transuranium nuclei known as of 2005. These nuclei are all radioactive, with half-lives ranging from $\sim 10^{-9}$ seconds to 10^{17} seconds. As Z increases, the half-lives of the elements become shorter, in general. All these nuclei are unstable with respect to α-decay (positive Q_α). Those with n/p ratios differing from the nuclei along the valley of β-stability decay by either β^- or EC decay. As the atomic number increases, so does the importance of spontaneous fission decay. Detailed descriptions of the nuclear and chemical properties of these elements exist (Seaborg and Loveland, 1990; Morss *et al.*, 2006). The story of the discovery of these elements is a fascinating one and the reader is referred elsewhere for details (Seaborg and Loveland, 1990; Hoffman, Ghiorso and Seaborg, 2000; Hofmann, 2002).

Up to 1970, it was thought that the practical limit of the periodic table would be reached at about element 108. By extrapolating the experimental data on heavy-element half-lives, we concluded that the half-lives of the longest lived isotopes of the heavy elements beyond about element 108 would be so short ($<10^{-6}$ seconds) due to spontaneous fission decay, that we could not produce and study them. However, in the late 1960s and early 1970s, nuclear theorists predicted that special stability against fission would be associated with proton number $Z = 114$ and neutron number $N = 184$. These ‘‘superheavy elements’’ were predicted to have half-lives of the order of the age of the universe. They were predicted to form an ‘‘island’’ of stability separated from the ‘‘peninsula’’ of known nuclei.

We now know these predictions were wrong, in part. While we believe there are a group of ‘‘superheavy’’ nuclei whose half-lives are relatively long compared to lower Z elements, we do not believe they form an ‘‘island’’ of stability. Rather, we picture them as a continuation of the peninsula of known nuclei. We also believe that their half-lives are short compared to geologic timescales. Therefore, they do not exist in nature. While most current theoretical predictions attach special stability to $N = 184$, there is a division of opinion

Tab. 11.1 Summary of transuranium element synthesis.

Atomic number	Name and symbol	Synthesis reaction
93	Neptunium (Np)	$^{238}\mathrm{U} + \mathrm{n} \longrightarrow {}^{239}\mathrm{U} + \gamma$
		$^{239}\mathrm{U} \xrightarrow{\beta^-} {}^{239}\mathrm{Np}$
		$^{238}\mathrm{U} + {}^{2}\mathrm{H} \longrightarrow {}^{238}\mathrm{Np} + 2\mathrm{n}$
94	Plutonium (Pu)	$^{238}\mathrm{Np} \xrightarrow{\beta^-} {}^{238}\mathrm{Pu}$
95	Americium (Am)	$^{239}\mathrm{Pu} + \mathrm{n} \longrightarrow {}^{240}\mathrm{Pu} + \gamma$
		$^{240}\mathrm{Pu} + \mathrm{n} \longrightarrow {}^{241}\mathrm{Pu} + \gamma$
		$^{241}\mathrm{Pu} \xrightarrow{\beta^-} {}^{241}\mathrm{Am}$
96	Curium (Cm)	$^{239}\mathrm{Pu} + {}^{4}\mathrm{He} \longrightarrow {}^{242}\mathrm{Cm} + \mathrm{n}$
97	Berkelium (Bk)	$^{241}\mathrm{Am} + {}^{4}\mathrm{He} \longrightarrow {}^{243}\mathrm{Bk} + 2\mathrm{n}$
98	Californium (Cf)	$^{242}\mathrm{Cm} + {}^{4}\mathrm{He} \longrightarrow {}^{245}\mathrm{Cf} + \mathrm{n}$
99	Einsteinium (Es)	"Mike" thermonuclear explosion (leading to $^{253}\mathrm{Es}$)
100	Fermium (Fm)	"Mike" thermonuclear explosion (leading to $^{255}\mathrm{Fm}$)

[a] Unconfirmed.

as to what proton numbers have special stability, with some calculations indicating $Z = 114$ to be stable while others indicate the next proton magic number will be near $Z = 120$ or $Z = 126$. One thing is clear, however, and that is that the half-lives of he longest lived isotopes of a given Z do not continue their sharp decrease with increasing atomic number, observed for elements 93–102. Rather there is a leveling off in the observed half-lives with the reported half-lives of elements 112–118 being of the order of milliseconds to microseconds.

Synthesis reactions for heavy nuclei are divided into "cold" or "hot" fusion. Cold fusion reactions involve a heavier projectile (Ar–Kr) interacting with a Pb or Bi nucleus, where the excitation energy of the completely fused system is low (~13 MeV), giving high survival probabilities. Unfortunately, the fusion probability in such systems is low. Hot fusion reactions involve the use of lighter projectiles (^{11}B–^{48}Ca) interacting with actinide nuclei, giving a high fusion probability, but a high excitation energy (E*~30–50 MeV) with a resulting low survival probability. In Figure 11.4, we show the current cross sections for heavy-element synthesis using these two methods.

The current challenge in heavy-element science is to understand the apparent leveling off of the production cross sections using the hot fusion approach. Some attribute this trend to an increased survival probability for the nuclei as they approach the proton and neutron magic numbers.

11.3
Radioactive Decay Kinetics

11.3.1
Basic Decay Law

Radioactive decay is a first-order reaction, that is, the number of decays per unit time is directly proportional to the number of nuclei present. Thus, if $-dN/dt$ is the decay rate, we can say that

$$\frac{-dN}{dt} = \lambda N \qquad (1)$$

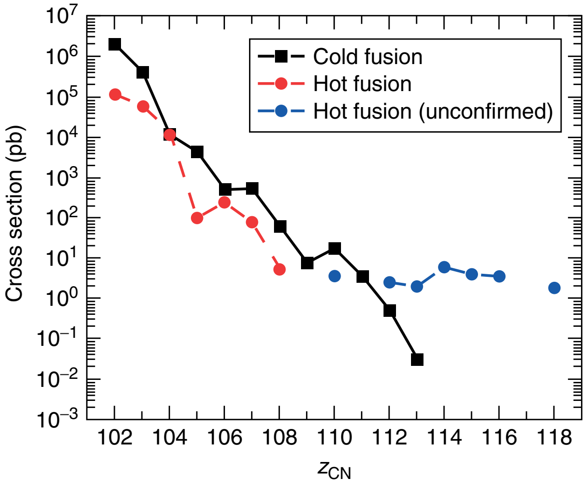

Fig. 11.4 Cross sections for heavy-element synthesis by hot and cold fusion reactions.

where λ, the decay constant, is the probability of decay per unit time and N is the number of radioactive nuclei present. The rate of disappearance of radioactive nuclei can easily be shown to be given by

$$N = N_0 e^{-\lambda t} \tag{2}$$

where N is the number of radioactive nuclei present at time t and N_0 the number of nuclei present at $t = 0$. A companion equation expresses the decrease in activity of a radioactive sample, $A(\equiv -dN/dt)$, as a function of time t, that is,

$$A = A_0 e^{-\lambda t} \tag{3}$$

where A_0 is the sample activity at time $t = 0$.

The half-life $t_{1/2}$ is defined as the time it takes the number of nuclei or the number of disintegrations per unit time to decrease by a factor of 2. A related quantity is the mean life τ, the average lifetime of a radioactive nucleus. Since the decay constant λ is the probability per unit time that a nucleus will decay, it is easy to show that τ equals $1/\lambda$. (The mean life τ is the appropriate quantity to be used in the energy–time statement of the uncertainty principle,

$$\Delta E \cdot \tau \geq \hbar \tag{4}$$

where ΔE is the uncertainty about the energy of a state while τ is its mean life.)

The natural unit of radioactivity is disintegrations per second. One *becquerel* (Bq) is defined as 1 disintegrations per second. An older unit that is still used is the curie (Ci), which corresponds to 3.7×10^{10} Bq. Most radioactive samples have activities ranging from nCi to μCi although irradiated reactor-fuel activities are frequently at the MCi level.

11.3.2
Radioactive Decay Equilibrium

When a nucleus decays, frequently a new nucleus appears that is also radioactive. This nucleus can decay to another, to another, and so on. For the general situation where species 1 decays to 2, which in turn decays to 3, and so on, one can show that

$$N_n = N_1^0 \sum_{i=1}^{n} C_i e^{-\lambda_i t} \tag{5}$$

where N_1^0 is the number of species 1 nuclei present initially and

$$C_i = \frac{\lambda_1 \lambda_2 \lambda_3 \ldots \lambda_{n-1}}{(\lambda_1 - \lambda_i)(\lambda_2 - \lambda_i)\ldots(\lambda_n - \lambda_i)} \tag{6}$$

and we omit the term in the denominator of Eq. (6) that is zero. Special cases of this general equation exist. One of the most important of these is secular equilibrium where $\lambda_1 < \lambda_2$. Here the parent is very long lived relative to the daughter. In this case, one can show that

$$\lambda_1 N_1 = \lambda_2 N_2 \tag{7}$$

or A_1 is equal to A_2. This condition applies to the heavy-element decay series discussed previously. There the half-lives of the parent nuclei are so long that the conditions for secular equilibrium are met. Consequently, the activities of all the members of a given series are equal. For further details, see Loveland, Morrissey and Seaborg (2006).

11.3.3
Dating

An important application of the basic radioactive decay law is that of dating. The basic decay law tells us that

$$P = P_0 e^{-\lambda t} \tag{8}$$

where P is the number of parent nuclei at time t and P_0 is the number at $t = 0$. Rearranging Eq. (8) we get

$$t = \frac{\ln(P_0/P)}{\lambda} \tag{9}$$

where t is the age of an object. The most famous application of Eq. (9) is that of *radiocarbon dating* (Libby, 1946; Arnold and Libby, 1949).

^{14}C ($t_{1/2} = 5730$ years) is formed continuously in the upper atmosphere by cosmic rays via the reaction $n + {}^{14}\mathrm{N} \rightarrow {}^{14}\mathrm{C} + p$, or, in a shorthand notation, $^{14}\mathrm{N}(n, p)^{14}\mathrm{C}$. This radiocarbon (^{14}C) exchanges with the stable carbon (mostly ^{12}C) in living things. If the cosmic-ray flux is constant, then a constant level of ^{14}C in all living things is found (corresponding to ∼1 atom of ^{14}C for every 10^{12} atoms of ^{12}C or about 14.9 disintegrations per minute · (g C)(P_0)). When an organism dies, it ceases to exchange its carbon atoms with the pool of radiocarbon, and its radiocarbon content decreases in accordance with Eq. (8). Measurement of the specific activity (disintegrations per minute · (g C)) of an old object allows one to calculate the age using Eq. (9). When matter has decayed for 10 or more half-lives of ^{14}C, it is no longer possible to measure directly the radioactivity content of an object. In that case, one uses *accelerator mass spectrometry* to count the number of ^{14}C atoms directly. An accelerator, such as a cyclotron or tandem Van de Graaff, is used as a mass spectrometer to separate the ^{14}C atoms from the more prevalent ^{12}C or ^{13}C. Using this technique, it has been possible to determine ages as long as 100 000 years (Kutschera and Paul, 1990).

Another variant of the dating technique is to measure the relative number of parent and daughter atoms in an object. Since every parent decay will lead to a daughter, the number of daughter atoms D at time t is

$$D = D_0 + (P_0 - P) = D_0 + P(e^{\lambda t} - 1) \tag{10}$$

where D_0 is the number of daughter nuclei present at $t = 0$. Solving for t gives

$$\begin{aligned} t &= \frac{1}{\lambda}\ln\frac{P + D - D_0}{P} \\ &= \frac{1}{\lambda}\ln\left(1 + \frac{D - D_0}{P}\right) \end{aligned} \tag{11}$$

Equations (10) and (11) assume that there is no gain or loss of either parent or daughter except by radioactive decay. If one can assume that $D_0 = 0$, then a measurement of the relative numbers of parent and daughter nuclei will give the age of the sample. (If $D_0 \neq 0$, then further assumptions can be made to deduce the age; see Wetherill, 1975). Examples of this technique involve $^{40}\mathrm{K}/^{40}\mathrm{Ar}$, $^{87}\mathrm{Rb}/^{87}\mathrm{Sr}$, and U/Pb dating.

11.4
α-Decay

α-Decay involves the spontaneous emission of a doubly charged ^{4}He nucleus (an α-particle) by another nucleus, resulting in a loss of two protons and two neutrons by the parent nucleus. The energy released in the decay, Q_α, is defined as

$$Q_\alpha = (M_A - M_{A-4} - M_\alpha)c^2 \tag{12}$$

where M_A, M_{A-4}, and M_α refer to the atomic masses of the parent nucleus, the daughter nucleus, and a ^{4}He atom and

c is the speed of light. The decay energy Q_α is shared between the α-particle ($T_\alpha = M_{A-4}Q_\alpha/M_A$) and the recoiling daughter nucleus ($T_{\text{recoil}} = M_\alpha Q_\alpha/M_{A-4}$), with a small amount being used to compensate for the change in the total electronic binding energies of the atoms ($\sim 65.3Z^{7/5}$–$80Z^{1/2}$ eV). Thus, for heavy nuclei, the α-particle carries away about 98% of the decay energy. The emitted α-particles are monoenergetic with α-particle energies ranging from 1.83 MeV (^{144}Nd) to 11.65 MeV (^{212}Po^{m}), typical energies being $\sim$6 MeV. The half-lives corresponding to these decays range from 3.0×10^{-7} seconds (^{212}Po^{m}) to 2.1×10^{15} years (^{144}Nd). This unusually strong dependence of the half-life on the α-particle kinetic energy was first noted by Geiger and Nuttall and found its explanation in the theory of α-decay developed independently by Gamow (1928) and Gurney and Condon (1928).

In this theory, we assume the α-particle exists as a preformed particle within the nucleus. In Figure 11.5, we show the potential energy $V(r)$ between the α-particle and the daughter nucleus as a function of their separation. At small distances, the two nuclei are bound by the attractive nuclear potential ($-V_0$), while at larger distances, the repulsive Coulomb force between the two nuclei defines the shape of the potential-energy function. The α-particle can be considered to be trapped in the nuclear potential well. Quantum mechanics allows the α-particle to "tunnel" through the potential-energy barriers, although it is a relatively improbable event. (e.g., for the decay of ^{238}U, $Q_\alpha = 4.27$ MeV, and $t_{1/2} \sim 4.5 \times 10^9$ years. The α-particle strikes the barrier about 10^{20} times per second for about 10^9 years before a decay occurs.) Because the probability of penetrating the barrier, P, is given by

$$P = e^{-2G} \tag{13}$$

where

$$G = \left(\frac{2m}{\hbar^2}\right)^{1/2} \int_{\text{barrier}} [V(r) - Q_\alpha]^{1/2} dr; \tag{14}$$

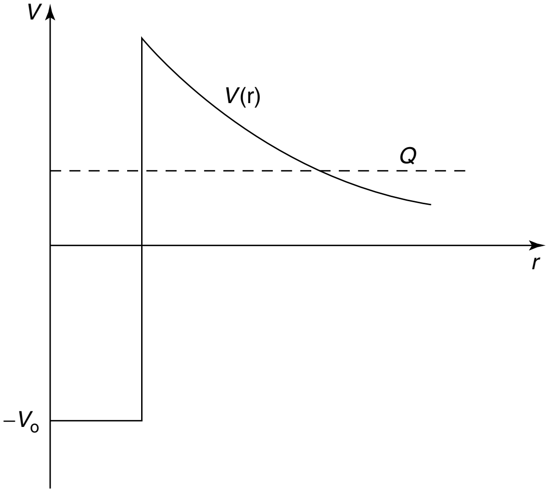

Fig. 11.5 The potential energy between an α-particle and a heavy daughter nucleus as a function of their separation. The horizontal line represents the decay energy, Q_α.

the penetrability of the barrier (i.e., the half-life for the decay) is a sensitive function of the decay energy Q_α. As a result of this, α-decay favors transitions to the ground and low-lying states of the daughter nuclei (large Q_α). From Eq. (14) one can see that $\log t_{1/2}^{\alpha}$ is a linear function of $1/Q_\alpha^{1/2}$ (the Geiger–Nuttall rule). The Geiger–Nuttall rule is used as the basis for semiempirical prescriptions relating the α-decay half-life, T_α, to Q_α, that is, the Viola–Seaborg formula (Viola and Seaborg, 1966)

$$\log_{10} T_\alpha = (aZ + b)Q_\alpha^{-1/2} + (cZ + d) + h_{\log} \tag{15}$$

where the parameters $a, b, c,$ and d are determined by fitting data for even–even nuclei and $h_{\log}$ is a hindrance factor for nuclei with unpaired nucleons. Modern versions of these semiempirical prescriptions exist (Dong and Ren, 2005; Hatsukawa, Nakahara and Hoffman, 1990) that allow one to predict T_α from Q_α to within a factor of ~1.5.

The decay of odd-A or odd–odd nuclei is hindered relative to the decay of even–even nuclei primarily by problems of the overlap (or lack of same) between the states of the parent and daughter nucleus when there are an odd number of nucleons. Typical hindrance factors, (measured $t_{1/2}$/calculated $t_{1/2}$), for even–even nuclei range from near unity to several thousands. These hindrance factors can give information about the parent and daughter states involved in the decay. Transitions with hindrance factors between 1 and 4 are called *favored* transitions; in these decays the parent and daughter states have similar wave functions.

Strict angular-momentum and parity-selection rules govern α-decay. The orbital angular momentum L_α carried away by the α-particle is given by

$$|I_i - I_f| \le L_\alpha \le I_i + I_f \tag{16}$$

where I_i and I_f are the total angular momenta of the parent and daughter states. The parity-selection rule can be written as

$$\frac{\pi_i}{\pi_f} = (-1)^{L_\alpha} \tag{17}$$

where π_i, π_f are the parities (−1 or +1) of the initial and final nuclear states. Thus, a $0 \to 3$ decay must have $L_\alpha = 3$ (Eq. (16)) and $0^+ \to 3-$ is allowed (Eq. (17)), but not $0^+ \to 3^+$. Also it should be noted that higher values of L_α are inhibited relative to lower values because of a "centrifugal potential" that raises the height of the barrier against α-decay and decreases its penetrability. A detailed discussion of α-decay is found in Rasmussen (1965).

11.5
β-Decay

11.5.1
Types of β-Decay

In nuclear β-decay, the total number of nucleons in the nucleus, A, remains constant while the number of neutrons and protons changes. The three types of β-decay are

$$\begin{aligned} n &\longrightarrow p + \beta^- + \overline{\upsilon}_e \,(\beta^-\text{decay}) \\ p &\longrightarrow n + \beta^+ + \upsilon_e \,(\beta^+\text{decay}) \\ e^- + p &\longrightarrow n + \upsilon_e \,(\text{EC decay}) \end{aligned} \tag{18}$$

In β^- decay, a nuclear neutron changes into a proton with the emission of an electron (designated β^-) and an electron antineutrino ($\overline{\upsilon_e}$). In β^+ (positron) decay, a nuclear proton changes into a neutron with the emission of a positron (β^+) and an electron neutrino (v_e). In EC decay (Alvarez, 1938), a nuclear proton changes into a neutron upon capture of an orbital atomic electron with emission of only an electron neutrino (v_e). The emitted electrons and neutrinos are created in the decay and do not exist within the nucleus. β^- decay is thus the mode of β decay for neutron-rich nuclei while EC and β^+ decay are competing decay modes for proton-rich nuclei. Examples of these decay modes are

$$\begin{aligned} {}^{14}_{6}\text{C} &\longrightarrow {}^{17}_{7}\text{N} + \beta^- + \overline{v}_e \\ &\qquad (\beta^-\text{decay}) \\ {}^{22}_{11}\text{Na} &\longrightarrow {}^{22}_{10}\text{Ne} + \beta^+ + v_e \\ &\qquad (\beta^+\text{decay}) \\ e^- + {}^{207}_{83}\text{ Bi} &\longrightarrow {}^{207}_{82}\text{Pb} + v_e \\ &\qquad (\text{electron capture}) \end{aligned} \tag{19}$$

All nuclei not lying in the valley of stability will undergo β-decay.

11.5.2
Energetics

The energy release in β-decay, Q_β, is shared among the products. In the case of EC decay, the decay energy Q_{EC} is given as

$$Q_{\text{EC}} = (M_Z^A - M_{Z-1}^A)\,c^2 - B \tag{20}$$

where M_Z^A, M_{Z-1}^A are the atomic masses of the parent and daughter species and B is the binding energy of the captured orbital electron. The recoiling daughter nucleus and the emitted neutrino share the decay energy with $T_v \approx Q_{\text{EC}}$. In β^- decay, the energy release Q_{β^-} is given as

$$Q_{\beta^-} = (M_Z^A - M_{Z+1}^A)\,c^2 \tag{21}$$

This discrete energy is shared among the recoiling daughter nucleus (a very small energy) and the two emitted particles, the electron (β^-) and the electron antineutrino ($\overline{v_e}$). Unlike EC decay, the energy of the emitted particles is variable, ranging from zero up to some maximum energy (Figure 11.6). Only the sum of the electron and antineutrino energies is a constant. On the average, about 40% of the decay energy appears as β^- energy while 60% appears as $\overline{v_e}$ energy. In β^+ decay, the decay energy Q_{β^+} is given as

$$Q_{\beta^+} = (M_Z^A - M_{Z-1}^A)c^2 - 2M_ec^2 \tag{22}$$

where M_e is the mass of the electron ($2M_ec^2 = 1.02$ MeV). The latter term in Eq. (22) reflects the need to supply additional energy to create a positron (β^+) in this decay. Thus, while EC and β^+ decay are competing modes of decay for proton-rich nuclei, EC decay is the only possible decay mode when the masses of parent and daughter nuclei differ by less than 1.02 MeV. Among the lighter elements, EC and β^+ decay are about equally probable. With increasing Z, EC decay is favored and positron emission is not observed in the heavy elements. The decay energy Q_{β^+} appears primarily as shared energy between the emitted positron and the electron neutrino (Figure 11.6).

11.5.3
Decay Mechanism

The measured half-lives for β-decay are long, varying from 10^{-3} seconds to 10^{16} years. Thus, we conclude that the processes to create simultaneously an electron and a neutrino are improbable. β-Decay must involve some sort of interaction between a nucleon, an electron, and a neutrino. This interaction is called the

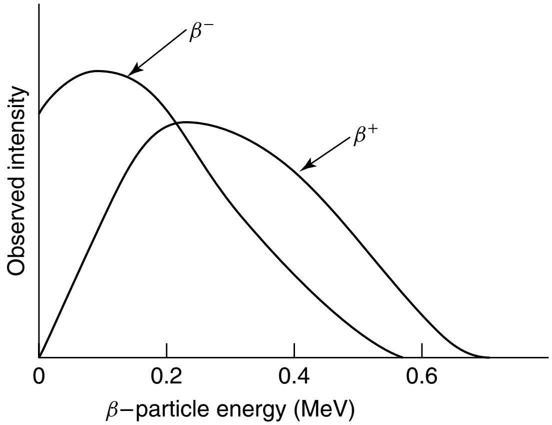

Fig. 11.6 The kinetic energy of the emitted electrons (positrons) in β^- (β^+) decay.

weak interaction and is different from the strong, electromagnetic, and gravitational forces. This weak interaction is responsible for the long half-lives associated with β-decay. The basic theory to describe β-decay was set forth by Fermi (1934). In addition to a constant g that expresses the strength of the weak interaction, analogous to the constants e and G that express the strengths of the electromagnetic and gravitational forces, the theory contains reference to the properties of the initial and final nuclear states in the decay. β-Decay will be enhanced when the initial and final states are similar. Formally, if the interaction between the initial and final states of the system is V, the decay probability will be proportional to the square of the matrix element

$$V_{\mathrm{f}i} = \int \psi_f^* V \psi_i dv \tag{23}$$

The available β-decay energy Q can be divided between the electron and the neutrino in an infinite number of ways, but these are not all equally probable. The probability of emission of a particle is proportional to the square of its momentum. Sharing the energy between two particles produces a most probable division of energy when each takes roughly half the energy. However, we also expect an attraction (repulsion) between the positively charged nucleus and the electron (positron). This effect has been reduced to a parameter $\mathrm{F}(Z, E_e)$, the Fermi function, that is tabulated. Thus, the decay constant for β-decay will be given as

$$\lambda(E_e) = (\text{constants})g^2 \times \int_0^{P_e^{\max}} |V_{\mathrm{f}i}|^2 \, \mathrm{F}(Z, E_e)(Q - E_e^2)P_e^2 dP_e \tag{24}$$

The term $((Q - E_e)^2$ is proportional to the square of the neutrino momentum. Equation (24) will describe the observed β^+, β^- spectra shown in Figure 11.6. If we assume that the matrix element does not depend on P_e (and we remove it from the integral) and we then designate the resulting integral as f, we have

$$\ln 2 = (\text{constants})g^2 |V_{fi}|^2 ft_{1/2} \tag{25}$$

or

$$ft_{1/2} = \frac{(\text{constants})}{|V_{fi}|^2} \tag{26}$$

Thus, the product $ft_{1/2}$ only depends on the square of the matrix element, that is, the similarity between initial and final nuclear states.

Transitions are classified by their change in angular momentum and parity. If the parities of the parent and daughter nuclei are the same and their angular momenta differ by one or less units, the transitions are termed *allowed*. If the spin difference is more than 1 and/or the parity changes, the transitions are "forbidden". There are different degrees of forbiddenness: first-forbidden, second-forbidden, and so on, depending on the spin change. For an increase of one degree of forbiddenness, the half-life increases by $\sim 10^3$. Values of $ft_{1/2}$ (or more conveniently, log $ft_{1/2}$) should have similar values for transitions involving similar changes in angular momentum and parity. Nomographs and semiempirical equations exist that allow one to calculate f for a given transition (Browne and Firestone, 1986). Measurement of the half-life $t_{1/2}$ along with the calculated value of f allows one to identify the angular momentum and parity change in a given β-decay. The spins of the electron and neutrino in β^- or β^+ decay can be parallel (Gamow–Teller decay) or antiparallel (Fermi decay). Individual transitions may take place by a mixture of Fermi and Gamow–Teller decays. The values of log $ft_{1/2}$ differ for Gamow–Teller and Fermi decays. A detailed discussion of β-decay is found in Wu and Moszkowski (1966).

11.5.4
Electron Capture

EC decay is the only β-decay mode for p-rich nuclei when the decay energy is <1.02 MeV and is the preferred decay mode for heavy p-rich nuclei. The captured orbital electron can come from any shell, but capture of K electrons is most probable because of their higher electron density in the nucleus. The theory of EC is similar to that of β^- or β^+ decay, except that it also involves the wave function of the captured electron, which determines its probability of being found within the nucleus. With increasing Z, the large positive charge of the nucleus causes the atomic electron shells to shrink, increasing the probability of electron capture. As mentioned previously, the only directly emitted radiation in EC decay is the electron neutrino. But the capture of an orbital electron leaves a hole in a low-lying orbital of the atomic electron configuration. The atomic electrons rearrange to fill this hole and in doing so, X-rays (especially in the heavy elements) or Auger electrons (especially in the light elements) are emitted. These extranuclear processes give rise to the useful experimental signatures of EC. The relative ratio of vacancies filled by X-ray emission or Auger-electron emission is given by the fluorescence yield or the Auger yield, which is the fraction of vacancies filled by X-ray emission or Auger-electron emission.

The rate of EC decay is sensitive to the atomic electron density at the center of the nucleus. Thus, the half-life for decay is sensitive to the chemical environment of the nucleus. Measurements of this effect in ^{7}Be, which decays only by EC, have shown a small but definite change in the half-life in different chemical environments (Johlige, Aumann and Born, 1970). In astrophysics, highly ionized nuclei occur and half-lives can be dramatically altered. In bare nuclei, EC decay can be switched off completely (^{52}Fe). In bare nuclei, internal conversion (IC) decay is also not possible.

11.5.5
Double β-Decay

There are many nuclei that are unstable with respect to the emission of two β^- particles simultaneously. Several cases are known of "two neutrino double β-decay ($\beta\beta(2\nu)$)" where two β^- particles and two electron antineutrinos are emitted, such as ^{48}Ca, ^{76}Ge, ^{82}Se, ^{96}Zr, ^{100}Mo, ^{116}Cd, ^{128,130}Te, ^{136}Xe, ^{150}Nd, and ^{238}U. This mode of decay is improbable with half-lives ranging from 10^{19}–10^{24} years (Elliott and Vogl, 2002). Of current interest is neutrinoless double β-decay, $\beta\beta(0\nu)$ where no neutrinos are emitted. This decay violates lepton conservation and is forbidden by the standard model. Searches for this mode of decay constrain the neutrino mass. Also of interest is another neutrinoless β-decay, $\beta\beta(0\nu, \chi)$ in which a light neutral boson, χ, is emitted. To date, neither of the neutrinoless decays has been observed.

11.5.6
β-Delayed Radioactive Decay

When β-decay occurs, the product nucleus can be formed in an excited state or its ground state. If the primary β-decay leads to an excited state at high enough energy, then a second decay process (such as neutron or proton emission or fission, etc.) can occur. Such processes are referred to collectively as *β-delayed radioactivities*. The most famous of these processes is β-delayed neutron emission, where the excitation energy of the daughter nucleus following β-decay is greater than the binding energy of the last neutron in that nucleus. This situation occurs frequently in *n*-rich fission products, where there are over 100 known examples of this decay mode, ranging in half-life from 0.2 to 55 seconds. Many of these nuclei are clustered above $N = 50$ and $N = 82$ because of the low values of the neutron-binding energies in the daughter nuclei. These β-delayed neutron emitters are of great technological importance in that the timescale of release of these neutrons is slow enough to allow servomechanisms controlling neutron absorbers to regulate the number of such neutrons in fissioning assemblies. This process makes possible the control of nuclear reactors. It is also possible to see β-delayed double neutron emission when the excitation energy of the daughter nucleus following β-decay is greater than the energy necessary to remove two neutrons. This phenomenon was first observed in ^{11}Be formed by the β-decay of ^{11}Li (Azuma *et al.*, 1979). In a similar manner, β-delayed triple neutron emission has also been reported for ^{11}Be (Azuma *et al.*, 1980).

When the excitation energy of the daughter nucleus following β^+ decay, E^*, is greater than the proton separation energy, β-delayed proton emission may occur. This process has been observed for a number of proton-rich nuclei. The emitted protons are monoenergetic with energies equal to $E^* - B_p$ where B_p is the proton-binding energy. Remembering that these protons have to overcome a Coulomb barrier like an α-particle to be emitted, one does not generally see delayed protons whose energy is <1 MeV. β-Delayed double proton emission has been observed in the decay (Cable *et al.*, 1983)

$$^{22}_{13}\mathrm{Al} \xrightarrow{\beta^+} {}^{22}_{12}\mathrm{Mg}^* \longrightarrow {}^{20}_{10}\mathrm{Ne} + 2p \tag{27}$$

The phenomenon of β-delayed radioactivity has a long history in nuclear science. Rutherford reported in 1916 the observation of β-delayed α-particle emission. In this case, ^{212}Bi is the parent nucleus (Figure 11.3). Numerous workers have also studied β-delayed fission where the excitation energy following a $\beta\pm$ or EC decay is large enough that the resulting nuclei undergo fission, either promptly or with some additional delay (Hall and Hoffman, 1992).

11.6
Electromagnetic Decay

11.6.1
Types and Classification

Most β- and α-decays that lead to an excited state of the daughter nucleus result in electromagnetic decay. Electromagnetic decay can take place by the nucleus emitting a photon (γ*-ray emission*) or by transferring energy to an orbital electron causing its ejection (*IC*). The result of these decay processes is to produce a lower-lying excited state or the ground state of the emitting nucleus. The emitted γ-ray photon is monoenergetic with an energy (E_γ) equal to the transition energy less a small amount of energy ($\sim 10^{-5} E_\gamma$) carried by the recoiling nucleus. The timescale for electromagnetic decay is usually 10^{-15} s. Occasionally, the emitting state will have a lifetime that is long enough to measure directly ($\sim 10^{-9}$ s). Such states are referred to as *metastable* or *isomeric* states. In such cases, the decay of the metastable state is inhibited, usually because of large spin change in its deexcitation. The γ-ray decays that depopulate isomeric states are called *isomeric transitions* (*ITs*).

The emission of γ-rays from nuclei resembles in many respects the emission of radio waves from an antenna. Both processes are due to the movement of charged particles: nucleons in the nuclear case, electrons in an antenna. In both cases, the radiation carries away energy and angular momentum. A photon can carry off any number of units of angular momentum, equal to or greater than 1 ħ. (This minimum is due to the spin of the photon, which is equal to 1 ħ.) Therefore, the initial and final nuclei must not both have zero spin, for then there would be no way to conserve angular momentum.

The greater the energy of the emitted photon, the greater the probability of γ-ray decay. The greater the angular momentum removed by the photon, the less probable γ-ray decay is. γ-Ray transitions are classified by transition type. The letters E and M are used to stand for electric and magnetic transitions; they are followed by a number equal to the number of units of angular momentum removed by the γ-ray. Thus, an E3 transition involves the loss of three units of angular momentum as a result of an electric transition. These rules are summarized in Table 11.2.

11.6.2
Transition Rates

The transition rates for γ-ray transitions are compared with those expected when a single proton makes a transition between nuclear states, as predicted by the shell model. These extreme single-particle estimates of transition rates are called the *Weisskopf estimates* after Weisskopf who first made them. These estimates are summarized in Table 11.3.

One can see that the half-lives for electric transitions are about 100 times shorter than for magnetic transitions of the same energy and multipolarity (angular momentum carried away). Each higher multipolarity for a given transition type and energy has a probability that is $\sim 10^7$ lower. Thus, γ-ray transitions usually occur by the lowest multipolarity transition possible. Quite often, γ-ray transition rates are expressed in Weisskopf units, that is, multiples of the

Tab. 11.2 γ-Ray emission rules.

Radiation type	Name	Angular momentum carried away	Does nuclear parity change?
E1	Electric dipole	1	Yes
M1	Magnetic dipole	1	No
E2	Electric quadrupole	2	No
M2	Magnetic quadrupole	2	Yes
E3	Electric octupole	3	Yes
M3	Magnetic octupole	3	No
E4	Electric 2^4 pole	4	No
M4	Magnetic 2^4 pole	4	Yes

estimates shown in Table 11.3. Most γ-ray transition rates are less than the Weisskopf estimates; the notable exception to this are E2 transitions, whose lifetimes are typically two orders of magnitude smaller than the Weisskopf estimate. (The E2 transitions are enhanced by a large-scale collective motion of several nucleons.) The result is that mixed M1–E2 transitions are common. A detailed discussion of electromagnetic decay is found in Siegbahn (1966).

11.6.3
Internal Conversion

Another form of nuclear electromagnetic decay is IC. In IC, the electric and magnetic disturbances (which cause the emission of a photon in γ-ray decay) interact directly with an orbital atomic electron, causing that electron to be ejected from the atom. The kinetic energy of the conversion electron is $E\gamma - E_B$, where E_γ is the transition energy and E_B the electron-binding energy. Another important quantity that characterizes IC is the IC coefficient α, which is defined as the (number of decays proceeding by IC)/(number of γ-ray decays). IC (large values of α) is favored by low transition energies and large spin changes in the decay. IC is favored in heavy nuclei since $\alpha \sim Z^3$. IC mostly involves ejection of K-shell electrons, since $\alpha \propto 1/n^3$ where n is the principal quantum number for the atomic electrons. Large tabulations of calculated IC coefficients exist. Measured values of α can be compared with the calculated values to determine the multipolarity of a given transition. Because no photon is emitted, E0 transitions are permitted to take place by IC.

11.7
Other Types of Radioactive Decay

11.7.1
Direct Proton Emission

Spontaneous proton emission is only energetically possible for the most proton-rich nuclei. Such nuclei can be formed in nuclear reactions with $N \approx Z$ projectile nuclei interacting with $N \approx Z$ target nuclei to create heavy nuclei with $N \approx Z$. The first example of this decay mode, observed in 1982, was ^{96}Ru(^{58}Ni,p2n)^{151}Lu.

The product ^{151}Lu was observed to decay by the emission of 1.23 MeV protons with $t_{1/2} \sim 0.085$ seconds (Hofmann *et al.*, 1982). Other cases have been observed since then.

Tab. 11.3 Gamma transition rates. The energies E are expressed in mega electronvolt. The nuclear radius has been taken as $1.3A^{1/3}$ fm and the A dependence of the transition rates has been incorporated in the formulas. It is to be noted that $t\gamma$ is the partial half-life for γ-emission only; the occurrence of internal conversion will always shorten the measured half-life.

Transition type	**Partial half-life t_γ (seconds)**	**Illustrative t_γ values for $A = 125$, $E = 0.1$ MeV (seconds)**
E1	$5.7 \times 10^{-15} E^{-3} A^{-2/3}$	2×10^{-13}
E2	$6.7 \times 10^{-9} E^{-5} A^{-4/3}$	1×10^{-6}
E3	$1.2 \times 10^{-2} E^{-7} A^{-2}$	8
E4	$3.4 \times 10^{4} E^{-9} A^{-8/3}$	9×10^{7}
E5	$1.3 \times 10^{11} E^{-11} A^{-10/3}$	1×10^{15}
M1	$2.2 \times 10^{-14} E^{-3}$	2×10^{-11}
M2	$2.6 \times 10^{-8} E^{-5} A^{-2/3}$	1×10^{-4}
M3	$4.9 \times 10^{-2} E^{-7} A^{-4/3}$	8×10^{2}
M4	$1.3 \times 10^{5} E^{-9} A^{-2}$	8×10^{9}
M5	$5.0 \times 10^{11} E^{-11} A^{-8/3}$	1×10^{17}

11.7.2
Heavy-Particle Radioactivity

In 1984, Rose and Jones reported the first example of a new mode of radioactive decay, decay by spontaneous emission of heavy particles ($Z \geq 6$), in the decay $^{223}\text{Ra} \rightarrow {}^{14}\text{C} + {}^{209}\text{Pb}$. The probability for this decay was 10^{-9} of the α-decay probability. Since that pioneering experiment, a number of other examples of heavy-particle radioactivity have been observed, such as ^{24}Ne and ^{28}Mg emission by nuclei with $Z \geq 88$ (allowing the daughter nucleus to be stabilized by the $Z = 82$ or $N = 126$ shell closures) (Price, 1989).

11.7.3
Spontaneous Fission

Spontaneous fission is a decay mode for the heaviest elements, increasing in importance with increasing atomic number. It is frequently a stability-limiting mode of decay for nuclei with $Z \geq 98$. The spontaneous fission half-lives change by a factor of 10^{29} in going from the longest-lived uranium isotopes ($t_{1/2} \sim 10^{19}$ years) to the shortest-lived isotopes of element 106 (∼milliseconds). Spontaneous fission is a barrier-penetration phenomenon with the nucleus "tunneling" from its ground state through a fission potential-energy barrier to the configuration of two touching fission fragments. The penetrability of this barrier depends on the parameter Z^2/A, which can be shown to be proportional to the ratio of the disruptive Coulomb force to the attractive nuclear force. Semiempirical relations exist that correlate the spontaneous fission half-life with Z^2/A of the fissioning system, although such predictions of spontaneous fission half-lives are only good to within a factor of 10^3–10^5.

In the late 1960s and early 1970s, there was considerable interest in another type of spontaneously fissioning nuclei, the spontaneously fissioning isomers. These were nuclei in excited states with relatively short half-lives ($\sim 10^{-9}$ s), much shorter than ordinary nuclei undergoing spontaneous fission, but that did not decay by γ-ray decay. We have since come to understand these nuclei as the first example of superdeformed nuclei, that is, ellipsoidal nuclei with a ratio of axes $\sim 2:1$. γ-Ray decay is inhibited by the large shape change involved in decaying back to the ground state, but spontaneous fission is enhanced.

11.8
Detection and Measurement of Radioactivity

11.8.1
Choice of Detector

Although the various types of nuclear radiation detectors are discussed, it seems useful to summarize the properties of these detectors in detecting radioactivity (Table 11.4).

The inverse of the resolving time (Table 11.4) is a rough measure of the maximum acceptable counting rate that a device can detect. For assay of α-emitting nuclides, the detector of choice is the semiconductor detector because of its superior energy resolution, allowing one to identify one nuclide in the presence of others. For detecting β^- emitters, a variety of devices is available, ranging from the inexpensive Geiger counter to the more sophisticated proportional counter. Occasionally, the superior energy resolution of a Si(Li) semiconductor detector is needed. The detection of the X-rays accompanying EC or IC can be done with either a proportional counter or a Si(Li) semiconductor detector. The detection of the two 0.511-MeV γ rays emitted when a β^+ annihilates is usually done with NaI(Tl) solid scintillation detectors. Most modern measurements of γ-rays from radioactive decay are made with Ge semiconductor radiation detectors. Liquid scintillation counting is the method of choice for assaying the low-energy β^- emitters, ^{3}H, and ^{14}C, as well as other nuclides frequently encountered in biological research (see (Knoll, 1989) or (Wang, Willis and Loveland, 1975), for details).

11.8.2
Sample Preparation

As important as the choice of a proper detector for radioactivity is, it is also important to prepare a sample properly for counting. Table 11.5 summarizes the sample preparation methods for α- and β-counting. No special sample preparation is needed for γ-ray counting or spectroscopy.

The preparation of samples for liquid scintillation counting is usually the most important part of the assay.

11.8.3
Correction Factors and Uncertainties

The results of a measurement of radioactivity frequently have to be corrected for a number of factors. The first of these is *background counts*, due to cosmic radiation, natural radioactivity in the vicinity of the detector, noise in the electronics, and so on. In some cases, where absolute activity measurements are being made or where a number of samples of differing size, shape, activity, and so on, are being assayed, a straightforward correction has to be made for the *solid angle* subtended by the sample with respect to the detector. The intrinsic *efficiency* of the detector for the radiation of interest must be evaluated.

Tab. 11.4 Summary of radiation detector characteristics.

Detector type	Energy discrimination	Detection medium	Reproducibility	Detector amplification factor	Relative electronic amplification required	Resolving time (microseconds)	relative background	Relative detection efficiency			Most commonly used sample form	Relative degree of difficulty in preparing sample
								α	β	γ		
Ion chamber	Yes	Gas	Excellent	1	Very high	Not applicable	Low	Good	Good	Poor	Gas	High[a]
Proportional detector	Yes	Gas	Good	10^2-10^4	High	1–2	Low	Good	Good	Poor	Solid	Medium[b]
Geiger-Müller detector	No	Gas	Fair	10^7	Low	100–300	Medium	Good	Good	Poor	Solid	Medium[b]
Solid scintillation detector	Yes	Solid	Good	10^6	Low	0.3 to >1	High	Fair	Fair	Very good	Solid or liquid	Medium[b] or low[c]
Semiconductor detector	Yes	Solid	Good	1	High	0.05	Low	Very good	Fair	Fair	Solid ($\alpha\beta\gamma$) Liquid (γ)	Low
Liquid scintillation detector	Yes	Liquid	Fair	10^6	Medium	0.05 to <1	Low	Very good	Very good	Fair	Solution	Low

[a] Usually involves individual combustion of samples to gaseous form.
[b] Usually involves preparation of planchet-mounted samples.

Tab. 11.5 Sample preparation required for α- and β-assays.

Original sample form	Detector	Sample activity[a]	Sample preparation	Sample preparation time
(a) Sample preparation for α-assay				
Gas	Ionization chamber	Low–high	Count directly in gaseous form by introduction into detector in suitable mixture with counting gas	Moderate
Liquid	Semiconductor	Low–high	Convert to solid thin source and assay	Moderate–long
Liquid	Liquid scintillation counter	Low–medium	Dissolve or suspend in suitable scintillator-solvent mixture and assay	Short
Solid	Semiconductor	Low–high	If sample is very thin source, count directly. If not, dissolve sample and redeposit as thin source.	Moderate–long
Solid	Liquid scintillation counter	Low–medium	Dissolve in suitable solvent and treat as liquid, or count directly as a suspension in a gel mixture	Short–moderate
Solid	Nuclear track detectors	Low	Same as semiconductor detector	Moderate–long
(b) Sample preparation for β-assay				
Gas	Geiger–Müller	Low–medium	Sample (1) trapped in suitable solution and converted to solid form, or (2) may be counted directly in gaseous form by introduction into suitable detector chamber with counting gas	Moderate

(*continued overleaf*)

Tab. 11.5 (*continued*).

Original sample form	Detector	Sample activity[a]	Sample preparation	Sample preparation time
	Proportional counter	Low–high		
Gas	Semiconductor	Low–high	Trap sample in solution and convert to thin solid source	Long
	Solid scintillation detector	Medium–high		
Gas	Liquid scintillation counter	Low–medium	Must be trapped in suitable solution and treated as liquid sample	Moderate–long
Liquid	Geiger–Müller	Low–medium	Sample (1) preferably converted to solid form for counting, or (2) may be counted directly with suitable detector if particle energy is sufficiently high	Moderate–long
	Proportional counter	Low–high		
Liquid	Semiconductor	Low–high	Same as Geiger–Müller counter	Moderate–long
	Solid scintillation detector	Medium–high		
Liquid	Liquid scintillation counter	Low–medium	May be dissolved or suspended in a suitable scintillation solvent mixture and assayed directly without pretreatment	Short
Solid	Geiger–Müller	Low–medium	May be counted directly unless low energy of particles requires pretreatment of sample.	Short
	Proportional counter	Low–high		

(*continued overleaf*)

Tab. 11.5 (*continued*).

Original sample form	Detector	Sample activity[a]	Sample preparation	Sample preparation time
Solid	Semiconductor	Low–high	Same as Geiger–Müller counter	Short
	Solid scintillation counter	Medium–high		
Solid	Liquid scintillation counter	Low–medium	(1) Should be dissolved in suitable solvent and treated as liquid sample, or (2) may be counted directly as suspension in a suitable gel mixture, or (3), in the case of ^{3}H and ^{14}C, samples can be burned to H_2O and CO_2, which can be dissolved or trapped as in (1)	Moderate–long

[a] Low $\approx <$ 1 pCi; medium $\approx$ 1μCi; high $\approx$ >1 mCi.

Loss of counts due to *absorption* of the radiation by the sample, detector windows, and so on, must be made, as well as correction for *electronic losses* due to the finite resolving time of the detector and electronics. In β^- assay, corrections must also be made for *backscattered* radiation.

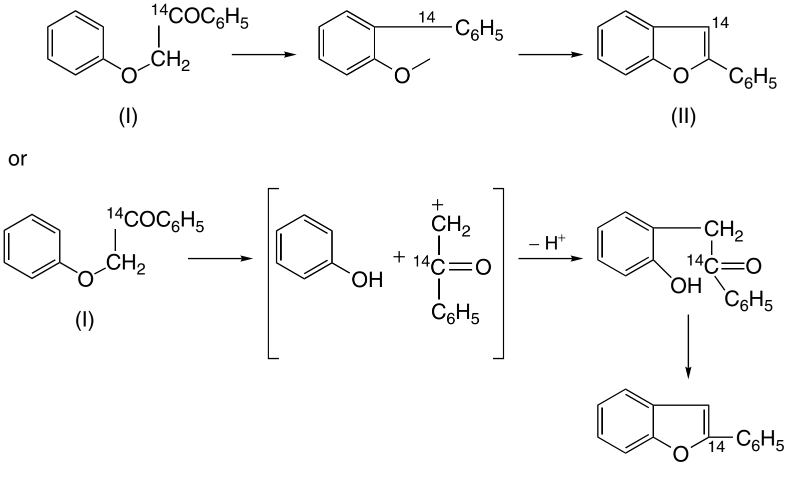
Radioactive decay is a random process and as such, consideration of the statistical nature of radioactive decay is needed to extract the maximum amount of correct information from any measurement. In Table 11.6, we summarize some pocket formulas for frequently encountered statistical quantities in radioactivity measurement (Wang, Willis and Loveland, 1975).

11.9
Applications of Radioactivity

The applications of radioactivity and radiation to medicine, industry, and science are so numerous as to defy counting. To give the reader the flavor of some of these applications, we cite the following examples.

11.9.1
Tracers

In most phenomena, the isotopes of a given element behave similarly. Thus, one can replace a stable isotope in a compound or atom by a radioactive isotope, and expect similar behavior. By using the superior sensitivity of detecting radioactivity (where one atom gives rise to one disintegration), one can measure the path, location, and so on, of a radioactive species in a system and infer the behavior of a stable species. Applications of this type have been used for decades in the study of chemical reactions. For example, consider the cyclization of 2-phenoxyacetophenone (I) to 2-phenylbenzofuran (II). Two possible mechanisms are



Note that the two mechanisms can be distinguished by the position of the labeled atom in 2-phenylbenzofuran (Wang, Willis and Loveland, 1975).

11.9.2
Thickness Gauges

In industry, one common use of radioactivity is in thickness gauges. The intensity of β^- radiation transmitted through a sheet of material can be used to measure its thickness. The number of β^- particles, I (from a radioactive source), that pass through a sheet of thickness x is given by

$$I = I_0 e^{-\mu x} \tag{29}$$

where I_0 is the β-intensity with no absorber and μ is a characteristic of the material whose thickness is being measured.

11.9.3
Nuclear Medicine

The application of radionuclides in both diagnosis and therapy is widespread. Radiotracers such as ^{123}I, ^{131}I, or ^{99}Tc^{m} can be caused to be taken up by an

Tab. 11.6 Frequently encountered quantities in radioactivity measurements.

Uncertainty in a single measurement of an activity, x	$\sigma_x = \sqrt{\text{no. of counts}} \equiv x^{1/2}$
Uncertainty in the average counting rate, $R = x/t$	$\sigma_R = \sqrt{R/t}$
Optimum ratio of time spent counting sample and background, t_{s+b}, to time spent counting background, t_b	$\frac{t_{s+b}}{t_b} = \sqrt{\frac{R_{s+b}}{R_b}}$
Distribution of intervals between counts (i.e., most probable interval is 0)	$I(t) = \lambda e^{-\lambda t}$
Figure of merit (FOM) for judging relative assays of sample with disintegration rate D using a detector with efficiency E and background B	$\text{FOM} = \frac{DE}{(DE+2B)^{1/2}}$

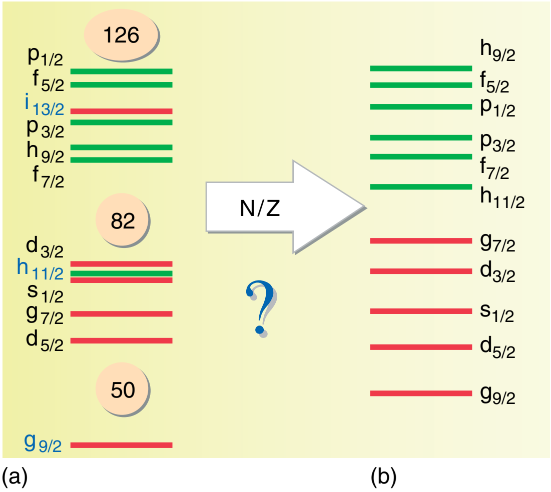


Fig. 11.7 (a) Nuclear shell structure in spherical nuclei close to the valley of stability. (b) The neutron shell structure predicted for very neutron-rich nuclei. Note the disappearance of the nuclear shell gaps due to the shallow binding potentials in the *n*-rich nuclei and the reduced spin-orbit coupling.

organ of interest. The most commonly used radionuclide is 6-hour $^{99}\mathrm{Tc}^{\mathrm{m}}$. It is used in over 10 million procedures in the U.S. each year and 20 million procedures in the world per year. $^{99}\mathrm{Tc}^{\mathrm{m}}$ is produced by the decay of $^{99}\mathrm{Mo}$. "Cows" (stock solutions) of $^{99}\mathrm{Mo}$ are "milked" to produce $^{99}\mathrm{Tc}^{\mathrm{m}}$, which will decay quickly leaving no residual radioactivity in the body. Imaging techniques can then be used to study the function of an organ or the location of a tumor. A widely used imaging technique is positron emission tomography (PET). Positron-emitting nuclides, such as $^{18}\mathrm{F}$, $^{11}\mathrm{C}$, $^{13}\mathrm{N}$, and $^{15}\mathrm{O}$, are introduced into a region to be studied. The two 0.511-MeV photons, produced when the β^+ annihilates, emerge in opposite directions and define a line passing through the point where the decay occurred. The two photons are detected by scintillation detectors placed outside the body. After observation of many decays, computer techniques are used to reconstruct a three-dimensional image of the area where the decays occurred (Krane, 1988).

11.9.4
Nuclear Science

The use of radioactivity has been a cornerstone in our studies of nuclear structure. In the past, the detection and assay of radioactivity in radiochemistry was used in studies of nuclear reactions while radioactive targets have been widely used in studies of both nuclear structure and reactions.

More recently, a great deal of attention has been paid to the use of radioactive nuclei as projectiles to induce nuclear reactions. These radioactive nuclear beams (RNBs) are also called *radioactive ion beams* (*RIBs*). The long-range plans for much of low-energy nuclear science have the use of these beams as the highest research priority.

Why the interest in RNBs? In Figure 11.1, we can see that there are about 1800 known stable and radioactive nuclei (the colored regions). But the large blank areas in Figure 11.1 correspond to some 5000 nuclei. Thus, we can say that most nuclei are unknown and unexplored at this time. As part of our ancient quest to explore the frontiers of knowledge, the study of the limits of existence of nuclei is important and RNBs are the vehicle to take us to these frontiers.

Among the nuclear structure issues that can be addressed are the location of the neutron and proton drip lines (the loci of nuclei where the Q values for neutron and proton emission become positive), and what combinations of n/p ratios are possible in bound nuclei. New neutron-rich heavy nuclei with longer half-lives are predicted to be produced with RNBs. It is anticipated that in very neutron-rich nuclei, the nuclear level spacings (shell gaps) will change leading to a washing out of the nuclear shells. (Figure 11.7)

In nuclear astrophysics, one hopes that RNBs will allow us to better understand the equation of state of neutron-rich matter such as that involved in supernovae and that we will learn more about the nuclear reactions involved in nucleosynthesis, in particular, the rapid neutron capture process (the r-process) involved in making the heavier nuclei, the rp process that makes proton-rich nuclei and the reactions that terminate the hot Carbon–Nitrogen–Oxygen (CNO) cycle.

Glossary

Atomic Number: The number of protons in the nucleus (Z).

Auger Electron: Orbital atomic electron ejected when an outer electron fills a vacancy in an inner electron shell and transfers its excess energy to another (Auger) electron, causing it to be ejected from the atom.

Even–Even Nuclide: A nucleus with an even number of neutrons and an even number of protons.

Isotopes: Nuclei with the same number of protons in the nucleus; for example, ${}^{12}_{6}\mathrm{C}$, ${}^{13}_{6}\mathrm{C}$, ${}^{14}_{6}\mathrm{C}$ are isotopes of carbon.

Mass Number: The total number of neutrons and protons in the nucleus, $A . A = N + Z$.

Neutrino/Nucleon: A neutron or a proton.

Nuclide: A specific nucleus with a given number of neutrons (N) and protons (Z).

Odd-A Nuclei: Nuclei with an odd number of particles in the nucleus; odd-A nuclei include those with even Z and odd N or odd Z and even N.

Odd–Odd Nuclei: Nuclei with both an odd number of neutrons and an odd number of protons in the nucleus.

Parity: A symmetry property of the nuclear wave function. If the signs of all the space coordinates of the wave function are changed, and the sign of the wave function does not, the system has even or $+$ parity. If the sign of the wave function does change, the system has odd or $-$ parity.

Radionuclide: A radioactive nuclide.

Secular Equilibrium: A limiting case of radioactive equilibrium in which $\lambda_1 \ll \lambda_2$ and in which the parent activity does not decrease measurably during many daughter half-lives.

Shell Closures: The complete filling of all states with a given shell (a nuclear or atomic configuration of special stability).

Strong Force (Interaction): The short-range force (interaction) responsible for nuclear binding; the attractive force between all nucleons.

INTRODUCTION

Radiochemistry was once defined as all applications of chemistry and nuclear physics to each other. It has now come to be understood more narrowly as the methods and skills, plus the underlying basic science, concerned with the production, manipulation, and application of radioactive materials. By radioactivity is meant the spontaneous transformation of an atomic nucleus, where the energy released appears as photons and fast particles (see RADIOACTIVITY). Even with the more restricted definition, however, radiochemistry touches on a wide swath of areas in science and technology.

After a few brief remarks about the history of the development of radiochemistry, we describe the areas of technology and research that are encompassed by this field as it is presently understood. An account of where radioactivity is found or how it is produced is first presented. We then draw attention to the battery of techniques that have been developed for handling and measuring radioactive matter. Finally, a few of the many applications are described.

The following areas have much in com-

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

mon with radiochemistry, but are not discussed in this article. Nuclear chemistry, once synonymous with radiochemistry, has evolved to mean principally the study and understanding of atomic nuclei, their reactions, and allied phenomena. It is now the same as nuclear physics, except that the investigators are employed in chemistry departments, and thus are more likely than physicists to utilize techniques that require chemical skills. Radiation chemistry, which began as a subfield of radiochemistry, is the study of the chemical effects of ionizing radiation on matter. The application of nuclear accelerators to chemistry has also become a well-established specialty, concerned with such matters as the study of channeling in crystals and the use of nuclear reactions for depth profiling.

1. HISTORY

The need to manipulate radioactive material chemically arose as soon as radioactivity was discovered, by Henri Becquerel, in 1896. Chemical operations were crucial, since at that time the major effort was, of necessity, concentrated on understanding the three radioactive decay chains associated with thorium and uranium. A radioactive decay chain is so called because an atom of one element makes a radioactive transformation into another element that is also radioactive, which gives rise to still another radioactive element, and so on. For thorium and uranium this phenomenon results in chains of up to 14 such transformations. Some of the scientists prominent in this earliest work were, in addition to Becquerel, William Crookes, Pierre and Marie Curie, Ernest Rutherford, and Frederick Soddy. The first synthesis of radioactive nuclides, by Irène and Frédéric Joliot-Curie, in 1933, began a tremendous expansion of the number of radioactive species demanding new chemical techniques, especially after the invention and development of nuclear accelerators in the years immediately following. Tracer applications of radioactivity, already originated by George Hevesy in 1913, were significantly extended by him when accelerator-produced activities became available. Then, the discovery of nuclear fission, by Otto Hahn and Fritz Strassmann in 1938, ushered in an entirely new era in radiochemistry, as well as in nuclear science, because it revealed a way to practical nuclear power. The subsequent wartime development of nuclear reactors and the atomic bomb vastly expanded the lexicon of techniques available for the chemical manipulation of radioactive matter and brought operations to an industrial scale. The number of practitioners burgeoned. The most noted radiochemist of that era was Glenn T. Seaborg, who, together with Edwin M. McMillan, Joseph W. Kennedy, and Arthur C. Wahl, had first synthesized and characterized plutonium. The most recent four decades have witnessed the development of powerful new instrumentation, the birth of new subdisciplines in radiochemistry, such as Mössbauer spectroscopy, and expansion into new areas such as environmental monitoring. Radiochemistry has now taken its place, along with scores of other chemical disciplines, such as x-ray crystallography or infrared spectroscopy, as a well-developed craft to be employed whenever it is the most appropriate approach to solving a problem (Rutherford *et al.*, 1930; Glasstone, 1950; Choppin and Rydberg, 1980).

2. SOURCES OF RADIOACTIVE MATERIAL

2.1 Natural

Fourteen of the 90 naturally occurring elements of the Earth's surface are radioactive because they possess isotopes having lifetimes for nuclear decay comparable to or longer than the time since the terrestrial elements were formed, about 4.6 billion years ago. Another seven, with much shorter lifetimes, belong to the decay chains of thorium or uranium, and owe their existence in nature to their membership in these chains because they possess no sufficiently long-lived isotopes to have survived since the Earth was formed. Radium is an example. In addition, sensitive measurements show that most of the elements on or near the surface of the Earth are slightly radioactive. This is caused by nuclear reactions with cosmic radiation. Also, the solar wind continuously contributes tritium, the radioactive isotope of hydrogen, to the top of the atmosphere.

2.2 Artificial

Radioactive nuclides, also called radionuclides, are usually synthesized by irradiation of the elements by neutrons, energetic ions, or photons. The most common techniques, those used in commercial production and at medical facilities, are irradiation with thermal neutrons and bombardment by hydrogen or helium ions accelerated to energies of a few million to a few tens of millions of electron volts. Thermal neutrons are available in nuclear reactors especially constructed to carry out such radioactivation, while for activation by ions small cyclotrons are customarily employed. An example of a commercial radionuclide is ^{99}Mo, which is used in medicine for diagnostic imaging. This material has a half-life, $t_{1/2}$, of 66.7 h, and is shipped packaged in kits from which its decay product ^{99m}Tc, $t_{1/2} = 6.0$ h, is readily extracted in isotonic saline solution ready for intravenous injection. Bulk radionuclides for commerce or research, such as tritium, technetium, and californium, are synthesized in nuclear power reactors or in reactors designed for such production. Radioactive nuclides for frontier research often cannot be prepared by the above methods, but must be generated in machines that feature ionic projectiles much heavier than helium, and bombarding energies much higher than simple cyclotrons can produce. Such machines include synchrocyclotrons, proton synchrotrons, and tandem Van de Graaf accelerators (see ACCELERATORS, LINEAR; PARTICLE SOURCES, ION; TARGETS FOR PARTICLE ACCELERATORS; ACCELERATORS, POTENTIAL DROP; CYCLOTRONS; SYNCHROTRONS AND STORAGE RINGS).

Radioactive isotopes are known for every element; more than 2200 radioactive nuclides with lifetimes of milliseconds or longer (including isomers) had been cataloged by 1986. For comparison, only 265 nuclides are stable (Browne *et al.*, 1986).

3. RADIOCHEMICAL TECHNOLOGY

3.1 Radionuclide Production

3.1.1 Nuclear Reactors Here, target nuclides are exposed to the reactor's neutrons, and the activated products are then recovered. The target, usually mounted in a small cylinder, is inserted into the region of high neutron flux via a long, cylindrical channel or "port." Thus, not only the target, but all of its containment structure, is subject to activation. Structural materials must therefore be chosen to minimize neutron absorption, both to avoid appreciably perturbing the neutron flux available to the target material, and to curtail unwanted radioactivity. Aluminum is often chosen, because its neutron absorption cross section is reasonably small, 0.23 b [1 b (barn) = 10^{-24} cm^2], and the ^{28}Al produced by neutron capture has a half-life of only 2.3 min. Its radioactivity therefore dies away quickly, which simplifies safe handling of the irradiated target. For short irradiations of liquids or materials incompatible with aluminum, plastic containers may be used. The plastic is made of carbon, hydrogen, nitrogen, and oxygen, which produce either nuclides that decay away rapidly, i.e., 7.2-s ^{16}N and 29-s ^{19}O, or the long-lived nuclides 12.3-y ^{3}H and 5730-y ^{14}C, radiation intensities from which build up only slowly. Irradiations must be kept short, however, to avoid destruction of the organic material. For more stringent conditions, especially for gases or liquids, sealed containers of fused silica may be used. One must then deal with 2.6-h ^{31}Si, for which waiting times of 12 h to a day for the target's radioactivity to subside (i.e., to "cool") are appropriate. Purity is important. Traces of copper in the aluminum will absorb neutrons rapidly to form 12.9-h ^{64}Cu, greatly increasing the cooling time. The boron in Pyrex glass would absorb so many neutrons, since the cross section of ^{10}B is more than 3800 b, that the flux available to the target would be seriously reduced. Aside from consideration of materials, however, targets are designed to serve a host of different applications, and so it is difficult to generalize. Some special problems are the use of extremes of low and high temperature, gas evolution and pressure buildup, self-shielding of target material when its neutron absorption cross sections are very large, degradation of fragile target materials, and investigation of activities of short lifetime.

3.1.2 Nuclear Accelerators Many radionuclides are best synthesized via the bombardment of suitable targets with energetic ions. The ion beams can either be contained within the accelerator, e.g., within the vacuum chamber of a cyclotron, or be extracted into a beam transport system, an array of evacuated tubes with focusing and guiding magnets. The latter permits much greater flexibility of target design, but higher beam intensities can be achieved with the former. As with the targets for reactors, the number of different applications defies classification, but there are some general considerations that most targets share. The target material to be exposed to the accelerator beam should be physically robust. The ion beams lose much of their energy in penetrating the targets, which must therefore survive temperature changes and stresses caused by measures taken for temperature control. In addition, the effects of severe radiation damage and of mechanical strain must be considered. Metal foils serve best. However, there are many elements for which metal foil targets are not feasible, and techniques have been developed for making stable, adherent coatings on metal foil backings. As with reactor irradiations, gaseous, and especially liquid, targets pose serious challenges. The latter become important when fast chemical processing must be carried out. (See PARTICLE SOURCES, ION; TARGETS FOR PARTICLE ACCELERATORS.)

3.2 Operations with Radionuclides

3.2.1 Measurement The most common modes of radioactive transformation are beta decay, alpha decay, deexcitation of nuclear excited states, and spontaneous fission (see RADIOACTIVITY). Beta decay may be accompanied by the creation and emission of either electrons or positrons (both are called beta particles), or by the capture of orbital electrons with concomitant emission of x rays or Auger electrons. Alpha decay is the emission of energetic ^{4}He nuclei (alpha particles). The product nucleus may be excited, and either emit photons (gamma rays) or expel orbital electrons (conversion electrons) accompanied by the resulting x rays and Auger electrons. These different kinds of emissions differ sharply in their properties, such as ease of deflection by a magnetic field, depth of penetration into matter, or density of ionization in liquids or gases, and so a variety of instruments that exploit these properties have been developed for carrying out the measurements. Some provide a relatively nondiscriminatory capability to observe the presence of radioactivity: ion chambers, proportional counters, Geiger counters. Others can resolve energy spectra of emitted particles (silicon surface barrier detectors, magnetic spectrometers), or of gamma rays and x rays [Ge(Li) detectors]. (See DETECTORS, SCINTILLATION; SPECTROMETERS, ELECTRON AND ION; SPECTROMETERS, GAMMA; PARTICLE DETECTORS, TRACKING; DETECTORS, SEMICONDUCTOR; RADIOACTIVITY.)

Amounts of radioactivity are usually measured via the intensity of emitted particles and photons. These emissions are always far more energetic than the laboratory thermal background, permitting the decays to be counted individually. Calibration of the instruments then allows the determination of absolute amounts of radioactivity, and thus of the absolute numbers of radioactive atoms via the equation

$$R = \lambda N, \quad \lambda = (\ln 2)/t_{1/2}, \qquad (1)$$

where R is the absolute radioactive decay rate of the sample in disintegrations per unit time, λ is the first-order rate constant, and N is the number of radioactive atoms. The standard units of radioactive decay rate are the *curie*, Ci, which is 3.7×10^{10} decays/s, and the *becquerel*, Bq, which is exactly one decay/s.

3.2.2 Separation and Purification

3.2.2.1 Wet-Chemistry Methods. Modern instruments obviate much of the burden once borne by chemical separations, but the latter remain indispensable. Commercial production of radionuclides and radiopharmaceuticals demands high standards of separation and purification, as do many problems in nuclear spectroscopy, assay, and tracer applications. The raw product from irradiations of targets by either neutrons or energetic ions usually contains a mixture of radioactive elements. Radiochemists process such mixtures in four steps:

1. dissolution—dissolve the target in a liquid, usually aqueous, and perhaps add some stable elements as carriers;
2. separation—carry out an appropriate

chemical separation of the desired element from the other radioactive elements;

3. purification—repeat the separation, perhaps several times, using different methods;
4. mounting—convert the isolated radioelement into the form required for the experiment.

Carrier may be added in steps **2** and **3** because when only a few atoms of an element are present, as often happens when the radioelement is different from the target material, its chemical behavior can differ from that of the bulk element (see Secs. 3.2.2.2 and 4.5.1).

Of the four steps listed above, we discuss only **2** and **3**. The main separation operations are precipitation, solvent extraction, chromatography, selective adsorption, distillation, and electrochemical deposition. Radioisotope isolation may require magnetic separation as well. The characteristics sought in these operations depend on the technical goal. For example, radioelement purity usually takes precedence over yield, or even bulk elemental purity. Sometimes carrier-free nuclides are needed, and this excludes certain manipulations. If a rapidly decaying nuclide is desired, the short half-life will dominate the separation strategy because only the fastest precipitations, solvent extractions, etc., can be used, and adaptability to automation may be demanded (see Sec. 3.2.2.3).

To exemplify the special characteristics exploited, consider precipitation. Precipitation can scrub impurities from a supernatant solution. For this, certain gelatinous or amorphous hydroxides, sulphides, or fluorides can absorb and remove many carrier-free impurity radionuclides. Conversely, the precipitate can reject radionuclide impurities. Here, one chooses a microcrystalline form for the precipitate, while holdback carriers, previously added for this purpose, are present in the supernate.

A decontamination factor $f_k(D,I)$ for purification method k can be measured for the desired element, D, and impurity element, I:

$$f_k(D,I) = (R^s_I/R^i_I)(R^i_D/R^s_D), \qquad (2)$$

where R^i_j is the initial disintegration rate of element j before the separation, and R^s_j is the corresponding disintegration rate remaining after the separation. To design a procedure to achieve a specified purity of D from I, one calculates the product of the decontamination factors for each separation step to be included.

A compilation of separation procedures, several for every element, is available as the series *Radiochemistry and Radiochemical Techniques* (see Further Reading).

3.2.2.2 Problems of Quantity. Most preparative irradiations yield very little material. For example, 1 μCi of ^{24}Na, $t_{1/2} = 15.0$ h, is equivalent to only 2.9×10^9 atoms, or 1.15×10^{-13} g of sodium. This amount of material in volumes of 1 to 100 mL of solution (10^{-11} to 10^{-14} molar) is very susceptible to surface effects. The radioactivity could be entirely adsorbed onto the vessel walls, or even onto the surface of a single dust particle. Impurities or minor constituents of a reagent, the effects of which would go unnoticed at ordinary concentrations, can become dominant, important if carrier-free nuclides are needed. Such considerations gave rise to a subfield called *tracer chemistry* (Bonner and Kahn, 1951).

At the opposite extreme, some applications require processing of kilogram amounts of radioactive nuclides, at megacurie levels of radioactivity. Mostly these involve extraction of elements, notably plutonium, from spent reactor fuel, which is fuel removed from reactors because the depletion of its fissionable component and the buildup of neutron-consuming fission products have curtailed its efficiency. Some of the special problems are self-heating of solutions, avoidance of critical assemblies of fissionable materials, radiation degradation of processing reagents, shielding of personnel from the intense radiation fields surrounding the material, and assuring that there is no escape of traces of radioactivity to contaminate the surrounding area.

The early stages of spent-fuel processing must be carried out in sealed cells behind massive radiation shielding, using mechanical manipulators. Certain processing methods, such as precipitation and filtration, are difficult to adapt to these remote operations, and so whenever possible solvent extraction and ion exchange are used instead (see NUCLEAR FUELS AND ISOTOPES; Benedict *et al.*, 1981; Choppin and Rydberg, 1980).

3.2.2.3 Fast and Ultrafast Methods. The ongoing effort to synthesize and study new nuclides makes it necessary to deal with species of ever shorter lifetimes. Although much can be learned via instrumental methods, chemical separations are often required—for example, to relieve congestion of gamma-ray lines in spectroscopic measurements, or to provide proof of elemental identity. Of the more than 2200 radioactive nuclides listed in 1986, about 800 have lifetimes of 1 min or less, and many more have been identified since then.

The problem falls naturally into three parts. First, transport the irradiated target from the reactor or accelerator. Second, carry out the chemical separation. Finally, transfer the product to the measuring instrument.

In pneumatic systems, air pressure forces a container containing the target from the site of activation into the laboratory within 0.1 to 0.2 s. The speeding target, liquid contained in a plastic capsule, smashes itself on the wall of the processing vessel, and the fast chemistry begins. In another approach, a solid target is permanently mounted at the site of irradiation, but is thin compared to the recoil range of the nuclear reaction products. Rapidly flowing gas containing aerosol particles—for example, submicroscopic clusters of sodium chloride suspended in helium—bathes the target surface. The newly produced radionuclides stop in the gas, diffuse to and are adsorbed on the aerosol particles, and then move with the flowing gas to the site of chemical separation. A heated plug of quartz wool set in the gas stream removes the activity from the aerosol and renders many of the radionuclides gaseous. Transport times in the millisecond range have been achieved. As an alternative to collection of reaction recoils, some elements will rapidly volatilize into the flowing gas from a strongly heated target.

Chemical processing may be either via a series of batches or continuous. Batch processing is appropriate for the smashed-capsule method described above. Such short times demand automated processing, and one seeks special properties of the elements under investigation that lend themselves to rapid separations in such devices. Examples are volatilization of hydrides (As, Se, Sn, Sb, Te, I, At) followed by suitable gas handling, adsorption of ions from aqueous solution onto preformed precipitates, and solvent extractions with quasisolid solvents in which the organic phase is fixed on the surfaces of a fine-grained inert carrier. These operations are combined into overall procedures, with computer control of the timing for each step. Figure 1 depicts such an apparatus. A serious drawback to batch techniques is the need to repeat the operations incessantly. Often each bombardment yields only a few events, so that hundreds to thousands of cycles must be carried out to build up adequate data.

Continuous processing offers a remedy to the disadvantages of batch processing, and also interfaces well with the gas flow transport method. Unfortunately, the necessary procedures are less well developed, because few exploitable techniques are known. Examples are thermochromatography, the use of differential sticking coefficients, and the high-speed minicentrifuge. We illustrate thermochromatography here, and an example utilizing differential sticking is presented in Sec. 4.6.4. The nuclides to be separated arrive from the accelerator adsorbed on aerosol particles and are rendered gaseous by encountering a plug of quartz wool at a high temperature in the presence of an injected reactant gas. The radioactive product gas then flows down a long tube that has a much higher temperature at the entrance than at the exit, with a smooth temperature gradient between. The radionuclides deposit on the tube walls in distinct zones, the location of the zone depending on the element and the compound in which it is bound. The tube could also be operated in vacuum or with inert carrier gases. Similarly the material of the tube's walls may be chosen to be inert or reactive. Figure 2 shows an example. For reviews, see Herrmann and Trautmann, 1982; Herrmann and Denschlag, 1969.

3.2.2.4 Methods without Separate Chemical Manipulation. Separations can sometimes be effected by ion-optic and dynamic techniques alone. One thereby gains a large advantage in speed. Most such experiments utilize an on-line isotope separator. For example, sodium isotopes can be continuously produced by GeV proton bombardment of a stack of thin thorium foils alternating with thin graphite slabs enclosed in a cylindrical tantalum foil, all maintained at 1800 °C. Recoiling sodium nuclei from fragmentation of the thorium stop in the graphite, and quickly diffuse from there into the gas phase, from

FIG. 1. Apparatus and time schedule for the automated rapid separation of zirconium from fission products. The capsule shoots in from the reactor and smashes against the opposite wall at the top. The encircled numbers on the left show the sequence in which nitrogen gas pressurizes the indicated sections. Similarly, those on the right show the pattern in which partial vacuum is applied. The numbers enclosed in squares give the sequence for manipulation of stopcocks. In the final step the zirconium is extracted into tri-*n*-butylphosphate (TBP) supported on a special powder, washed, and projected into a shielded position for gamma-ray spectroscopy (Trautmann *et al.*, 1972; reproduced by permission of Oldenbourg Verlag GmbH).

which they encounter the hot tantalum surface where they undergo surface ionization and reevaporation. Electric fields then accelerate and focus the sodium ions into a beam, which a magnetic field splits into several beams according to their mass-to-charge ratios, thus isolating the sodium isotopes. Finally, the isotopic beam of interest comes to rest in a beam stop positioned before a gamma-ray spectrometer or other instrument. In this way nuclides having lifetimes down to 0.01 s may be studied. Separation and study of a few elements other than the alkali metals can also be done with suitable target and ionizer design.

More direct techniques afford separation of nuclides, with respect to both charge and mass, as they recoil from nuclear reactions. Species with lifetimes shorter than a microsecond may thus be identified. However, the methodologies of these studies are outside our definition of radiochemistry and will not be discussed further (Hansen, 1979).

FIG. 2. (a) Diagram of a thermochromatographic system. Nitrogen gas, containing in suspension aerosol particles of KCl to which fission products are adsorbed, jets in on the left side. The analysis gas mixture indicated is nitrogen plus hydrogen chloride. (b) The distribution of separated fission product elements resulting from the use of 6% hydrogen chloride in nitrogen as the analysis gas (Hickmann *et al.*, 1980; reproduced by permission of Elsevier Science Publishers BV).

diochemical manipulations involve labeling, but for simple separation and purification of radionuclides trivial substitutions are chosen. However, labeling used in concert with tracer studies to elucidate reaction pathways can be very complex. It is an indispensable skill in research on radiopharmaceuticals. The challenges are to make the isotopic substitution cleanly in a specified position in a molecule, to achieve high specific activity, and to work with sufficient speed if the radioactivity is short lived. As a simple example, place a radiocarbon atom, C*, in either the 1- or 2- position in acetic acid. For acetic acid-2-C*,

$$\mathrm{C^{*}O_2(g)} \xrightarrow{\mathrm{H_2,catalyst}} \mathrm{C^{*}H_3OH} \xrightarrow{\mathrm{PI_3}} \mathrm{C^{*}H_3I}$$
$$\xrightarrow{\mathrm{KCN}} \mathrm{C^{*}H_3CN} \xrightarrow{\mathrm{H_2O}} \mathrm{C^{*}H_3CO_2H}.$$

For acetic acid-1-C*,

$$\mathrm{C^{*}O_2(g)} \xrightarrow{\mathrm{CH_3MgBr}} \mathrm{CH_3C^{*}O_2H}.$$

The decarbonylation of benzoylformic acid provides an example of the use of labeling:

$$C_6H_5\text{—CO—}^{14}COOH \xrightarrow{H_2SO_4} {}^{14}CO + C_6H_5\text{—COOH.}$$

Without a label, one cannot tell whether the carbon in the product carbon monoxide comes from the carbonyl group, —CO—, or from the carboxyl group, —COOH. With the labeling illustrated above, the ^{14}C tracer appears in the carbon monoxide, but not in the benzoic acid. When the carbonyl carbon is labeled instead, i.e., $C_6H_5\text{—}^{14}CO\text{—COOH}$, the ^{14}C appears in the benzoic acid but not in the carbon monoxide. This shows that the carbon monoxide arises from the carboxyl carbon (Fowler and Wolf, 1982; Murray and Williams, 1958).

High *specific activity,* i.e., a high intensity of radioactivity per unit of mass of labeled material, sometimes causes problems. The time such material can be stored can be quite limited because of radiation damage, or *radiolysis.* Some applications demand a high specific activity, however.

4. APPLICATIONS

Applications of radiochemistry appear in nearly every aspect of science and technology, but only a few examples can be mentioned here. Others are described in other articles in this Encyclopedia (see RADIOACTIVITY; MUONIC, MESONIC, AND BARYONIC ATOMS AND MOLECULES; MÖSSBAUER EFFECT; NUCLEAR FUELS AND ISOTOPES; NUCLEAR MEDICINE), or are listed in Sec. 4.7.

Most applications rely on three properties of radioactivity:

1. The disintegration rate of a sample of a given radionuclide is directly proportional to the number of its nuclei that are present.
2. The disintegration rate of a nuclide does not depend on its chemical form.
3. Chemical properties are not affected by nuclear instability.

On the other hand, violations of these properties, although slight or unusual, give rise to special applications and areas of investigation.

4.1 Analysis

The use of radioactivity is indispensable in analytical chemistry. This is now a vast area with numerous subfields, three of which are described below. The literature is voluminous. Fortunately, an exhaustive review appears biennially in a supplement to the *Journal of Analytical Chemistry* (Ehmann *et al.,* 1992; Ehmann and Vance, 1991; Tolgyessy and Kyrs, 1989).

4.1.1 Activation Analysis In this technique, radioactivity is induced in the material to be analyzed. The identity and quantities of the radionuclides produced reveal which elements are in the sample, and in what quantity. Most often the material to be analyzed is exposed to the transmuting radiation together with a sample of known composition for calibration. Usually resolved gamma and x rays, and their lifetimes, measured with Ge(Li) detectors, suffice for complete identification and determination of the elements present.

Important advantages of activation analysis are its great sensitivity, nondestructive character, applicability to nearly every element, capability for analysis of many elements simultaneously, capability for rapid results, and, with correct design, low unit cost. Disadvantages include insensitivity to chemical form, expense and awkwardness of provisions for radiation safety, and the need to choose among several techniques, since no single one is applicable to all elements (Alfassi, 1989).

Activation may be by neutrons, ion beams, or high-energy photon beams. The first two are the most useful, and are described below.

4.1.1.1 Neutrons. The usual method is to expose the sample to thermal neutrons in a nuclear reactor. This is most suitable when the induced radioactivity can be produced by neutron capture, i.e., (n,γ) reactions. However, sometimes the radioactivity needed requires energetic neutrons, via reactions such as $(n,2n)$, (n,α), or (n,p). A flux of circa 2.3-MeV neutrons is provided by the spontaneous fission of a sample of ^{252}Cf. Alternatively, a titanium tritide target can be irradiated with 100-keV deuterons from a small Cockroft–Walton accelerator to produce 14.7-MeV neutrons (see ACCELERATORS, POTENTIAL-DROP; PARTICLE SOURCES, ION; TARGETS FOR PARTICLE ACCELERATORS).

4.1.1.2 Ion Beams. Radioactivity induced by energetic charged particles allows for the analysis of elements that cannot be adequately analyzed by neutron irradiation—for example, boron, carbon, nitrogen, oxygen, and phosphorus. Small ions are most commonly used—protons, deuterons, and ^{3}He and ^{4}He nuclei—typically as beams 2 to 40 MeV in energy, produced by Van de Graaf electrostatic generators and cyclotrons (Vandecasteele, 1988; ACCELERATORS, POTENTIAL-DROP; PARTICLE SOURCES, ION; TARGETS FOR PARTICLE ACCELERATORS).

4.1.2 Isotope Dilution Let a sample that contains an unknown amount M_t of a given element be thoroughly mixed with a known, but much smaller mass, M_k, of the same element containing a radioactive isotope of specific activity S_k. Then it is only necessary to isolate a small fraction of the element from the mixture and measure its specific activity S_a to determine M_t:

$$M_t = (S_k/S_a - 1)M_k. \tag{3}$$

This technique is useful in a number of situations—for example, where quantitative isolation of the element is difficult or impossible, where other techniques would be much slower, or where the entire sample is unavailable, as in the blood of a living organism.

Recently, the most frequent application of isotope dilution analysis has been in radioimmunoassay (RIA) and related techniques. The unique specificity of antibodies and the high selectivity of RIAs has compelled widespread use of these methods to measure biologically active substances, such as drugs, enzymes, and hormones, in blood and other body fluids. (See NUCLEAR MEDICINE; Abraham, 1977.)

4.1.3 Radiometric Techniques Radioactive tracers can function as very sensitive indicators in titrations. One arranges a method where one of the reagents is radioactive and the product of the titration reaction goes into a different phase, i.e., precipitates as a solid, is extracted into a different liquid phase, is adsorbed into an ion-exchange medium, or is evolved as a gas. Depending on which reagent is radioactive, one can observe either the sharp appearance or disappearance of radioactivity in the sample to find the end point. These methods lend themselves well to automation, and also find use where end points are otherwise difficult to detect, such as when the sample is very dilute (Ehmann and Vance, 1991; Choppin and Rydberg, 1980).

4.2 Tracers

Perhaps the single most widespread and familiar use of radionuclides is as a tag to follow the behavior of some material through some process. The uses of radioactive nuclides as markers in this way are far too numerous to even classify here, and so we highlight only a few examples. The study of chemical and biological reaction paths has been one of the most productive tracer applications, and indeed the use of ^{14}C to elucidate mechanisms of organic reactions has become routine. See Sec. 3.2.3 for an example. Radioactive tracers expedite, and even make possible, the study of a great variety of diffusion and migration problems, from the diffusion of metals in metals to atmospheric and oceanic currents and movement in underground aquifers. Problems in erosion and corrosion of surfaces and studies of friction, wear, and lubrication are important in industry. Tracer applications in biochemistry are also ubiquitous, and we mention only the historic work on photosynthesis, which revolutionized our understanding of this crucial process.

4.3 Isotopic Exchange and Substitution

4.3.1 Reaction Kinetics and Mechanisms The simplest chemical equation expressing exchange is

$$AX + BX^* = AX^* + BX, \tag{4}$$

where X represents a common moiety, X^* being that moiety in which one element's isotopes serves as a radioactive label, while A and B are two other moieties. At equilibrium the specific activities of X in AX and BX are equal, and one measures the rate of approach to this equilibrium. Such measurements can be done under conditions in which equilibrium conditions already prevail among A, B, and X except for the asymmetry of the labeling. Begin with BX labeled and AX unlabeled, and at measured times thereafter recover a sample of AX for measurement. The appropriate expression for this experiment is

$$\ln(1 - f) = [-(a + b)/ab]k_r t, \tag{5}$$

where k_r is the rate for the reaction to proceed to the right, $a = [AX] + [AX^*]$, $b = [BX] + [BX^*]$, t = time elapsed since the start, and $f = a_t/a_e$, where a_t and a_e are the specific activities of X^* in AX at time t and at equilibrium. The square brackets around a chemical formula denote concentration. In this case the rate k_r is evaluated from the slope of a plot of $\ln(1 - f)$ vs t. In more complex reactions—e.g., in which species in addition to AX and BX participate, in which there is more than one reaction pathway, or in which the reaction proceeds in more than one step—the experiment and its analysis become more complicated than the simple straight-line behavior of Eq. (5).

Although the isotopic exchange technique is usually limited to reactions having half-completion times of a few minutes or longer, it has become a standard tool in chemistry. An example is the measurement, in aqueous equilibrium mixtures, of the iodide-catalyzed exchange of radioactive arsenic between arsenious and arsenic acids,

$$H_3AsO_4 + 3I^- + 2H^+ \leftrightharpoons HAsO_2 + I_3^- + 2H_2O.$$

The rate at which the reaction proceeds to the right, R, was found to be

$$R = k_r[H_3AsO_4][I^-][H^+], \tag{6}$$

with $k_r = 0.057\ L^2\ mol^{-2}\ min^{-1}$ (Friedlander *et al.*, 1981).

4.3.2 Electron-Exchange Reactions These are reactions in which a chemical species and its isotopic partner oxidize and reduce each other, in the study of which radioactive labeling has played an important role. An example is the measurement of the rates at which aqueous ferrous and ferric ions exchange labels (indicated by the asterisk),

$$Fe^{*2+} + Fe^{3+} = Fe^{*3+} + Fe^{2+},$$

as a function of the presence of other reagents, such as hydrogen or chloride ions.

The mechanisms involved in electron exchange reactions are unusually amenable to theoretical interpretation, and their study has substantially deepened our understanding of oxidation-reduction reactions. For example, such work led to the discovery that for complexed metals or their ions in aqueous solution the reactions fall into two broad classes, outer sphere and inner sphere. Outer-sphere reactions are those in which each of the two reactants retains its full complement of coordinated ligands throughout the exchange of electrons. Inner-sphere reactions are those in which the reactants share a common ligand during the transition state (Sutin, 1973).

4.3.3 Effects of Isotopic Substitution Although small, these effects are measurable under favorable circumstances. They stem from two causes, molecular symmetry and isotopic mass differences, and affect both equilibrium constants and reaction rates (*kinetic isotope effects*). Their understanding contributes insight into statistical mechanics, and into molecular potential surfaces. The changes are largest for muonium (Mu) and the isotopes of hydrogen, viz. deuterium (^2H) and tritium (^3H), and rapidly become smaller as the elements become heavier (Bigeleisen *et al.*, 1973).

4.4 Hot-Atom Chemistry

When radioactive nuclides are formed by nuclear transformations within molecules, chemical reactions may occur. The study of these processes is one branch of hot-atom chemistry. More generally, hot-atom chemistry is the study of the chemical reactions of atoms or ions that are significantly more energetic than chemical bond strengths, where the energy may be in either translation or excitation, and the energetic atoms or ions may be either free or bound in a molecule. This section focuses on the special case in which the hot atom is radioactive.

Translational energy may arise via nuclear recoil from radioactive decay or from induced nuclear reactions. Characteristic energies range from tens of MeV for fission to tenths to hundreds of eV from beta decay and gamma-ray emission. Excitation energy stems, for example, from electron capture decay and internal conversion of gamma transitions (see RADIOACTIVITY).

The chemical reaction pathways depend on whether the system is solid, liquid, or gaseous, and on other reagents that may be mixed with the target compound. For the gaseous and liquid phases, substantial efforts have been made to develop a theory of hot-atom chemistry. Since it is essentially never possible to follow the chemical events from a unique initial state to a specified final state, stochastic theories are appropriate. One example is the systematization of reactivity data as a function of translational energy and the proportion of inert material mixed with a target. The hot atom's energy is systematically reduced by a sequence of collisions until it comes into the energy range in which reaction is most likely. Much of this work is now being superseded by experiments with lasers and crossed molecular beams, although nucleogenic hot-atom studies in gases may still be the most accessible means for probing reactions at kinetic energies larger than 5 eV.

Important applications of hot-atom chemistry are provided by the Szilard–Chalmers process. For example, when liquid ethyl iodide is irradiated with thermal neutrons, the capture of a neutron by ^{127}I plus the emission of gamma rays from the resulting highly excited state of ^{128}I, at 6.83 MeV, causes the carbon–iodine bond to be broken. The bond breaks because the iodine-atom recoil energies from the gamma-ray emission are in the range of 10–200 eV while the carbon–iodine bond strength is only 2.4 eV. This phenomenon affords a convenient and efficient way to separate the radioiodine from the stable iodine compound, for when the irradiated ethyl iodide is shaken with water, most of the radioactive ^{128}I goes into the aqueous phase. Analogous systems have been developed for the production and separation of many radionuclides, often with high specific activity.

Hot-atom chemistry is also exploited for the synthesis of labeled compounds. For example, an organic reagent from which the labeled compound is to be recovered is mixed with lithium carbonate and irradiated with thermal neutrons. The reaction $^{6}\mathrm{Li}(n,{}^{3}\mathrm{H})^{4}\mathrm{He}$ produces hot tritium nuclei, which are slowed and neutralized by penetration into the surrounding reagent until the labeling reaction occurs. Sometimes a hot-atom method provides the only known route to synthesize a compound; an example is disilene, $H_2Si{=}SiH_2$, the silicon analog of ethylene.

The use or study of hot-atom effects has spread into many different fields. In solids, Mössbauer and perturbed-angular-correlation spectroscopy (see Sec. 4.6.3) have made possible studies of fast processes occurring within nanoseconds of the nuclear decay. In Earth and environmental science, hot-atom effects disrupt the equilibria of the natural radioactive series, with consequences important for geochemistry and uranium prospecting, and for the disposal of radioactive waste. In nuclear medicine, hot-atom effects on tumor cells and bulk tumors are being studied (Tominaga, 1988; Harbottle and Maddock, 1979; Maddock and Wolfgang, 1968).

4.5 Artificial Elements

The effort to discover new elements has demanded the skills of radiochemistry since early in the twentieth century. All of the recently discovered elements are radioactive, many of them short lived, for which studies made using radiochemical techniques are the principal, or even the only, source of chemical information. The transuranium elements were first studied at tracer levels, although several are now available in macroscopic or even bulk quantities. The syntheses of positronium, muonium, muonic atoms, and the like contributed a number of elements outside the traditional periodic system, and gave rise to an exotic chemistry (Ponomarev, 1973). Discussions of the chemistry of positronium and muonium are deferred to Secs. 4.6.1 and 4.6.2.

4.5.1 Observation of Chemical Properties When Only Tracer Amounts Are Available Several elements—astatine, radon, francium, and all those with atomic numbers greater than 101 (nobelium and beyond)—possess no isotopes having half-lives longer than a few days, and so studies of their chemistry must be carried out with very small samples, sometimes only a single atom at a time. Under these circumstances the experiments can be dominated in unpredictable ways by trace impurities that would not noticeably affect the same experiments done with bulk amounts. Formulation of solutions so that *p*H and oxidation-reduction couples are controlled is mandatory. Then solvent extraction, ion exchange, selective adsorption, and various forms of chromatography become reproducible. These are the same kinds of problems already mentioned in Secs. 3.2.2.2 and 3.2.2.3. A more subtle problem associated with experiments with fewer than about a hundred molecules or atoms is that chemical behavior can no longer be described straightforwardly in terms of classical thermodynamics (Guillaumont *et al.*, 1991).

4.5.2 Astatine as an Example The results of investigations on this element, the heaviest halogen, exemplify what can be learned with only tracer methods. Most work has been done with astatine's second longest-lived isotope, ^{211}At, $t_{1/2}$ = 7.2 h (for ^{210}At, $t_{1/2}$ = 8.3 h), though the short-lived ^{217}At ($t_{1/2}$ = 0.032 s) has also proved useful. Many compounds have been synthesized and characterized, both inorganic and organic, such as HAt, AtCl, CH_3At, C_6H_5At, plus aqueous species, At^-, AtO_2^-, AtO_3^-, AtO_4^-, $AtCl_2^-$. Simple molecular ions, e.g., HAt^+, CH_3At^+, $AtOH^+$, $AtCl^+$, have been identified by mass spectrometry. The compounds now known reveal that astatine, like iodine, displays formal valences from -1 to $+7$. The bond dissociation energy of HAt was measured to be 58 kcal mole^{-1} via the temperature dependence of its reaction with oxygen, and the strengths of carbon–astatine bonds in n-C_3H_7At and C_6H_5At were measured to be about 39 and 44 kcal mole^{-1}, respectively, by measurements of the rates of thermal decomposition in gaseous mixtures. In many ways astatine forms compounds and reacts as expected for a halogen heavier than iodine, but it also resembles the more metallic polonium. In aqueous solutions, oxidation potentials relating At^-, At^0, and AtO_3^- were measured by the combination of a variety of methods. By a solvent extraction method, the acid dissociation constant of aqueous astatoacetic acid, $AtCH_2COOH$, was found to be (1.5–1.8) × 10^{-4} mol L^{-1} at room temperature, ten times more acidic than acetic acid, but one-fifth as acidic as iodoacetic acid. Boiling points of many organic compounds, such as C_2H_5At (98 °C), and C_6H_5At (217 °C) have been estimated via gas chromatography and high-pressure liquid chromatography, where the apparatus was calibrated with the corresponding compounds of iodine and bromine. Organic reactions such as electrophilic substitution, diazotization, and catalyzed exchange have been successfully applied to prepare a wide range of materials. The motivation for much of this synthetic effort is that if an astatine-labeled compound can be found that concentrates in a malignant tumor, the densely ionizing and short-range alpha radiation, essentially unaccompanied by other radiation if ^{211}At is used, would be ideal for sharply localized destruction of the diseased tissue (Roessler, 1989; Kugler and Keller, 1985).

4.5.3 The Heaviest Elements The discovery and characterization of the transuranium elements demanded the development of new radiochemical techniques as novel ideas were exploited for the nuclear syntheses, and as the nuclear and chemical properties of the new elements became known. Cyclotron irradiations with deuterons and helium ions typified the earlier work, often using as targets elements that had only recently been discovered. The latter were synthesized in amounts sufficient for the experiments by prolonged irradiations in nuclear reactors, with subsequent radiochemical preparation. Further progress was achieved by bombardment of such targets with heavy ions, i.e., atoms of elements far beyond helium, such as ^{11}B, ^{12}C, and ^{22}Ne, stripped of all or most of their orbital electrons. However, two elements, einsteinium and fermium, were first identified, by radiochemical methods, among the products of thermonuclear explosions.

The elements from actinium to lawrencium were found to have properties that justify their description as actinides, i.e., the series of elements in which the 5*f* electron shell is being filled, in analogy to the lanthanides, whose properties reflect the filling of the 4*f* shell. This actinide series behavior causes a useful regularity in ion-exchange chromatography that was exploited both to help establish elemental identities and to codify some chemical properties, even when only a few atoms of a new element were present. A dramatic change of chemical properties in proceeding from lawrencium (Lr), atomic number $Z = 103$, to rutherfordium (Rf), $Z = 104$, is expected if Lr is the highest member of the actinide family while Rf belongs to the hafnium/zirconium family, Group IVb of the periodic table. That this behavior actually occurs was first established by ion-exchange chromatography, later confirmed by thermochromatography, and reconfirmed by solvent extraction experiments, even though the longest-lived isotopes of Lr and Rf then known had half-lives of only 180 and 65 s, respectively. (The elemental names used in this section are those recommended in 1995 by the Committee on Nomenclature of the American Chemical Society. However, at the time of this writing the assignments are still tentative.)

To date, hahnium, Ha ($Z = 105$) is the element of highest atomic number for which chemical studies have been carried out. For nielsbohrium, Ns ($Z = 107$), hassium, Hs ($Z = 108$), meitnerium, Mt ($Z = 109$), and elements 110 and 111, the half-lives range from 2 μs to 1 s. Identification and separation are therefore carried out by nonchemical techniques, and determination of chemical properties seems not to be possible with known methods. Recently, however, an isotope of seaborgium ($Z = 106$), ^{266}Sg, is reported to possess a half-life of 20–30 s (Seaborg, 1995; Hoffman, 1994; Seaborg and Loveland, 1990; Armbruster, 1985).

Substantial but unsuccessful efforts by several groups to synthesize and characterize still heavier elements were motivated by theoretical predictions that elements in the range $Z = 110$ to 114 might have lifetimes of many years. More recent theory predicts a region of increased stability for deformed nuclei around ^{270}Hs. The relatively long half-life of ^{266}Sg lends support to this theory (Möller and Nix, 1994).

4.6 Joint Use of Radioactivity and Chemical Properties for Probes and Techniques

4.6.1 Positron Annihilation and Positronium When a positron (antielectron) interacts with matter it undergoes a reaction with a normal electron in which both particles are annihilated, and the energy represented by their mass appears as gamma radiation. The experiments are usually performed with the energetic positrons emitted by radioactive nuclides, such as 2.6-y ^{22}Na. In condensed phases the annihilation reaction essentially does not occur, however, until the positron slows to thermal energies. Most of the gamma radiation appears as two photons of 511 keV each, emitted in opposite directions, but a small fraction appears as three photons, of total energy 1.022 MeV. The ratio of three-quantum to two-quantum annihilation depends on the chemical composition of the material in which it takes place. The explanation is that a fraction of the positrons form *positronium* atoms, analogous to hydrogen atoms with the protons replaced by positrons.

Positronium (Ps) is formed in one of two states, orthopositronium (*o*-Ps), with electron and positron spins parallel, and parapositronium (*p*-Ps), with spins opposed. Orthopositronium has an intrinsic lifetime of 10^{-7} s and decays by three-photon emission, while *p*-Ps, mean life 10^{-10} s, decays via two-photon emission. However, the interactions of *o*-Ps with matter during its relatively long lifetime usually cause its positron to decay by two-photon emission also. One such interaction is electron pickoff, where the positron annihilates with an electron other than that to which it is bound. Another is the transition from *o*-Ps to *p*-Ps induced by a magnetic field, either via an encounter with a paramagnetic species such as O_2, or by an externally imposed field. A third is chemical reactions of *o*-Ps, e.g., oxidation, reduction, or addition, which cause either an ortho-to-para conversion or the liberation of the positron from combination.

Much has been learned with relatively simple apparatus, viz., two gamma detectors tuned to 511 keV in variably delayed coincidence, arranged to view at an angle of 180° the material in which annihilation is occurring. From the lifetime of the delayed events, which at times longer than 10^{-9} s come from the converted *o*-Ps, one can measure its chemical reactivity. More complex experiments have allowed measurements of the momentum distribution of the annihilated electrons, and studies of imperfections in solids. Positron annihilation has also become an important tool for surface studies, because, for example, it is able to measure surface areas of highly convoluted materials for which other methods, such as the determination of the amount of an adsorbed gas, fail (POSITRON ANNIHILATION SPECTROSCOPY; Cheng *et al.*, 1989; Berko and Pendleton, 1980).

Positron emission tomography (PET) (see TOMOGRAPHY, POSITRON EMISSION) is an imaging technique that exploits the properties of annihilation radiation. Using PET, one has the unique capability to study ongoing metabolic processes localized within a living organism, notably the human brain. The method has spurred vigorous efforts to synthesize and test radiopharmaceuticals labeled with positron-emitting nuclides, especially 110-min ^{18}F (Kilbourn, 1990).

4.6.2 Muon Spin Rotation and Muonium Muon beams are generated by the decay of pion beams, from which process they emerge with spins aligned along the direction of motion. This polarization and the muon's long lifetime of 2.2 μs have led to the development of a unique research technique. If positively charged muons are stopped in matter, most of the polarization remains and evolves according to the properties of the sites that the muons then occupy. A muon with specified spin direction decays anisotropically into a positron, neutrino, and antineutrino, where the greatest probability is for the positron to be emitted in the direction of the spin vector, so that detection of positrons in the original forward direction of the beam allows any changes in the polarization to be monitored. Such changes are termed *muon spin rotation.* To carry out these experiments, a delayed-coincidence technique is used, where the entry of the energetic muon into the stopping region provides the start signal, and the detection of the positron is the stop. It is important to use beams of low-energy (4.1-MeV) muons, which are easily stopped. Targets can then be made small, and even gaseous, allowing a wide range of experiments. The necessary low-energy beams are obtained by tuning the beam line to collect only muons of a momentum consistent with the decay of pions at rest near the surface of the production target.

The muon possesses a substantial magnetic moment, 3.18 times that of the proton; so if a transverse magnetic field is applied to the stopping region, the residual polarization can be monitored via the precession of the muons, which appears as an oscillation superimposed on the exponential decay of the muon, as recorded by the intensity of the emitted positrons. The frequency of this oscillation depends on the imposed field plus any local field at the sites where the muons come to rest. In general, the stopping material will offer more than one kind of site and a dynamic fluctuation of the sites' field strengths, which will give rise to more than one oscillation frequency plus a gradual loss of polarization. It is the measurement of this spectrum of frequencies and their relaxations for chosen stopping materials that is the aim of most muon spin rotation experiments.

In many systems *muonium* (Mu) is formed, i.e., an atom in which an electron has become bound to the positive muon, which then serves as the nucleus. This atom behaves like a radioactive isotope of hydrogen of only 0.11 atomic mass units. Typically, in reactions such as $\mathrm{Mu} + \mathrm{Cl}_2 \rightarrow \mathrm{MuCl} + \mathrm{Cl}$ one can relate the attenuation of the muonium oscillation to the transfer of the muon from paramagnetic Mu into diamagnetic MuCl, and thereby measure the reaction rate. Rate measurements for this and similar reactions have substantially improved the theoretical understanding of isotope effects and tunneling, and thus of the reactant potential hypersurfaces. Another application is the synthesis of free radicals by muonium addition—for example, $\mathrm{C_2H_4} + \mathrm{Mu} \rightarrow \mathrm{C_2H_4Mu}\cdot$—and measurement of their muon spin rotation spectra. These data produce values of the hyperfine coupling constants, from which information about the molecular structure can be extracted.

Besides applications to chemistry (Percival, 1991; Ito, 1990), there are investigations into high-temperature superconductors (Emery, 1991; Uemura, 1991) and magnetic materials, semiconductors, metals, and other aspects of condensed matter (Cox, 1987) (see MUON SPIN ROTATION/RELAXATION/RESONANCE; MUONIC, MESONIC, AND BARYONIC ATOMS AND MOLECULES).

4.6.3 Perturbed Angular Correlations When a nucleus undergoes two successive emissions, such as two gamma-ray photons, the angle between them is not, in general, random, unless the spin of the intermediate state is less than 1. The angular distribution is described by

$$W(\theta) = \sum_n A_n P_n(\cos\theta), \quad n = 0, 2, 4, \ldots \qquad (7)$$

Here, $W(\theta)$ is the coincidence counting rate where θ is the angle between the two emissions, and $P_n(\cos\theta)$ is the Legendre polynomial of order n. Often the fit to the data is carried only as far as $n = 2$, and seldom further than $n = 4$. If the lifetime of the intermediate nuclear state is comparable to its precession rate, one can observe the effect of the environment as a time-dependent perturbation of the angular correlation:

$$W(\theta) = \sum_n A_n G_n(t) P_n(\cos\theta), \qquad (8)$$

where $G_n(t)$ is the perturbation factor. The precession can arise both from the interaction of the nuclear magnetic moment with any magnetic field present, and from the interaction of the nuclear quadrupole moment with an electric field gradient. When the transforming nuclei occupy sites in a crystal lattice, $G_n(t)$ is periodic. Thus, in delayed coincidence at a favorable angle, one sees not only the exponential decay of the intermediate state, but also a superimposed oscillation. If the transforming nuclide is the radioactive label of a molecule in liquid solution, the perturbations operate randomly as the molecule tumbles in response to thermal motion, and the factor $G_n(t)$ is not periodic, but decays exponentially at a rate characteristic of the viscosity of the solvent and the structure of the labeled molecule.

The method of perturbed angular correlations has found wide application for studies in both solids and liquids, and in the life sciences. The probe-atom concentration can be so low that the properties of host materials are not influenced. For quadrupole interactions the probes are sensitive to their local environment and thus provide information on microscopic properties. Thus, for metals, it is a powerful tool to study impurity interactions in dilute alloys, provides a spectroscopy for point-defects, and has supplied most of the experimental data on the quadrupole interaction. For semiconductors, this method is particularly sensitive to complex formation between radioactive dopant atoms and defects, and can be used to gain insight into diffusion, short-range order, segregation, ordering, and dynamic effects, where local jump motion of acceptor–donor pairs is examined via fluctuations in the strength and orientation of the electric field gradient. In liquids the method is used to study the solution chemistry of metal complexes and the rotational diffusion of macromolecules, and to measure the dissociation energies of complexes and addition compounds, and the correlation time of simultaneous equilibria for addition reactions. It is a sensitive method for measuring the electric field gradients in chemical compounds, results of which can be related to molecular structure, including protein–metal interactions. The perturbed angular correlation method complements Mössbauer spectroscopy, as it can be used for elements lacking suitable gamma-ray resonances, although it is insensitive to electric monopole interactions. It operates without solid-state and temperature restrictions, so that, for example, liquids and high-temperature phase transitions can be studied (Collins *et al.*, 1990; Bauer, 1985; Rinneberg, 1979; Adloff, 1978).

4.6.4 Matching of Nuclear Lifetimes to Chemical Rates in Tracer Studies For experiments in which a radioactive tracer is used to measure the time dependence of a chemical process, there is a regime of nuclide half-lives for which the measurement is most sensitive. We have already seen this without explicit mention in several sections above, for the reactions of Ps (Sec. 4.6.1) and muonium (Sec. 4.6.2), for perturbed angular correlations (Sec. 4.6.3), and in fast radiochemical techniques such as thermal chromatography (Sec. 3.2.2.3). In general, one has a signal rate S, and a background rate B, in counts per unit time, while there is some relationship between S and the quantity ξ that one wishes to measure. As examples ξ can be a chemical rate, a diffusion constant, or a cross section. If one wants to measure ξ to within one standard deviation $\pm\Delta\xi$, then the time T_m required to carry out the measurement is

$$T_m = \left(\frac{\xi}{\Delta\xi}\right)^2 S^{-1}\left[1 + 2\left(\frac{B}{S}\right)\left(1 + \left\{1 + \frac{S}{B}\right\}^{1/2}\right)\right] \times \left(\frac{d\,\ln\xi}{d\,\ln S}\right)^2. \qquad (9)$$

The factor $(d \ln\xi/d \ln S)^2$ quantifies the insensitivity for specifying ξ via S.

If the nuclear lifetime is too short, too much tracer will decay away before the chemical process has had time to affect it appreciably, the factor S^{-1} becomes large, and sensitivity is reduced. If the nuclear lifetime is too long, two problems may arise.

1. The chemical process is completed within a small fraction of the nuclear lifetime and therefore may have only a small effect on the nuclear counting rate, i.e., the insensitivity factor $(d \ln\xi/d \ln S)^2$ becomes large, increasing T_m.
2. The measurement may be susceptible to background contributed by the tracer itself if the experiment is of such a nature that the tracer cannot be removed after it has been used, and T_m then increases because B/S grows large.

As an example, consider the measurement of the mean time t_d that it takes radon atoms, produced by the decay of a radioactive precursor, to escape from barium stearate powder into the gas phase, where the decays of gas-phase radon atoms are counted to provide S. The value of t_d is calculated from the ratio of gas-phase to solid-phase radon atoms. Then $\xi = t_d$ and the insensitivity factor is easily shown to be $(d \ln t_d/d \ln S)^2 = ([\tau + t_d]/t_d)^2$, where $\tau = t_{1/2}/\ln 2$, $t_{1/2}$ being the radon's half-life. The resulting dependence of T_m on $t_{1/2}/t_d$, assuming that $B/S = 0$, is displayed in Fig. 3(a), and shows that for optimum sensitivity (minimum counting time) the half-life of the radon isotope chosen should be within an order of magnitude of t_d. If, for a given amount of radon radioactivity, S is too small, one needs to use an isotope of longer half-life, but if essentially all of the radioactivity is in the gas phase, an isotope of shorter half-life is needed. In this case measurement of t_d could be made over a wide range of temperature using 0.035-s ^{218}Rn, 4.0-s ^{219}Rn, and 56-s ^{220}Rn, from which it was learned that two mechanisms contribute to the emanation: diffusion, and prompt emission via nuclear recoil.

To illustrate the role of the background, consider the measurement of differential cross sections for chemically reactive scattering in crossed molecular beams, where one of the reagent molecular beams is labeled with a radioactive tracer. The experimental situation is diagrammed in Fig. 4. The beams cross each other at right angles in a vacuum chamber. A detector capable of chemical discrimination, whose position is well defined and whose aperture subtends a known small solid angle with respect to the collision zone, collects the radioactive product. The detector is movable, and product intensities, measured as counting rates of the captured product, are obtained at many positions around the collision zone until the whole scattering distribution has been mapped. Here, the background level due to the back-diffusion of small amounts of tracer limits the sensitivity. Application of Eq. (9) reveals that the most pertinent quantity is the time for the reaction product to fly from the collision zone to the detector, t_a, typically a few milliseconds. Best sensitivity, Fig. 3(b), requires that the tracer radioactive half-life $t_{1/2}$ fall in the range $0.5 \leq t_{1/2}/t_a \leq 10^2$, i.e.,

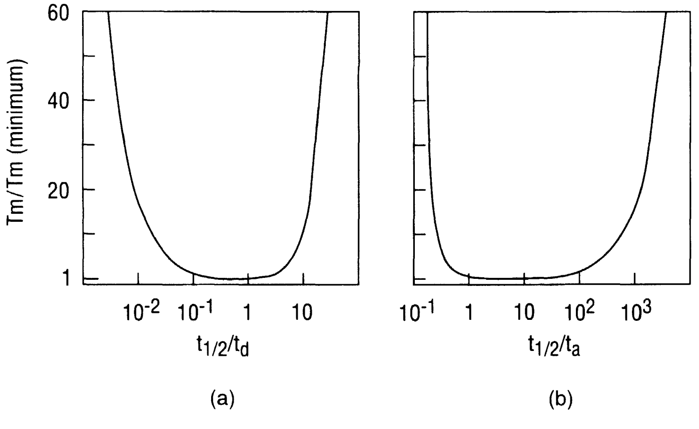

FIG. 3. The relationship between measurement sensitivity and nuclide half-life. T_m is the time required to measure to a specified precision at a given half-life, and T_m(minimum) is the minimum possible time required for that measurement. (a) Measurement of emanation rate of radon from barium stearate powder into the gas phase. (b) Measurement of differential cross sections for reactive scattering in crossed molecular beams.

from one to a few hundred milliseconds. For suitable systems, radioactive molecular beams offer much greater sensitivity than any other known method for the measurement of differential cross sections in chemically reactive scattering (Grover, 1979; Grover *et al.*, 1976).

4.7 Other Applications

Space does not permit even a brief description of the many other areas in which radiochemistry plays an important role. We list some of those not mentioned above, with suggested reading for each: nuclear reactions (Friedlander *et al.*, 1981); Earth, solar system, cosmos studies (Das *et al.*, 1989); dating (see RADIOACTIVITY; Koppenaal, 1988, 1990; Faure, 1986; Libby, 1952); biomedical applications (see NUCLEAR MEDICINE; Iyengar, 1989; Cesareo, 1988; Abraham, 1977); Mössbauer spectroscopy (see MÖSSBAUER EFFECT; Long and Grandjean, 1989; Greenwood and Gibb, 1971); nuclear use of lasers (Otten, 1989); environment (Tolgyessy and Klehr, 1987); environmental perturbation of nuclear decay rates (Dostal *et al.*, 1977); nuclear energy fuel cycle (Benedict *et al.*, 1981; Choppin and Rydberg, 1980); radioactivation applied to forensic science (Guinn, 1974); and archaeometry (Harbottle, 1990).

GLOSSARY

Atomic Number, *Z*: The number of units of positive charge on the atomic nucleus.

Barn, b: A unit of cross section, equal to 10^{-24} cm^2.

Becquerel, Bq: A unit of nuclear disintegration rate, equal to one disintegration per second.

Carrier: A weighable quantity of an element mixed with the radioactive isotope of that element.

Carrier-Free: A radioactive isotope for which no stable isotope has been added, although one or more stable isotopes might already be present as contaminants or nuclear coproducts.

Curie, Ci: A unit of nuclear disintegration rate, equal to 3.7×10^{10} disintegrations per second, or 3.7×10^{10} Bq.

Decontamination Factor: The factor by which the ratio of a given impurity nuclide to a desired nuclide is reduced in a single purification operation.

Holdback Carrier: A weighable quantity of a stable isotope(s) of a radionuclide impurity introduced to aid in radiochemical purification.

Label: A radioactive isotope chemically bonded in a defined position in a compound.

Muonium, Mu: A radioactive analog of hydrogen, whose nucleus is a positively charged muon.

Nuclear Chemistry: The study of the atomic nucleus, nuclear reactions, and related phenomena by scientists employed in chemistry departments, who often utilize techniques that require chemical skills. Synonymous with radiochemistry in earlier times.

Nuclear Mass Number: The number of nucleons in a nucleus.

Nucleon: Generic name for a proton or neutron.

Nuclide: A species of atom for which both the atomic number and nuclear mass number are specified.

On-Line Isotope Separator: A mass spectrometer operated simultaneously with the nuclear production and ionization of radionuclides.

Positronium, Ps: An atomiclike system consisting of an electron and a positron bound together. In parapositronium the electron and positron spin vectors are opposed in direction, and it decays with a mean lifetime of about 10^{-10} s, into two photons. In orthopositronium the spin vectors are parallel in direction, and it decays with a mean lifetime of about 10^{-7} s, into three photons.

Radiation Chemistry: The study of the chemical effects of ionizing radiation on matter. Once a subfield of radiochemistry.

Radioactive Decay Chain: A sequence of more than two elements connected to one another by radioactivity.

Radioimmunoassay: An isotope dilution technique for measuring small concentrations of biologically active substances, such as hormones, drugs, enzymes, and viruses, in the body fluids of living organisms.

Radiolysis: Chemical decomposition by the action of ionizing radiation, especially self-irradiation of a radioactively labeled compound.

Radionuclide: A radioactive nuclide.

Specific Activity: Radioactive disintegration rate per gram of matter, usually expressed either as Ci/g (or mg) or Bq/g (or mg).

Spent Reactor Fuel: Nuclear fuel removed from reactors, and replaced with fresh fuel, because the depletion of its fissionable component and the buildup of neutron-consuming fission products have curtailed its efficiency.

Thermochromatography: A type of gas chromatography in which thermal gradients are exploited to effect chemical separations.

Tracer: A radioactive nuclide used as an indicator, via detection of its disintegration products.

Transuranium: Describes any element with atomic number greater than 92, i.e., greater than that of uranium.

INTRODUCTION

Raman scattering refers to most types of the inelastic scattering of electromagnetic radiation, which in quantized form consists of photons. Photons entering a medium can lose energy to the sample, which is referred to as a Stokes process, or gain energy, which is an anti-Stokes process. Raman scattering is often described in terms of the excitation or de-excitation of quantized elementary excitations in the medium, such as optical phonons in condensed matter or vibrations in molecules, magnons (magnetic excitations), and single or collective excitations of electrons. Raman scattering has been used in the fundamental spectroscopic study of excitations in a wide range of solids, liquids, and gases, and it has also been used in materials characterization and for *in situ* diagnostics during processing.

One exception to the range of inelastic scattering phenomena called Raman scattering is scattering from density changes due to pressure fluctuations, which is instead called Brillouin scattering. These fluctuations propagate as sound waves, or acoustic phonons in quantized form. A broader definition of Brillouin scattering includes the scattering of any excitation with a linear dispersion relation, such as acoustic phonons and plasmons, and any other very low-frequency excitation $<5\ \mathrm{cm}^{-1}$. Raman scattering is also to be distinguished from Rayleigh scattering, which is quasielastic scattering by nonpropagating density changes caused by entropy fluctuations. In Rayleigh scattering, the scattered light has the same frequency as the incident light but can have a broader spectral width.

Raman scattering is a coherent two-photon process in which the photon scatters only while the incident photon is present. It is formally different from the sequential absorption of a photon followed by fluorescence, though near resonance both types of processes can be important. Spontaneous Raman scattering, which is the version most commonly used in the study of materials and molecules, is very weak and only $\sim 10^{-12}$ of the incident photons are scattered and detected. Historically, it was first predicted by

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

Smekal (1923) and was first demonstrated by Raman (1928) and by Landsberg and Mandelstam (1928). Several stimulated versions of Raman processes have been studied, including stimulated Raman scattering where the scattered beam is strong.

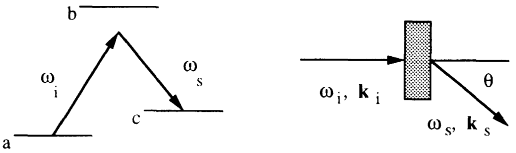
1. FEATURES OF RAMAN SCATTERING

1.1 Kinematics

The scattered frequency is $\omega_s = \omega_i \pm \omega_x$ for Stokes $(-)$ and anti-Stokes $(+)$ scattering, where ω_i and ω_x are the frequency of the incident light and the quantized excitation of the material (Fig. 1). With the conservation of momentum q, the scattered wave vector is $q_x = 2q_i \sin(\theta/2)$ when $\omega_i \gg \omega_x$, where θ is the scattering angle. In solids, when $\omega_x(q_x) = a_1 q_x$, as for acoustic phonons, ω_s is sensitive to the observed scattering angle. For excitations where $\omega_x(q_x) = \omega_x(0) + a_2 q_x^2$, as for optical phonons and plasmons, the frequency of scattered light is fairly independent of θ for near-zone-center scattering. Only near-zone-center (Γ) excitations, $q_x \sim 0$, contribute to first-order scattering in solids, where the incident photon interacts with only one excitation, because the change in photon momentum, $\sim 10^5$ cm^{-1}, is very small compared with the dimension of the Brillouin zone, $\sim 10^8$ cm^{-1}.

1.2 Dynamics of Scattering

The response of a material in the presence of an electric field E with frequency ω_i is described by the induced dipole moment $\mu = \alpha E$ (in molecules), where α is the electric polarizability, or the electric polarization $P = \epsilon_0 \chi E$ (in solids), where χ is the electric susceptibility. The total scattering cross section is $\sigma = (4\pi/3)\omega_i^4 \alpha^2/(4\pi\epsilon_0)^2 c^4$. Here χ (or α) can depend on a material excitation, such as a vibration, which is described in terms of a characteristic coordinate u that oscillates with frequency ω_x. To first order, χ can be expanded as $\chi(u) = \chi(u = 0) + (d\chi/du)u$. Classically, Raman scattering occurs because the polarization P (or μ) oscillates and therefore radiates at $\omega_i \pm \omega_x$. A vibrational transition in a molecule is Raman allowed if the polarizability varies with the normal coordinate of the vibrational mode (u), while it is allowed in absorption (IR or infrared active) if the dipole moment varies with the normal coordinate.



(a) (b)

FIG. 1. (a) Energy levels and (b) scattering geometry in spontaneous Raman scattering from state *a* to *c*, through intermediate state *b*. θ is the scattering angle.

In the macroscopic description of Raman scattering, the fluctuating components of the polarization lead to scattering. The spectral differential cross section for scattering photons from frequency ω_i to ω_s is (Hayes and Loudon, 1978)

$$\frac{d^2\sigma}{d\Omega\, d\omega_s} = A \frac{\omega_i \omega_s^3}{c^4} vV \frac{\eta_s}{\eta_i} |\mathbf{e}_s \cdot \chi' \cdot \mathbf{e}_i|^2 \langle u(\mathbf{q}) u^*(\mathbf{q}) \rangle_{\omega_s}, \tag{1}$$

where v is the scattering volume, V is the sample volume, η is the index of refraction, $\chi' = d\chi/du$ is the susceptibility derivative tensor, $\mathbf{e}_s$ and $\mathbf{e}_i$ are the polarization vectors of the scattered and incident beams, respectively, and $A = 1/16\pi^2$. The last term is the power spectrum of the fluctuations of the characteristic coordinate. It can be expressed in terms of quantum-mechanical second-quantization operators and then can be evaluated by use of the fluctuation-dissipation theorem. Since $\omega_s \sim \omega_i$, the frequency dependence for Raman scattering is similar to the $\sim \omega_i^4$ dependence for elastic scattering far below resonance. The rate of scattering photons is $(I_i/\hbar\omega_i) d^2\sigma/d\Omega\, d\omega_s$ where I_i is the intensity of the incident beam. A scattering efficiency S can also be defined as $S = \sigma/V$.

For phonons in solids, $\langle uu^* \rangle = (\hbar/2N\omega_p)[n(\omega_p) + 1]g(\omega_s)$ for Stokes scattering, where n is the phonon-occupation number, $1/[\exp(\hbar\omega_p/kT) - 1]$ in thermal equilibrium, ω_p is the phonon frequency, $g(\omega_s)$ is the normalized line shape whose linewidth is $\sim 1/$(phonon lifetime), and N is the number of scatterers in the volume. Using $\langle uu^* \rangle$ in Eq.

(1), the resulting V/N factor is the intensive parameter, the volume per species. The expression for anti-Stokes scattering is similar, with the corresponding anti-Stokes values used for ω_s, η, and χ in Eq. (1) and the bracket in the expression for $\langle uu^*\rangle$ replaced by $n(\omega_p)$. The final form of Eq. (1) is similar for other elementary excitations, which also have an $n + 1$ (n) factor for Stokes (anti-Stokes) scattering.

The microscopic description of Raman scattering uses quantum-mechanical time-dependent perturbation theory (Hayes and Loudon, 1978; Cardona, 1982). Photon interactions are mediated by either the $(e/mc)\mathbf{A}\cdot\mathbf{p}$ or the $(e^2/2mc^2)A^2$ term in the $(\mathbf{p} + e\mathbf{A}/c)\cdot(\mathbf{p} + e\mathbf{A}/c)/2m$ term in the Hamiltonian, where $\mathbf{p}$ is the electron momentum operator and $\mathbf{A}$ is the vector potential. The former term is important whenever interband transitions are important, as with phonons and magnons in solids and vibrations in molecules, while the latter term contributes when intraband transitions are important, as in the scattering of free electrons in vacuum. Sometimes both terms contribute, as in the scattering of free electrons in semiconductors. In molecules, $-e\mathbf{r}\cdot\mathbf{E}$, which is the same as $-\boldsymbol{\mu}\cdot\mathbf{E}$, is often used instead of $(e/mc)\mathbf{A}\cdot\mathbf{p}$, where $\mathbf{r}$ is the electron position operator.

Raman transitions from state 1, with irreducible representation Γ_1 of the space group of the crystal or molecule, to state 2 with representation Γ_2 are symmetry allowed if $\Gamma_2^* \times \Gamma_\chi \times \Gamma_1$ contains the totally symmetric representation. The term Γ_χ is the representation generated by the components of the second-rank polarization tensor χ. Consequently, Raman spectra are very sensitive to the polarization of the incident and detected scattered beams. The scattering arrangement is represented by $\mathbf{a}(\mathbf{b},\mathbf{c})\mathbf{d}$, where $\mathbf{a}$ and $\mathbf{d}$ are the directions of the incident and scattered beams, respectively, and $\mathbf{b}$ and $\mathbf{c}$ are their respective electric field polarizations. In solids, these can be related to the crystalline axes when the symmetry is at least orthorhombic. In backscattering geometry, $\mathbf{d} = \bar{\mathbf{a}}$. In a "polarized" spectrum $\mathbf{c} \parallel \mathbf{b}$, while in a "depolarized" spectrum $\mathbf{c} \perp \mathbf{b}$.

The depolarization ratio D is defined as the ratio of depolarized to polarized scattering intensities, and can indicate the symmetry and therefore the physical processes that induce the scattering. This ratio is a function of scattering angle θ and can be analyzed for incident polarization either parallel or normal to the scattering plane, which is defined by the wave vectors of the incident and scattered light. For randomly oriented species, such as the grains in polycrystalline material, molecules in most liquids, and rotating molecules in a gas, the polarization dependence must be averaged over angle. If the polarizability tensor of a given species is symmetric, then it can be diagonalized, with diagonal elements α_{xx}, α_{yy}, α_{zz}. This can be represented as a sum of two diagonal tensors, one isotropic with magnitude $a = (\alpha_{xx} + \alpha_{yy} + \alpha_{zz})/3$ and the other traceless that depends on the anisotropy factor b (or γ). When $\alpha_{xx} = \alpha_{yy} = \alpha_\perp$ and $\alpha_{zz} = \alpha_\parallel$, $a = (\alpha_\parallel + 2\alpha_\perp)/3$ and $b = |\alpha_\parallel - \alpha_\perp|$. After rotational averaging, $D(\theta = 90°) = 3b^2/(45a^2 + 4b^2) \leq \frac{3}{4}$ for incident light that is linearly polarized normal to the scattering plane, which gives an upper limit that is valid for elastic and inelastic scattering, and it is 1 for light polarized in the scattering plane. If the incident light is nonpolarized, $D(\theta = 90°) = 6b^2/(45a^2 + 7b^2) \leq \frac{6}{7}$. These upper boundaries do not apply for antisymmetric α, as in magnetic scattering. Depolarization ratios from randomly oriented species for different incident and scattered polarizations have been tabulated (Hirschfeld, 1973; Long, 1977).

The $|\mathbf{e}_s\cdot\chi'\cdot\mathbf{e}_i|^2$ term in Eq. (1) describes the polarization and angular patterns in Raman scattering for vibrational scattering and for electronic scattering that is mediated by changes in charge density. It is symmetric with respect to the exchange of the incident and scattered polarizations. In Raman scattering in magnetic materials and in electronic Raman scattering that involves spin effects or magnetic fields, the polarization term is $|(\mathbf{e}_i \times \mathbf{e}_s)\cdot\mathbf{e}_r|^2$, where $\mathbf{e}_r$ is a reference direction, such as that of the magnetic field. Raman scattering is then antisymmetric with respect to exchange of the incident and scattered polarizations.

Raman-scattering processes in solids can be divided into three areas: vibrational Raman scattering, which involves optical phonons (Sec. 3); magnetic scattering (Sec. 4), which involves collective processes specific to magnetic materials; and electronic scattering (Sec. 5), which involves transitions of free or bound electrons. In gases and liquids, vibrational Raman scattering involves excitation of molecular vibrations (Sec. 6). Additional features due to pure rotational Raman scattering appear in gases (Sec. 6).

In many materials, the inelastic light-scattering spectrum has peaks that can be assigned to excitations in either one of two or in any of the three categories. However, this division into vibrational, magnetic, and electronic scattering is not always precise. The scattering processes of these different excitations can interfere. Also, two different modes of excitation can directly couple, with either one mode or both modes having an intrinsic Raman cross section. For example, in some paramagnetic materials electron spin coupling with the lattice leads to sidebands on the optical phonon peaks (Ramdas and Rodrigues, 1988, 1991). In *p*-type Si, interference between vibrational and electronic scattering produces highly perturbed, non-Lorentzian Raman peaks (Cerdeira *et al.*, 1973). In terbium vanadate, complex Brillouin profiles are seen because the lower electronic levels of Tb^{3+} couple to acoustic phonons that propagate in specific directions (Harley *et al.*, 1980). Both excitations have scattering cross sections in each of these cases. In some solids, scattering of a mode is not allowed, but is still seen because of mode coupling. Vibrational Raman scattering is expected to be forbidden by symmetry in europium chalcogenides. It is seen only because of spin–phonon coupling (Guntherodt and Zeyher, 1984).

1.3 Nonlinear Raman Processes

Most Raman spectroscopic studies actually involve spontaneous Raman scattering, which has been discussed above. cw lasers are used, the scattered fields are weak, and in absorbing solids the intensity of the incident laser I_i is limited by laser heating. By using pulsed lasers, the incident intensity can be made much larger with minimal heating, and with these higher I_i nonlinear optical effects can become important, which can be classified as coherent and hyper Raman processes (Nibler and Knighten, 1979; Harvey, 1981; Druet and Taran, 1981; Vogt, 1982; Nibler and Yang, 1987; Levenson and Kano, 1988).

If three lasers are incident on a material, with electric fields E oscillating at frequencies ω_1, ω_2, and ω_3, the electric polarization can be written as

$$P_i(\omega) = \epsilon_0[\chi^{(1)}_{ij}E_j(\omega_1) + \chi^{(2)}_{ijk}E_j(\omega_1)E_k(\omega_2) + \chi^{(3)}_{ijkl}E_j(\omega_1)E_k(\omega_2)E_l(\omega_3) + \cdots]. \tag{2}$$

(with summation over repeated indices). The first term describes linear optical processes, while the higher-order terms detail nonlinear optical effects that are important only at strong fields. The second term describes processes such as second-harmonic generation and the electro-optic effect, and the third term describes several coherent Raman processes, which produce radiation at $\omega_s = \omega = \omega_1 \pm \omega_2 \pm \omega_3$ (Fig. 2), among other processes.

With one laser incident with frequency $\omega_1 = \omega_3$ $(= \omega_i)$, the $\chi^{(3)}$ term describes stimulated Raman scattering (SRS) at frequency $\omega = \omega_1 - \omega_3 + \omega_2 = \omega_2$ $(= \omega_s)$ [Fig. 2(a)]. There is laser gain at $\omega = \omega_1 - \omega_x$, with a gain coefficient proportional to the scattering cross section for spontaneous Raman scattering $d\sigma/d\Omega$ (Yariv, 1989). For sufficiently high gain, the scattered intensity I_s increases exponentially and there is lasing at ω. In vibrational Raman scattering, a coherent vibrational field oscillating at $\omega_x = \omega_p$ is created during SRS. This field can couple with ω_1 and ω_2 to create a series of higher-order Stokes and anti-Stokes laser lines at $\omega = \omega_1 \pm m\omega_p$, where m is an integer (Eimerl *et al.*, 1981). With the quantization of the electromagnetic fields, SRS can also be easily understood by time-dependent perturbation theory. The Raman-scattering rate is proportional to $n_s + 1$, where n_s is the number of photons at the scattered frequency ω_s per mode. The "1" term describes spontaneous Raman scattering, while the "n_s" term describes stimulated Raman scattering. Whenever two lasers are used to populate a state, say from state a to c through intermediate state b (as in Fig. 1) with lasers at frequencies ω_1 and ω_2, both sequential absorption (of ω_1 inducing $a \rightarrow b$) and stimulated emission (at ω_2 inducing $b \rightarrow c$), and the one-step, stimulated Raman process (directly $a \rightarrow c$) must be considered (Feld and Javan, 1969). Though stimulated Raman scattering is usually used to create new pulsed laser lines, it can also be used for spectroscopy by measuring the Raman amplification of a tunable

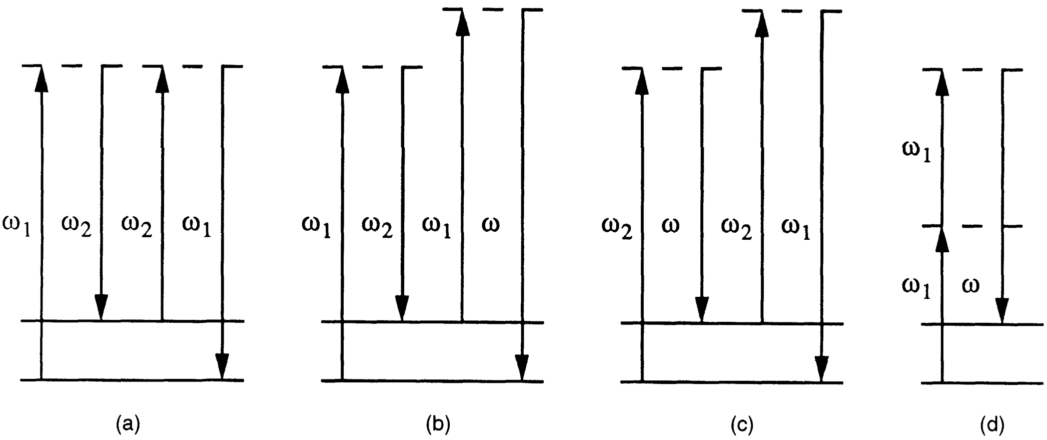


FIG. 2. Energy-level diagrams for (a) stimulated Raman scattering (SRS), $\omega_2 = \omega_1 - \omega_x$; (b) coherent anti-Stokes Raman scattering (CARS), $\omega = 2\omega_1 - \omega_2$; (c) coherent Stokes Raman scattering (CSRS), $\omega = 2\omega_2 - \omega_1$; and (d) hyper-Raman scattering (HRS), $\omega = 2\omega_1 - \omega_x$. ω_x corresponds to the excitation energy between the lowest two levels shown here.

laser in a medium that is irradiated by a strong, fixed-wavelength pump laser. The ($\omega = \omega_1 - \omega_2 + \omega_3$)-type term in Fig. 2(a) is also responsible for Raman-induced Kerr-effect spectroscopy (RIKES).

In coherent anti-Stokes Raman scattering (CARS), two pulsed laser beams at ω_1 and ω_2 ($\omega_1 > \omega_2$) intersect in a material to produce coherent light at $\omega = 2\omega_1 - \omega_2$ [Fig. 2(b)]. Usually at least one of these two lasers is tunable. CARS can be viewed as the scattering of ω_1 from the coherent oscillation produced by $\omega_1 - \omega_2 \sim \omega_x$. Spectroscopy is performed by tuning one of the incident lasers and by measuring its wavelength at resonance ($\omega_1 - \omega_2 \sim \omega_x$). This is quite different from spontaneous Raman spectroscopy where the wavelength of the weak scattered light is measured. In CARS, the interference of resonant and constant, nonresonant terms often produces an antiresonant line shape, instead of the typical Lorentzian-type resonant line shape seen in spontaneous Raman scattering. An analogous process, coherent Stokes Raman scattering (CSRS), involves the processes shown in Fig. 2(c).

Phase matching is necessary for efficient conversion in nonlinear optics. It is automatically satisfied in SRS and RIKES, but must be met by experimentally matching wave vectors of the incident laser beams in CARS and CSRS.

Just as spontaneous Raman scattering is induced by the dependence of $\chi^{(1)}$ on material excitation u, the higher-order susceptibility terms $\chi^{(2)}$ and $\chi^{(3)}$ can also depend on u, and can be expanded similarly. For example, $\chi^{(2)}(u) = \chi^{(2)}(u = 0) + (d\chi^{(2)}/du)u$. The $(d\chi^{(2)}/du)u$ term causes inelastic scattering at frequencies such as $2\omega_1 - \omega_x$ [Fig. 2(d)]. Such processes are known as spontaneous hyper-Raman scattering. It is extremely weak, even with high incident laser intensities, except when resonantly enhanced. Just as $\chi^{(1)}$ has the molecular polarizability analog α, which leads to $d\alpha/du$ terms, $\chi^{(2)}$ and $\chi^{(3)}$ have the molecular polarizability analogs β and γ, respectively, which lead to $d\beta/du$ and $d\gamma/du$ terms.

Hyper-Raman scattering has different symmetry constraints than does Raman scattering. Generally, infrared-active modes are hyper-Raman active, and so first-order hyper-Raman scattering can be allowed while first-order Raman scattering is forbidden. "Silent" modes that are both Raman and infrared forbidden can also be seen by hyper-Raman scattering. There are also stimulated versions of hyper-Raman scattering.

2. INSTRUMENTATION

Raman spectroscopy requires a light source, optics to deliver the light to the sample, optics to collect the scattered light, an instrument to provide spectral dispersion of the scattered light and to remove stray light, and a photon detector. Because the spontaneous scattering cross section is small, high-intensity light sources are essential in Raman scattering. Historically, Raman spectroscopy became relatively simple only after the development of lasers. Most studies of spontaneous Raman scattering use cw lasers such as argon-ion (4880, 5145 Å), krypton-ion (6471 Å), or dye lasers. Lasers with ~ns, ~ps, or ~multi-fs-long pulses, such as excimer lasers, Nd/YAG lasers, and pulsed and mode-locked dye lasers, are needed for nonlinear Raman scattering and time-resolved Raman spectroscopy. Time-resolved scattering is used when there is interference by high levels of background cw light and for the dynamical study of nonequilibrium distributions of phonons and carriers (Kash and Tsang, 1991). For adequate spectral resolution, the linewidth of the laser must be narrower than the linewidth of the elementary excitation, which for phonons is $\sim 2\ \mathrm{cm}^{-1}$. Tunable lasers, such as dye and Ti sapphire lasers, are useful in the study of resonance Raman scattering.

In Raman analysis of solids, the laser is often focused to a circular spot on the sample. In Raman microprobe scattering, the spot size can approach the far-field diffraction limit for visible light, ~0.5 μm. In absorbing samples, significant laser heating must be avoided. With cw laser irradiation, the temperature rise at the surface of a very strongly absorbing sample is $\Delta T = P_i/(2\sqrt{\pi}Kw)$, where P_i is the laser power transmitted into the sample, K is the thermal conductivity, and w is the laser spot size (half-width at $1/e$ intensity); this consideration puts a practical upper limit on P_i. Because the scattered light is imaged onto the slit of a spectrometer, the power of the incident laser can be increased, with no increase in heating, by focusing the laser to a line with a cylindrical lens, rather than to a circular spot.

When studying optically thick samples or thin films, experiments are usually performed in a backscattering configuration, with a scattering angle $\theta \sim 180°$. The effective scattering efficiency S^* is then

$$S^* = S\,\frac{1 - \exp[-(S + \alpha_i + \alpha_s)L]}{S + \alpha_i + \alpha_s} \times (1 - R_i)(1 - R_s), \tag{3}$$

where α_j and R_j are the absorption coefficient and (intensity) reflectance at ω_j ($j = i,s$). When $S \ll \alpha_i,\alpha_s$, the effective depth of the Raman probe is $\sim 1/(\alpha_i + \alpha_s)$, and the scattering volume v in Eq. (1) is $\sim w^2/(\alpha_i + \alpha_s)$. With transparent media, alternative geometries include side scattering ($\theta \sim 90°$) and in-line scattering ($\theta \sim 0°$), and the laser may not be focused at all. In any case, light is collected by small-f-number optics and directed, sometimes by optical fibers, to a spectrometer that must disperse the scattered light and reject any collected light from the incident laser.

It is common to collect scattered light at $\theta \sim 90°$ when studying gases and liquids. In Raman scattering of gases in cells that are external to the laser cavity, the exciting laser beam is often focused and a collecting mirror is put on the side opposite the collecting lens to collect also light scattered to $\theta \sim -90°$. To increase the incident laser intensity, either a multipass arrangement is used or the scattering cell is placed inside the laser cavity (Weber, 1979).

Triple-stage spectrometers, which have a subtractive double stage for rejecting the laser line followed by a single stage for dispersion, and double monochromators, with two additive stages, are commonly used for dispersion. An alternative approach is to use a single-stage spectrometer that is preceded by a narrow line filter to reject the laser line. This approach can have the relative advantage of greater throughput because of fewer diffraction gratings and mirrors. Improvements in laser filters, notably holographic notch filters, have lessened one earlier disadvantage of this approach, the high losses for light scattered within $\sim 200\ \mathrm{cm}^{-1}$ of the laser line; however, the lack of tunability of these filters is still a drawback. While monochromators can be used to examine line shifts as small as $\sim 5\ \mathrm{cm}^{-1}$, scanning Fabry–Pérot interferometers are needed to resolve the smaller line shifts seen in Brillouin scattering, sometimes with multipassing to reduce the level of stray light.

The classic mode of photon detection in spontaneous Raman scattering is to scan the spectrometer and to count photons with a photomultiplier. Recently, parallel detection of the dispersed radiation by multichannel detectors, such as intensity-enhanced photodiode arrays, imaging photomultipliers (which are also called mepsicrons), and, notably, charge-coupled-device (CCD) detectors (see CHARGE-COUPLED DEVICES) have greatly improved the signal-to-noise ratio in Raman spectra (Chang and Long, 1982; Tsang, 1989).

Spontaneous Raman spectra can be improved by increasing the flux of incident photons, improving photon collection, and using better detectors. Since the Raman cross section varies as ω^4, the use of shorter wavelengths improves signal strength, as does tuning ω_i to a resonance in the cross section (Cardona, 1982), the use of interference effects (Connell *et al.*, 1980), and the use of surface-enhanced Raman scattering on roughened metal surfaces (SERS) (Otto, 1984; Campion, 1985; Jha, 1985). SERS can increase Raman signals by $\sim 10^4$–10^6 and is caused by electromagnetic resonances and by other effects related to chemisorption. Because Raman processes are not surface selective, the measurement of monolayers (Campion, 1985) and very thin films (Tsang, 1989) on surfaces requires these signal-enhancing methods, and other techniques as well, such as the subtraction of the Raman signal from the substrate.

Because absolute measurement of the Raman-scattering cross sections is difficult, such measurements can be made by comparison with a standard, such as diamond or Si for solids (Cardona, 1982). The differential scattering efficiency $dS/d\Omega$ of diamond (at 2.41 eV, 1333 cm^{-1} Raman shift) and Si (at 1.9 eV, 521 cm^{-1} shift) are (6.5 ± 0.8) and $(168 \pm 50) \times (10^{-5}/\text{sr m})$, respectively. For gases, Q-band vibrational Raman scattering in gas-phase N_2 (2331 cm^{-1}) is the standard, with $d\sigma/d\Omega = (5.05 \pm 0.1) \times 10^{-48}(\tilde{\nu} - 2331\ \text{cm}^{-1})^4\ \text{cm}^6/\text{sr}$ (Schrotter and Klockner, 1979). Here $\tilde{\nu}$ is the laser wave number (in the visible and in the ultraviolet to 330 nm) expressed in cm^{-1}. For liquids, vibrational scattering in CCl_4 ($\tilde{\nu}_1$ at 459 cm^{-1}), C_6H_6 (992 cm^{-1}), and cyclohexane (C_6H_{12}) (802 cm^{-1}) are often used as standards with $(d\sigma/d\Omega)(\tilde{\nu} - \tilde{\nu}_m)^{-4}$ equal to 140, 225, and 70 respectively in units of $10^{-48}\ \text{cm}^6/\text{sr}$ (Schrotter and Klockner, 1979). The term $\tilde{\nu}_m$ is the cited vibrational quantum energy expressed in cm^{-1}.

Since Raman scattering is relatively inefficient, background photoluminescence (or fluorescence) must be kept to a minimum. Photoluminescence is not a concern when the photon energy is less than the fundamental gap E_0, and in materials that do not fluoresce at all, such as indirect semiconductors. Though scattering near the fundamental gap E_0 is inadvisable in direct semiconductors, Raman scattering can be resonantly enhanced at the associated spin–orbit-split gap $E_0 + \Delta$ or at larger gaps, such as E_1, without a strong photoluminescence background. In some materials, particularly organic compounds, the fluorescence intensity tends to increase with ω_i, thus rendering useless the ω^4 improvement in the Raman signal. Near-infrared light, such as that from Nd/YAG lasers (1.06 μm), is used to avoid fluorescence. Because optical detectors in the near infrared perform poorly, especially when employed with single-channel detection, an alternative method has developed, Fourier-transform Raman spectroscopy (Hendra *et al.*, 1991). In Fourier transform (FT) Raman, spectral dispersion and parallel detection are accomplished by using a scanning Michelson interferometer.

3. VIBRATIONAL RAMAN SCATTERING IN SOLIDS

3.1 Crystals

First-order vibrational Raman scattering is induced by the oscillation of the polarizability at vibrational-mode frequencies (Pinczuk and Burstein, 1975; Hayes and Loudon, 1978; Cardona, 1982). In nonlinear molecules with m atoms, there are $3m - 6$ vibrational modes ($3m - 5$ for linear molecules). In crystals with m atoms per primitive cell, there are $3m$ modes or branches, the three acoustic modes that can be observed in Brillouin scattering and $3m - 3$ optic modes. For relatively simple crystal structures, the vibration of the mode is parallel to the direction of propagation in $m - 1$ of these optic-mode branches [the longitudinal optical (LO) phonons], while in the other $2m - 2$ optical branches the vibration is transverse (TO). Symmetry determines whether these modes are Raman active (i.e., have a nonzero cross section for first-order scattering), infrared (IR) active (i.e., have a nonzero infrared-absorption cross section), Raman and IR active, or both Raman and IR inactive (silent). In centrosymmetric crystals and molecules, modes can be only Raman active, IR active, or silent. This is a consequence of the definite parity of vibrations in a centrosymmetric medium with respect to inversion. The matrix element of either the polarizability, which induces Raman scattering and transforms as *xx*, *xy*, *xz*, etc. (second-rank tensor), or the dipole moment, which induces IR absorption and transforms as *x*, *y*, or *z* (a vector), must vanish between vibrational states. In general, the polarization properties of Raman scattering and the number of modes that are observed can be used to determine the crystal symmetry.

The frequency of each branch $\omega_{p,i}$ is a function of wave vector $\mathbf{q}$ in the first Brillouin zone and is given by dispersion curves (see PHONONS IN CRYSTAL LATTICES). Because of momentum conservation, only phonons with $q < 10^5$ cm^{-1}, near zone center, can participate in one-phonon Raman scattering. The entire Brillouin zone can be studied by higher-order Raman processes and by neutron diffraction.

Phonon-dispersion curves can be determined by lattice-dynamics calculations with the aid of Raman and other experimental data, and at times *ab initio* electronic energy calculations (see PHONONS IN CRYSTAL LATTICES). This is relatively simple only when there are few atoms per unit cell. In more complex systems, some guidance is provided by symmetry arguments, which can determine the number and symmetry of Raman-active modes. Simplifications occur in molecular solids, where there are higher-frequency internal vibrations within the molecular group, which can be correlated with the Raman spectrum of the associated free molecule, and lower-frequency modes due to external vibration modes between these groups, librations (hindered rotation of the molecular units), and acoustic modes. Raman scattering from internal vibrations in molecular solids is similar to vibrational scattering in liquids (Sec. 6).

The symmetries and Raman-scattering tensors for Raman-active optical-phonon modes are well tabulated for $q = 0$ phonons (Hayes and Loudon, 1978; Cardona, 1982). The Raman signal varies as $|\mathbf{e}_s \cdot \mathbf{R} \cdot \mathbf{e}_i|^2$, where $\mathbf{R}$ is the Raman-scattering tensor ($\propto \chi'$), which has the symmetry of the scattered phonon, and is very sensitive to polarization. The tensor $\mathbf{R}$ is usually symmetric, though there are some cases where it is antisymmetric, such as the A_2 modes of Se, Te, and quartz.

In diamond-structure materials (O_h or $m3m$ point group), there is a single optic mode [$\Gamma_{25'}$ or Γ_5^+ (the Γ or Bethe notation), or T_{2g} (Mulliken notation) symmetry], which is threefold degenerate at zone center (LO, 2TO); it is Raman active. In backscattering, LO scattering is allowed from (100) and (111) surfaces, while TO scattering is allowed from (110) and (111) surfaces. In diamond, Si, and Ge, the LO/TO mode produces first-order Raman peaks at 1333, 521, and 301 cm^{-1}, respectively (Fig. 3). In zincblende materials, such as GaAs and ZnSe, the symmetry is T_d ($\bar{4}3m$), and the optical phonon [Γ_{15} (Γ_5) or T_2] has the same polarization selection rules as for diamond. In the closely related wurtzite structure (C_{6v}, $6mm$), as in CdS, the $A_1 + E_1 + E_2$ (or $\Gamma_1 + \Gamma_5 + \Gamma_6$) modes are Raman active. (The E modes are doubly degenerate.) In the rutile structure D_{4h} or $4/mmm$, as in TiO$_2$, MgF$_2$, and MnF$_2$, there are four Raman-active modes, $A_{1g} + B_{1g} + B_{2g} + E_g$ (or $\Gamma_1^+ + \Gamma_3^+ + \Gamma_4^+ + \Gamma_5^+$). The four Raman spectra of MnF$_2$ in Fig. 4 show how different Raman-active modes can be seen by using different polarization configurations.

High-T_c superconductors have the perovskite structure (Feile, 1989; Ferraro and Maroni, 1990; Thomsen, 1991). Tetragonal La$_{2-x}$(Ba/Sr)$_x$CuO$_4$ ($T_c \sim 40$ K) has D_{4h}^{17} or I_4/

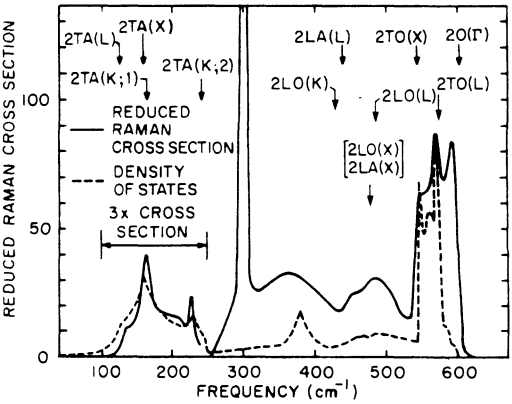

FIG. 3. Raman spectrum of Ge, showing the first-order peak near 301 cm^{-1}, which goes off scale, and the second-order peaks, which look similar to the also plotted normalized density of states (Weinstein and Cardona, 1973).

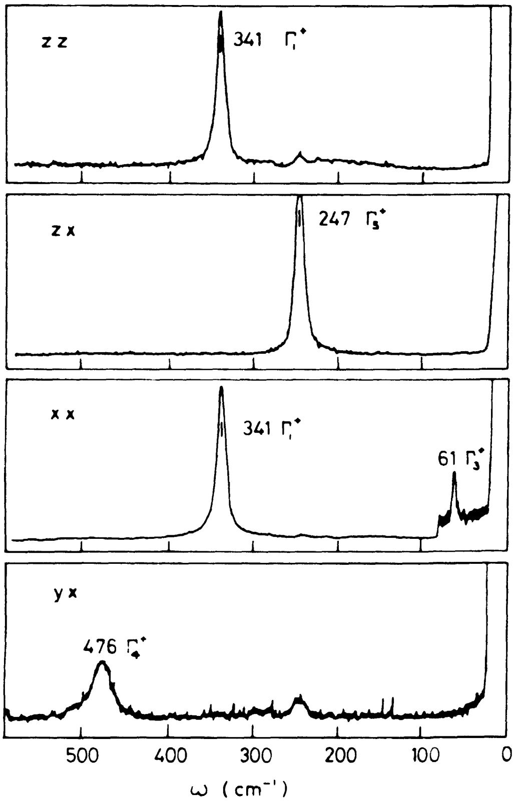

FIG. 4. Raman spectra of MnF_2 taken with different polarization configurations, in which different Raman-active modes are seen (Porto *et al.*, 1967).

mmm symmetry, and the Raman-active modes $2A_{1g} + 2E_g$. The lower-temperature, orthorhombic phase, D_{2h}^{18} or *Cmca*, has Raman-active modes $5A_g + 4B_{1g} + 3B_{2g} + 6B_{3g}$. Another high-$T_c$ material, $YBa_2Cu_3O_x$, has T_c as high as ~95 K when $x \sim 6.5$–7. With $x = 6$, it is tetragonal (D_{4h}^1 or P_4/mmm) and has Raman-active modes $4A_{1g} + B_{1g} + 5E_g$. For $x = 7$, it is orthorhombic (D_{2h}^1 or *Pmmm*) with Raman-active modes $5A_g + 5B_{2g} + 5B_{3g}$. The frequency of one Raman peak in $YBa_2Cu_3O_x$ increases linearly with oxygen content, increasing from ~475 cm^{-1} for $x = 6$ to ~501 cm^{-1} for $x = 7$.

Many metals have only one atom per primitive cell, and therefore have no optic modes to observe with Raman scattering. However, hexagonal close-packed metals have two atoms per cell and the Γ_6^+ (E_{2g}) optic mode is Raman active. In Be, Mg, and Zn, this mode leads to shifts of 455, 122, and 72 cm^{-1}, respectively. Bi has rhombohedral structure and two Raman-active modes A_{1g} and E_g near 70 and 96 cm^{-1}. The Raman spectra of these metals are weak because of the large absorption coefficient of the metal.

At zone center, LO and TO modes are degenerate for nonpolar materials. In partially ionic crystals, the zone-center frequency of the LO mode exceeds that of the doubly degenerate TO mode because it couples with the longitudinal electric field that is formed during LO vibration. Such LO vibrations are called polar modes, while those modes that do not couple with a macroscopic electric field, such as these TO vibrations and all optical modes in nonpolar crystals, are nonpolar modes. In cubic crystals, $\omega_{LO}^2 - \omega_{TO}^2 = 4\pi n_d e^{*2}/\epsilon_\infty \mu_m = \omega_{TO}^2(\epsilon_0/\epsilon_\infty - 1)$, where e^* is the ionic charge (also termed the Born transverse dynamic effective charge), n_d is the density of cation–anion pairs and μ_m is their reduced mass, and ϵ_∞ and ϵ_0 are the optical and static dielectric constants. For example, in GaAs the LO and TO modes are at 292 and 260 cm^{-1}, respectively, while in ZnSe they are at 250 and 205 cm^{-1}. In uniaxial crystals, such as the wurtzite structure, the TO further splits into two peaks at zone center when the phonon **q** is not along the *c* axis, leading to three nondegenerate optic phonons that can be observed in Raman scattering (Hayes and Loudon, 1978). The mode structure is even more complex in biaxial crystals.

At small scattering angles, nearly forward scattering, transverse (TO) phonons and the transverse electromagnetic radiation form a coupled excitation, known as phonon polaritons. This excitation looks like an unperturbed photon and a phonon at $\omega_{LO}(\Gamma)$ at $\theta \sim 0°$, a strongly coupled excitation for ~1–3° where the uncoupled photon and phonon-dispersion curves would have crossed, and an unperturbed photon and TO phonon at ω_{TO} at larger scattering angles, as is in backscattering geometry. Because of this interaction, the TO and LO modes are actually degenerate exactly at zone center. In addition to these bulk polaritons, there are surface polaritons that propagate along boundaries and exponentially decay into the bulk (Ushioda and Loudon, 1982).

Quantum mechanically, first-order vibrational Raman scattering in solids is a three-step process. First the incoming photon ω_i creates a virtual electron–hole pair through an intermediate level. Then the electron or hole interacts with the lattice, leading to the creation or annihilation of a phonon. Finally, the electron and hole recombine to form the scattered photon ω_s, leaving the material in the initial electronic state. Third-order perturbation theory leads to

$$\mathbf{e}_s \cdot \chi' \cdot \mathbf{e}_i \propto \frac{\langle v|\mathbf{p}\cdot\mathbf{e}_s|c_2\rangle\langle c_2|\mathrm{H}_{\mathrm{e-p}}|c_1\rangle\langle c_1|\mathbf{p}\cdot\mathbf{e}_i|v\rangle}{(\omega_i \pm \omega_p - \omega_0)(\omega_i - \omega_0)}, \tag{4}$$

where v is the initial valence band, c_1 and c_2 are the intermediate conduction-band states, $\mathrm{H}_{\mathrm{e-p}}$ is the electron–phonon interaction Hamiltonian, $\hbar\omega_0$ is the band gap, and $+/-$ correspond to anti-Stokes/Stokes transitions. The $\mathbf{A}\cdot\mathbf{p}$ term induces the first and third steps, which involve interband transitions. If the second step, the electron–phonon interaction, connects two different electron–hole intermediate states ($c_1 \neq c_2$ for electron scattering), which is an interband step, then three electronic states are involved and it is called a three-band process. If the same electron–phonon interaction does not change the electronic state ($c_1 = c_2$), an intraband intermediate step, it is a two-band process.

One effect that contributes to the electron–phonon coupling for both nonpolar and polar vibrations is the change in the electronic potential energy with the lateral displacement of atoms in a unit cell. This is characterized by the deformation potential and is short-range in nature. Lattice vibrations modulate the electronic energy structure, which modulates the electric susceptibility to give terms like $d\chi/du$ due to interband transitions, where u is the phonon coordinate. A second effect contributes only for polar vibrations, and it is caused by the modulation of χ by the quasistatic E_m, the macroscopic electric field, and is longer-range in nature. This interaction is described by the Fröhlich interaction, and has two components, a q-independent three-band interband term, which is allowed and can be characterized by the electro-optic tensor, and a q-dependent two-band intraband term, which is dipole forbidden away from resonance. The origin of the electro-optic term is the nonlinear polarization term $\chi^{(2)}E_iE_m$, as in Eq. (2), which can be expressed as a change in the linear susceptibility $(d\chi^{(1)}/dE_m)E_m$ with $d\chi^{(1)}/dE_m = \chi^{(2)}$.

Macroscopically, vibrational Raman scattering occurs as a result of fluctuations in u and E_m, respectively, in these two mechanisms. The ratio of the deformation potential and electro-optic contributions to this electron–phonon coupling is given by the Faust–Henry coefficient C. For most polar zinc-blende semiconductors, $C < 0$ and its magnitude is <1. Therefore, usually these two effects constructively interfere and the electro-optic effect is the stronger of the two. This means that LO scattering is usually stronger than TO scattering.

The interband terms in Eq. (4) have ingoing and outgoing resonances when the ω_i or the scattered photon frequency $\omega_s = \omega_i \pm \omega_p$ is near an energy gap. In some cases, these peaks can be resolved, though often there is one strong resonant Raman peak near $\omega_i \pm \omega_p/2$. By treating a classically bound electron, one can see the interactions in this resonance because $\chi = AF/(\omega_0^2 - \omega_i^2 - i\omega_i\gamma)$, where A is a constant, F is the oscillator strength, ω_0 is the resonance frequency, and γ is a damping (relaxation) term. Contributions to $\chi' = d\chi/du$ come from the $d\omega_0/du$ term, which is a two-band term due to diagonal matrix elements of the electron–phonon interaction, and the dF/du term, which is the three-band term due to off-diagonal elements. Integration of these highly resonant expressions [Eq. (4)] over the density of states gives line shapes that are finite at the resonances (Cardona, 1982). Occasionally, antiresonance line shapes are seen because of the interference of the resonance term with a nonresonant, constant background, as in TO phonon scattering in wurtzite ZnS near 1.9 eV.

In resonance vibrational Raman scattering, higher-order terms can also be important that can induce strong peaks not seen in the nonresonant Raman spectrum (Cardona, 1982). For example, there can be a breakdown in the symmetry properties for LO phonon scattering, so that LO phonons may be seen in a Raman spectrum for a given polarization configuration when $\hbar\omega_i$ is near a resonance, while it is forbidden off resonance. Also, in some cases multiple LO phonon lines can be seen at $\omega_s = \omega_i \pm n\omega_{\mathrm{LO}}$ with $n = 2, 3, 4, \ldots$. Since the intraband Fröhlich interaction depends on q, it does not contribute to nonresonant first-order scattering, but at resonance it can make "forbidden" first-order and higher-order scattering quite strong. Mechanistically, such multiphonon spectra can be attributed either to resonant Raman scattering or to hot luminescence, which is photoluminescence of highly excited electrons and holes that is assisted by the emission or absorption of one or more phonons.

The first step in vibrational Raman scattering is usually the formation of uncorrelated virtual electrons and holes. However, when there is strong excitonic structure, the first step may involve the production of a virtual exciton instead of an electron–hole pair. This is important in vibrational Raman scattering in Cu_2O where odd-parity forbidden Γ-point phonons are observed because of resonances with direct forbidden (quadrupole-allowed) excitons.

Second-order vibrational Raman scattering is due to the scattering of two phonons that shift ω_i by $\omega_{p1}(\mathbf{q}_1) \pm \omega_{p2}(\mathbf{q}_2)$. The phonons can be from the same branch ($p_1 = p_2$, overtones) or different branches ($p_1 \neq p_2$, combinations). Scattering cross sections for two-phonon scattering are much smaller than for first-order scattering because the higher-order susceptibility term $(d^2\chi/du_1du_2)u_1u_2$ leads to the scattering, where u_1 and u_2 are the normal-mode coordinates for the two modes. Since momentum can be conserved with contributions away from zone center, as long as $\mathbf{q}_1 + \mathbf{q}_2 \sim \mathbf{0}$, two-phonon Raman peaks are broad and resemble the joint density of states. In Stokes scattering, there is an $(n_1 + 1)(n_2 + 1)$ dependence on phonon density. The Raman peak near $2\omega_{\mathrm{LO/TO}}(q = 0)$, for example in Ge and Si, resembles the optical-phonon density of states scaled in frequency by 2, and has contributions from $\mathbf{q}$ and $-\mathbf{q}$ across the Brillouin zone. This is seen in Fig. 3 for Ge. Since $\omega(q)$ decreases from zone center for these branches, the overtone peaks below $2\omega_{\mathrm{LO/TO}}(q = 0)$. Two-phonon overtones are usually symmetry allowed for all modes, and they dominate the completely symmetric component of the spectrum Γ_1 since first-order vibrational scattering is not completely symmetric. In rocksalt crystals, such as NaCl and KBr, the optic mode is Raman inactive in first order and can only be seen in second order.

3.2 Disordered Structures

This discussion has been limited to large, pure, perfectly ordered crystals. New features in the Raman spectrum appear in crystals that are finite, impure, or disordered (see VIBRATIONAL STATES IN DISORDERED SYSTEMS). For example, when polycrystalline materials are examined with a laser focused to a spot size smaller than the grain size, the polarization selection rules can be used to determine grain orientation (Hopkins and Farrow, 1986). The polarization properties are randomly averaged over angle, as described earlier, when the grain size is smaller than the laser spot size. Further, if the grain size L is smaller than ~200 Å, phonon confinement within the grains leads to nonconservation of q, and phonons from zone center to $q \sim 1/L$ participate in Raman scattering. In Si, the Raman peak for such microcrystalline material is downshifted in frequency and asymmetrically broadened relative to that of the crystal (Campbell and Fauchet, 1986). The first-order Raman spectrum of amorphous materials resembles the optical-phonon density of states in the amorphous material, which is very similar to that of the crystal, because of the total breakdown of q conservation. This has been studied in many solids, including tetrahedrally bonded semiconductors (Si, Ge, GaAs), oxides, and chalcogenides (Brodsky, 1975). The effects of nonconservation of wave vector can also be seen in metals and highly opaque semiconductors, as a result of the large imaginary part of the photon wave vector in the material.

Point defects lead to new structure in the Raman spectrum (Srivastava, 1990). There can be local modes at frequencies above those of the host when the added impurities are lighter than the host atoms, gap modes in the frequency gaps of the host, or resonance modes within the spectrum of the host. Host modes that are forbidden in Raman scattering of the perfect crystal may appear because the defects lower crystalline symmetry.

At very high point-defect densities, the material is called a mixed crystal. Raman spectra of $A_xB_{1-x}C$ mixed crystals, such as $Ga_{1-x}Al_xAs$, often exhibit two-mode behavior with LO and TO phonons corresponding to both AC-like and BC-like vibrations, with frequencies that vary with x (Srivastava, 1990).

At $x \sim 0$ and 1, there are three peaks, the LO and TO modes of the pure crystal and that of the point defect. Some mixed crystals show one-mode behavior (a single LO and TO pair) or mixed one-mode/two-mode behavior. The polarization selection rules in these mixed crystals are relaxed from those of the *AC* and *BC* crystals because of chemical disorder, i.e., though the *A*/*B* sites have perfect crystalline order there is no *A*/*B* ordering at these sites. This can be distinguished from site disorder in microcrystalline and amorphous materials. The Raman spectrum of $Ge_{1-x}Si_x$ alloys is quite different from these other mixed crystals. It has three peaks, due to local Si–Si, Ge–Si, and Si–Si vibrations.

3.3 Two-Dimensional Structures

Raman scattering can be used to examine novel phonon features that are present in two-dimensional, layered heterostructures. This has been studied extensively for zincblende semiconductors (Klein, 1986; Jusserand and Cardona, 1989; Menendez, 1989). These heterostructures include multiple quantum wells and superlattices where very thin layers of materials *A* (e.g., GaAs) and *B* (e.g., AlAs) alternate, as in $A_{na}B_{nb}A_{na}B_{nb} \cdots$ where n_a monolayers of *A* of total width d_a (monolayer width t_a) alternate with n_b monolayers of *B* of total width d_b (monolayer width t_b). This superperiodicity lowers the symmetry, from cubic (T_d) to tetragonal (D_{2d}) for zinc-blende structures, and increases the number of atoms in the primitive cell, from 2 to $2(n_a + n_b)$.

If the frequency spans of the optic-phonon branches in bulk *A* (or *B*) do not overlap those in *B* (*A*), then optical phonons propagating along the growth direction are confined to the *A* (*B*) layer. Raman scattering will then excite standing waves in the *A* (*B*) layers corresponding to confined phonons at $\omega(m) = \omega_{\text{bulk}}(q_m)$ where $q_m = m[\pi/(n_i + 1)t_i]$ with $i = a$ (*b*), rather than at $\omega_{\text{bulk}}(q = 0)$. In $(GaAs)_{na}(AlAs)_{nb}$, optical phonons are confined in both the GaAs and the AlAs layers, as is seen in the spectra in Fig. 5, which were taken out of resonance. The $z(x,y)\bar{z}$ spectra are due to odd-*m* LO phonons, which have B_2 symmetry, while the $z(x,x)\bar{z}$ spectra are due to even-*m* LO phonons, which have A_1 symmetry. In the bulk semiconductor, phonons are seen only in $z(x,y)\bar{z}$ configuration when the laser is out of resonance.

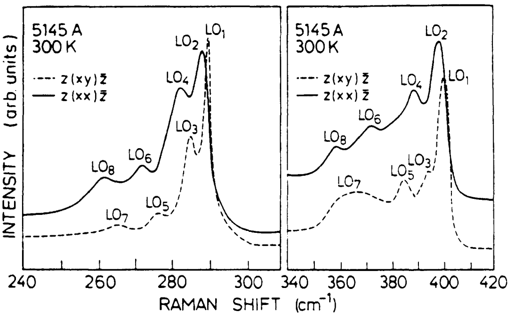

FIG. 5. Raman spectrum of $(GaAs)_8(AlAs)_8$ superlattice taken out of resonance, both for optical phonons confined to the (a) GaAs and (b) AlAs layers (Wang *et al.*, 1988).

When optical phonons propagate with a component of *q* parallel to the interface, the mode is confined near the interface. At the *AB* interface, these localized phonons, known as interface phonons, can be excited and seen in Raman scattering.

Because of the repetitive nature of the superlattice, the Brillouin-zone boundaries are at $\pm\pi/D$, where $D = d_a + d_b$, rather than at $\pm\pi/t_i$ $(i = a,b)$ for the bulk solid. This effectively leads to zone folding of the bulk dispersion curve for acoustic phonons propagating along the superlattice growth direction. In addition to the Brillouin peaks, Raman peaks now appear at $\omega_x(q)$ where $q = \pm q_{\text{SL}} + 2\pi m/D$ and $m = 1, 2, 3 \cdots$; $q_{\text{SL}} = (\omega/d)[d_a/v_a - d_b/v_b]$, where *v* is the sound speed in the respective medium. The Raman spectrum is a series of Stokes and anti-Stokes doublets with intensities that decrease with *m*; in Fig. 6 the Stokes doublets are seen for a GaAs/AlAs superlattice. These doublets are far enough away from the exciting line, ~10 cm^{-1}, to be seen with a monochromator (unlike bulk acoustic phonons), and can be seen in crystalline and amorphous superlattices.

3.4 Perturbations Due to Strain, Changes in Temperature, and Electric Fields

First-order vibrational Raman scattering is sensitive to the effects of strain on materials (Weinstein and Zallen, 1984). The appli-

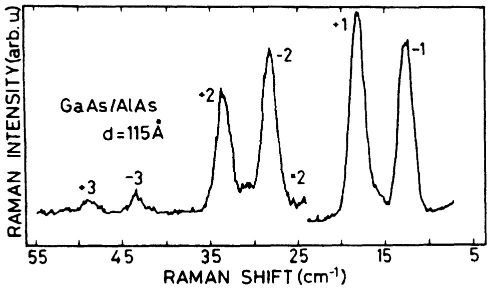

FIG. 6. Raman spectrum of folded acoustic lines in a GaAs/AlAs superlattice (Jusserand *et al.*, 1987).

cation of hydrostatic pressure (P_h) in diamond anvil cells causes uniform compressive strain and an increase in ω_p that is characterized by the mode Grüneisen parameter $\gamma = -d \ln\omega_p/d \ln V = (B/\omega_p)d\omega_p/dP_h$, where B is the bulk modulus and V is volume. The parameter γ for the TO mode at zone center increases with effective charge per cation electron for zinc-blende semiconductors, from $\gamma = 1.0$ for covalent Si to 1.9 in ZnS, while the increase of γ_{LO} with ionicity is relatively slower. By examining the pressure dependence of $\omega_{\mathrm{LO}} - \omega_{\mathrm{TO}}$ for polar modes, the change of the transverse effective charge e^* with volume can be measured. Since the two-phonon vibrational Raman spectrum has peaks from contributions near the critical points in the Brillouin zone, pressure measurements can give γ at these points.

The application of uniaxial pressure causes uniaxial/biaxial strain that splits the degenerate zone-center optical phonons (Cerdeira *et al.*, 1972; Pollak, 1991). For example, stress along the [001] and [111] directions in Si splits the triply degenerate Γ-point optical phonon into a singlet vibrating along the stress and a doublet vibrating perpendicular to it, while stress along [110] splits it into a triplet. These individual components can be seen by using different polarization configurations. Raman spectroscopy can also be used to measure biaxial strain in thin films with no applied pressure, such as in lattice-mismatched, strained-layer heterostructures that are grown commensurately by molecular beam epitaxy or MOCVD. In incommensurately grown films, film contraction in cooling from the growth temperature down to the observation temperature produces strains that can be analyzed by Raman scattering, as has been seen for Si films grown on silicon dioxide and sapphire.

Vibrational Raman scattering has shown that optical-phonon frequencies ω_p generally decrease with temperature T, while the linewidths Γ_p increase with T. This is due to anharmonicity, as can be shown by perturbation theory. The coupling of the optical phonon to two and to three phonons of lower energy leads to changes in ω_p and Γ_p that vary as $\sim T$ and $\sim T^2$, respectively, above the Debye temperature (Balkanski *et al.*, 1983). Thermal volume expansion also contributes to the decrease of ω_p with temperature, as $\sim T$.

One way to determine temperature *in situ* during processing is from the temperature dependence of ω_p and Γ_p in Raman scattering (Pazionis *et al.*, 1989). Temperature can also be determined from the the ratio of the Stokes (S) and anti-Stokes (AS) scattering intensities. Using Eq. (1), this ratio is $I_S/I_{AS} = A'(n + 1)/n = A' \exp(\hbar\omega_p/kT)$, where A' is the $\omega_s^3\eta_s\chi'^2$ ratio for the S and AS beams. Though $A' \sim 1$, it cannot be set equal to 1. To determine T without significant error, A' must be determined exactly, especially near resonances. Because $(n + 1)/n \rightarrow 1$ at high T, this method is useful only when $kT \ll \hbar\omega_p$. The ratio I_S/I_{AS} has the same temperature dependence in the scattering of other elementary excitations.

The application of a static electric field can change the symmetry of a crystal—for instance, by removing the center of inversion—and normally Raman-forbidden phonons can then be observed (Abstreiter *et al.*, 1984). When an electric field is applied along (001) of cubic perovskite paraelectrics such as $KTaO_3$ and $SrTiO_3$, the symmetry changes from O_h to C_{4v}, and the infrared-active mode F_{1u} modes split into A_1 and E components, while the silent mode F_{2u} splits into B_1 and E components. These modes are now Raman active and have a scattering intensity that varies as the square of the applied field. Electric fields can also change the polarization selection rules for modes that are Raman active with no applied field. These fields can be either externally applied or internally generated, as the internal space-charge field within the surface-depletion region of a doped semiconductor.

Changes in the Raman spectrum from changes in structure, such as those due to stresses or electric fields, are sometimes termed morphic effects.

3.5 Phase Transitions

Vibrational Raman scattering is a good probe of phase transitions (Hayes and Loudon, 1978; Cummins and Levanyuk, 1983). In a phase transition from a lower- to higher-symmetry structure, there is a loss of optical vibration modes, some of which are Raman active. This is seen in the temperature-induced transition from the orthorhombic to tetragonal phase of the perovskite high-T_c superconductor $La_{2-x}M_xCuO_4$, as was mentioned in Sec. 3.1. The frequencies of the lost modes can decrease to 0 as the transition is approached, and these are called "soft" modes. Pressure-induced phase transitions in bulk solids and superlattices have also been monitored by Raman scattering (Weinstein and Zallen, 1984; Venkateswaran *et al.*, 1992). For example, the LO/TO modes in zinc-blende GaAs disappear for $P_h > 173$ kbar because of the phase transition to a distorted NaCl structure, which has no Raman-active modes.

3.6 Time-Resolved Studies

The transient dynamics of phonons can be followed by time-resolved Raman scattering using subpicosecond lasers (Kash and Tsang, 1991). One laser beam can be split into a pumping beam, to create phonons by spontaneous Raman scattering, and a time-delayed probing beam, to analyze these phonons by spontaneous Raman scattering. Alternatively, two lasers at ω_i and $\omega_s = \omega_i - \omega_p$ can initially coherently excite lattice vibrations. The magnitude of the excitation can then be probed as a function of time by using time-resolved CARS (Bron *et al.*, 1986). Phonon lifetimes, such as ~5 ps for ZnSe, agree with the inverse of the linewidths in cw spontaneous Raman studies, and can be ascribed to anharmonic coupling to lower-energy phonons.

4. MAGNETIC RAMAN SCATTERING

In addition to the vibrational peaks, Raman spectra of magnetic solids have Stokes and anti-Stokes peaks that are shifted by collective magnetic excitations (Hayes and Loudon, 1978; Cottam and Lockwood, 1986; Ramdas and Rodriguez, 1988, 1991). Magnetic Raman scattering is observed in the low-temperature ordered states of ferromagnetic, ferrimagnetic, and antiferromagnetic solids, where the magnetic excitations are known as quantized spin waves or magnons. Scattering of electrons in the higher-temperature paramagnetic state can be classified as either magnetic or electronic Raman scattering. When collective effects are important, the magnetic scattering methods and theory in this section are most relevant. Section 5.1 on electronic Raman scattering covers paramagnetic materials where the interaction between magnetic ions is minimal. Magnetic Raman scattering is typically weaker than vibrational scattering, and the frequency shifts are typically smaller.

In the macroscopic description of scattering in ferromagnets, the electric polarization is $\mathbf{P} = \epsilon_0\chi\mathbf{E} + i\epsilon_0 G\mathbf{M} \times \mathbf{E}$ in cubic and isotropic materials, where χ is the electric susceptibility, $\mathbf{M}$ is the magnetization, and $iG = \partial\chi_{ij}(M)/\partial M_h$ (for ijh any cyclic permutation of xyz). The scattering cross section is proportional to the magnetization power spectrum $\langle M_i M_j\rangle_\omega$, and thermal fluctuations in $\mathbf{M}$ lead to the observed frequency distribution of the scattered light. Because of the $\mathbf{M} \times \mathbf{E}$ term, which arises because the magnetization and magnetic field are axial in nature (among other factors), scattering is purely antisymmetric in the incident and scattered polarizations, and linearly polarized incident light couples to circularly polarized scattered light and vice versa. There is an additional scattering contribution due to the precession of the fluctuating $\mathbf{M}$ about an applied magnetic field, which affects the magnetic susceptibility. However, its relative importance decreases with increasing ω_i, and it can usually be neglected in the scattering of visible and ultraviolet light.

The magnetization power spectrum is calculated by using the fluctuation-dissipation theorem and the Bloch equations of motion for $\mathbf{M}$ in a magnetic field $\mathbf{B}$. With $\mathbf{B}$ along the z direction, the longitudinal cross section, due to M_z, features a peak with zero frequency shift, while the transverse cross section, due to M_x and M_y, has Stokes and anti-Stokes shifts $\Delta\omega = \gamma B$, where $\gamma = g\mu_B/\hbar$ is the gyromagnetic ratio, with μ_B the Bohr magneton and g the gyromagnetic factor ($= -2$ for the electron spin). For $T \ll T_c$ (the Curie temperature), transverse scattering dominates. In these ferromagnets and paramagnets, $\Delta\omega$ is very small, $\sim 1\ \mathrm{cm}^{-1}$ for $B = 10^4$ G (0.1 T), and the spectroscopic methods used in Brillouin scattering are needed. For Stokes light, $d^2\sigma/d\Omega\, d\omega_s \propto |e_i^z e_s^+ - e_i^+ e_s^z|^2$, while for anti-Stokes e^+ is replaced by e^-, where $e^{\pm} = e_x \pm ie_y$.

In the microscopic approach, magnetic scattering in ferromagnets and paramagnets occurs by the creation or annihilation of magnons. Below the Curie temperature T_c, the magnetic moments of the transition-metal ions strongly couple to each other, through the Heisenberg exchange interaction, and to the external field B. Diagonalization of the Hamiltonian leads to elementary excitations from the ground state in units of the magnon frequency, which depends, to first order, linearly on the "exchange" field B_E and the applied field B_0. The scattering of light occurs by a two-step, electric dipole process that first couples the ground state, with the z component of spin S_z, to a virtual intermediate state, where spin and orbital motions are coupled, and then back down to the ground-state $S_z - 1$ component. Therefore the ground-state spin is decreased by 1 because of the spin–orbit coupling in the excited state. The scattering by magnons is then determined by the properly phased summations of the scattering of these individual ions. The scattering cross section has a similar form to that from macroscopic theory, but includes resonance effects when the laser frequency and the energy of the intermediate level are approximately equal.

For $T < T_c$ ($B = 0$), the ferromagnetic magnon linewidth increases with increasing T because of magnon–magnon coupling, and the peak amplitude first increases because of increasing $n(\omega)$ and then sharply decreases to 0 near T_c because of the decreasing magnetization.

The macroscopic and microscopic theories of scattering in antiferromagnets and ferrimagnets parallel those for ferromagnets. In antiferromagnets, spins line up in opposite directions on two sublattices and totally cancel the macroscopic $\mathbf{M}$. The Hamiltonian includes the exchange term (which causes ordering in each sublattice below the Néel temperature T_N), a term including the anisotropy field B_A (which acts differently on the two superlattices), and a term that couples with the external magnetic field. For each wave vector $\mathbf{q}$, there are two magnons $\uparrow\mathbf{q}$ and $\downarrow\mathbf{q}$, which correspond to a respective increase and decrease by one in the z component of spin of the crystal. The magnon frequencies are $\omega_{\downarrow\mathbf{q},\uparrow\mathbf{q}} = \omega_{\mathbf{q}} \pm \gamma B_0$, where $\omega_{\mathbf{q}}$ depends on B_A and B_E.

The differential cross section is $d\sigma/d\Omega \propto G^2 M_0\, |(\mathbf{e}_i \times \mathbf{e}_s)|^2\, (n + 1)$, where G contains the dynamical information from the macroscopic or microscopic theory, M_0 is the magnetization of a fully aligned sublattice, and n is the density of magnons. The polarization factor is seen to couple light linearly polarized in the z direction with light circularly polarized in the xy plane, with opposite senses for the two kinds of magnons. Though magnetic scattering cross sections in antiferromagnets are often smaller than for vibrational Raman scattering, the frequency shifts are on the same order, and so conventional Raman spectral dispersion methods can be used. The first-order magnetic scattering peak in $\mathrm{FeF_2}$ at zero magnetic field is at $\omega_{AF,\mathbf{q}=0} \sim 50\ \mathrm{cm}^{-1}$, as seen in Fig. 7, and symmetrically splits into two peaks when a magnetic field is applied. For $T < T_N$ ($B = 0$), as T increases ω_{AF} decreases, the magnon linewidth increases, and the peak amplitude decreases and approaches 0 near T_N.

Second-order or two-magnon scattering is observed in antiferromagnets, as is seen in $\mathrm{FeF_2}$ near $150\ \mathrm{cm}^{-1}$ in Fig. 7. As in two-phonon scattering, two-magnon scattering roughly reflects the one-magnon density of states scaled in frequency by a factor of 2. Because $\omega_{\mathbf{q}}$ increases with q, the strongest contribution in second-order magnetic scat-

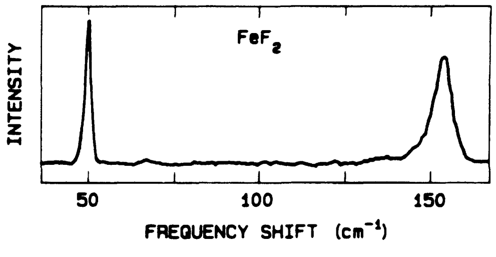

FIG. 7. Magnetic Raman scattering in antiferromagnetic $\mathrm{FeF_2}$ showing the one-magnon and two-magnon lines (Fleury and London, 1968).

tering is larger than $2\omega(q = 0)$, which is in contrast to that for optical phonons. The cross sections for one- and two-magnon scattering are of the same order, whereas two-phonon scattering is much weaker than one-phonon scattering, because second-order scattering in antiferromagnets is not caused by the first-order term taken to second order, as it is for vibrational Raman scattering, but it is due to a different mechanism. In this process, the exchange scattering mechanism, there is a double spin change of neighboring spins on the two sublattices. Because of this close spatial coupling of the magnons, the sum of the energies of the two magnons created in second-order scattering is somewhat less than twice the energy of two individual magnons. Two-magnon scattering is essentially unaffected by a magnetic field. For $B = 0$, with increasing T ($<T_N$) the peak ω decreases and Γ increases, and, unlike the one-magnon peak, the amplitude persists for $T \gg T_N$.

Coupling of spins and phonons is seen in magnetic materials (Güntherodt and Zeyher, 1984). First-order vibrational scattering in europium chalcogenides (EuX, X = O, S, Se, Te) is symmetry forbidden because they have the fcc (NaCl) structure. However, in the paramagnetic phase, broad first-order vibrational peaks are seen that are induced by spin disorder. With magnetic ordering, the spin–phonon coupling changes. In EuO and EuS, which are ferromagnets, vibrational scattering is quenched upon ordering and the shift increases from the phonon frequency ω_p to almost $\omega_p + \omega_{\text{magnon}}$. In EuTe, an antiferromagnet, scattering is enhanced upon ordering.

In some magnetic solids, in addition to the (usual) acoustic magnons, there are other excitations called optical magnons, which are caused by the anisotropy induced by the crystalline electric field. Inelastic scattering has also been observed in canted and metamagnetic antiferromagnets and in ferrimagnets, and for magnetic films and superlattices (Cottam and Lockwood, 1986).

5. ELECTRONIC RAMAN SCATTERING

5.1 Bound Electrons

Bound electrons can scatter by a two-step process, mediated by the $\mathbf{A} \cdot \mathbf{p}$ term in second order. Raman scattering between crystal-field–split electronic states with the same $4f^n$ electronic configuration has been studied in solids with rare-earth ions, such as $PrCl_3$ and $CeCl_3$. In semiconductors, electrons bound to donor atoms and holes bound to acceptor atoms can scatter efficiently to another donor/acceptor state, sometimes with the emission of an acoustic phonon, or to the conduction/valence band (Klein, 1975; Abstreiter *et al.*, 1984).

When a magnetic field is applied to a paramagnetic solid, there can be scattering between the Zeeman-split, bound electronic states of the magnetic ions with a shift $\omega_{PR} = \gamma B$ (electron paramagnetic resonance—EPR). Though it is now assumed that coupling between the magnetic ions is minimal in these materials, and individual ions, and not spin waves, are being probed, the microscopic mechanism and polarization selection rules for scattering are the same as those described for magnetic scattering in Sec. 4. One important example is scattering in diluted magnetic semiconductors (DMS), which are mixed crystals, such as $Cd_{1-x}Mn_xSe$, where there are antiferromagnetic interactions between the magnetic ions (Mn^{2+}) (Ramdas and Rodriguez, 1988, 1991). For small x, they are paramagnets at all temperatures, while for larger x, they can undergo a transition to a spin glass or antiferromagnet at low temperatures. Spin coupling with the lattice can lead to sidebands on the phonon peaks at $\omega_{LO} \pm \omega_{PR}$ and $\omega_{LO} \pm 2\omega_{PR}$. Also, spin-flip scattering between Zeeman-split levels of weakly bound electrons is seen in diluted magnetic semiconductors. The g factor for these electrons is very large, as a result of the exchange interaction between the Mn^{2+} ions and the band electrons, leading to large Zeeman splitting of the free exciton.

5.2 Free Carriers

Light scattering of free carriers in solids, as seen particularly in semiconductors, can involve scattering from single particles or collective oscillations (Klein, 1975; Abstreiter *et al.*, 1984, 1986). Single electrons (or holes) can scatter photons, and change the photon momentum by $\mathbf{q}$ and the photon frequency within the range $\hbar/m^*(q^2/2 - k_F q) < \omega_x < \hbar/m^*(q^2/2 + k_F q)$, where m^* is the effective mass of the particle and k_F is the particle wave vector at the Fermi surface. This leads to a distribution of scattered light that is centered at or near ω_i, and one from which the particle kinetic energy distribution can be determined. Light can also scatter from collective longitudinal charge-density oscillations, which are quantized as plasmons with frequency $\omega_P(\mathbf{q})$ given by $\omega_P^2(\mathbf{q}) = \omega_P^2 + (3v_F^2/5)q^2$, where the plasma frequency is $\omega_P = (4\pi ne^2/\epsilon m^*)^{1/2}$ with n the free particle density, ϵ the dielectric constant, and $v_F = \hbar k_F/m^*$. In addition to these more common optical plasmons, other collective modes can be observed in scattering in multicomponent plasmas with multivalley electrons or with electrons and holes. In these modes, there is partial or total cancellation of charge-density fluctuations, such as acoustic plasmons and intervalley density fluctuations. Optical plasmon scattering tends to dominate for $q < q_S$, where q_S is a characteristic plasma screening wave vector, while single-particle scattering dominates for $q > q_S$. The scattered wave vector is determined by $q = 2k_i \sin(\theta/2)$, where θ is the scattering angle.

Macroscopically, scattering by free electrons is attributed to fluctuations in the electron density. This can be subdivided into charge-density fluctuations, which can lead to the aforementioned single-particle and collective effects, and spin-density fluctuations, which lead only to single-particle effects in bulk nonmagnetic semiconductors. Quantum mechanically, scattering from electrons is a two-step process. In simple isotropic semiconductors with one type of carrier, the photon scattering cross section due to charge-density fluctuations is approximately (Blum, 1970)

$$\frac{d^2\sigma}{d\Omega d\omega_s} = \frac{\hbar q^2 V}{\pi e^2}\frac{m^2}{m^{*2}}\frac{\epsilon_0\epsilon_\infty^2\eta_s}{\eta_i}\frac{\omega_s}{\omega_i}\left(\frac{\omega_0^2}{\omega_0^2 - \omega_i^2}\right) \times (\mathbf{e}_i\cdot\mathbf{e}_s)^2 r_0^2[n(\omega) + 1]\mathrm{Im}\left(-\frac{1}{\epsilon(\omega,\mathbf{q})}\right) \tag{5}$$

for Stokes scattering, where $n(\omega) = 1/[\exp(\hbar\omega/kT) - 1]$, m^* is the effective mass, $r_0 = e^2/(4\pi\epsilon_0)mc^2$, and ϵ_∞ is the dielectric constant at high frequency. Equation (5) includes the contributions of the A^2 term in the Hamiltonian in first order, which describes contributions for electrons in vacuum, and the $\mathbf{A}\cdot\mathbf{p}$ term in second order, which includes the very important effects of interband scattering. This latter term adds the resonance denominator near band gap energies and the dependence on the effective mass rather than the free-particle mass. For an anisotropic band, $(\mathbf{e}_i\cdot\mathbf{e}_s)^2/m^{*2}$ is replaced by $[\mathbf{e}_i\cdot(1/\mathbf{m}_{ij}^*)\cdot\mathbf{e}_s]^2$, where m_{ij}^* is the effective mass tensor. The factor $\mathrm{Im}(-1/\epsilon(\omega,\mathbf{q}))$ describes plasmon scattering through a resonance near ω_P, and can also include the effect of a magnetic field and the coupling of plasmons with LO phonons. Since $\epsilon(\omega,\mathbf{q}) = \epsilon_\infty + \chi(\omega,\mathbf{q})$, $\mathrm{Im}(-1/\epsilon(\omega,\mathbf{q})) = (1/\epsilon_\infty) \times \mathrm{Im}(\chi(\omega,\mathbf{q})/\epsilon(\omega,\mathbf{q}))$, which is approximately $(1/\epsilon_\infty^2)\,\mathrm{Im}(\chi(\omega,\mathbf{q}))$ in dilute plasmas where $\epsilon_\infty \gg \chi(\omega,\mathbf{q})$. Therefore, the Raman spectra of dilute plasmas are determined by the factor $\mathrm{Im}(\chi)$, which is proportional to the density of states of single-particle excitations.

The scattering processes described by Eq. (5) are due to charge-density fluctuations. It is symmetric in the polarization and leads to polarized scattering in the simple case of an isotropic mass tensor. Scattering from spin-density fluctuations is mediated by the spin–orbit interaction, as are the spin-flipping terms in magnetic scattering, and has an $|\mathbf{e}_i \times \mathbf{e}_s|^2$ dependence on polarization. This is antisymmetric in the excitation and scattered polarizations, and therefore scattering from spin-density fluctuations is depolarized and $\mathbf{e}_s \perp \mathbf{e}_i$. The charge- and spin-density fluctuation terms do not interfere because their scattering amplitudes differ by i. In n-type GaAs, collective excitations are due to charge-density oscillations, while single-particle excitations are due to spin-density fluctuations.

With either scattering mechanism, the scattering cross section has an ω_s/ω_i dependence, which is different from the $\omega_i\omega_s^3 \approx \omega^4$ term in the macroscopic description of Raman scattering, as exemplified by vibrational Raman scattering below all resonances. This is analogous to behavior of the classical cross section for elastic scattering of bound electrons, which has a ω^4 dependence below resonance ($\omega \ll \omega_0$, Rayleigh scattering) and no frequency dependence for free electrons ($\omega \gg \omega_0$, Thomson scattering).

In polar semiconductors, LO phonons and plasmons interact through the longitudinal electric field that they both produce. They couple to form two modes $L_\pm$ observable in

Raman scattering at

$$\omega_\pm^2 = \tfrac{1}{2}(\omega_{\mathrm{LO}}^2 + \omega_{\mathrm{p}}^2) \pm \tfrac{1}{2}[(\omega_{\mathrm{LO}}^2 + \omega_p^2)^2 - 4\omega_p^2\omega_{\mathrm{TO}}^2)]^{1/2}. \qquad (6)$$

The TO mode is unaffected. For small electron density n, $\omega_\pm \sim \omega_{\mathrm{LO}}$ and $\omega_p \sim 0$, respectively, while for very large n, where electrons screen out the electric field that splits the LO and TO phonons, the modes are at ω_p and ω_{TO} (Fig. 8). The different scattering mechanisms (deformation potential, electro-optic, and plasmon) can be distinguished by polarization measurements. This strong LO-phonon–plasmon coupling has been seen in n-type semiconductors, but not in p-type materials.

Electronic scattering via the **A·p** terms can leave the solid in the initial electronic band (two-band term) or a different band (three-band). In the processes described so far, the free electron or hole returns to the initial state. Two-band, single-particle scattering can also affect the phonon spectrum, though it is usually less dramatic than the LO-phonon–plasmon coupling (Abstreiter *et al.*, 1984). After three-band scattering, the free carrier or bound electron, as described in the previous section, ends up in a different electronic state, as in p-type Si. Raman scattering from the light- to heavy-hole band in p-type Si, with the conduction band as the intermediate state, can lead to a spectrum that is several hundred cm^{-1} wide. Near 520 cm^{-1}, this electronic scattering interferes with the phonon peak to produce asymmetric or antiresonant profiles (Cerdeira *et al.*, 1973). This arises from the Fano-type interference between scattering with a continuum of levels (electronic) and a discrete level (vibrational). Even when electron–phonon coupling is relatively weak in doped semiconductors, phonon peaks are still affected by high carrier densities. Sometimes the peaks are softened, i.e., the peak frequency decreases.

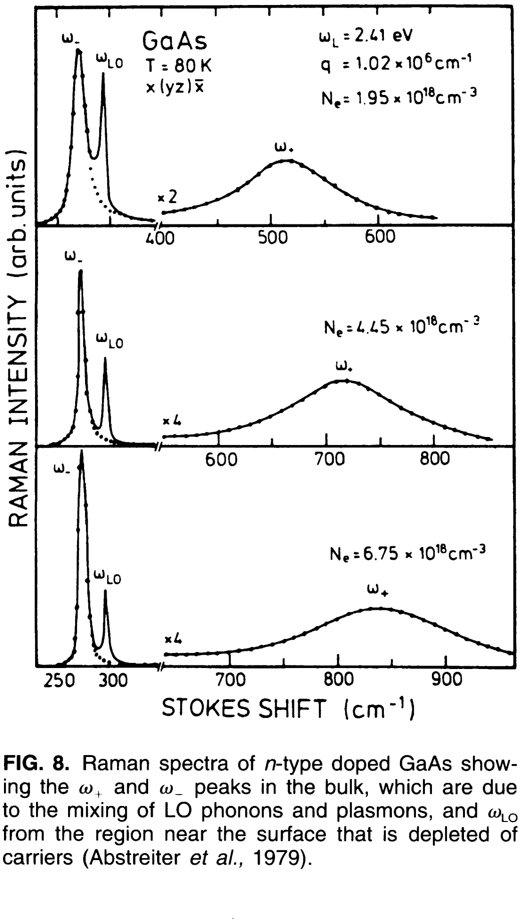

FIG. 8. Raman spectra of n-type doped GaAs showing the ω_+ and ω_- peaks in the bulk, which are due to the mixing of LO phonons and plasmons, and ω_{LO} from the region near the surface that is depleted of carriers (Abstreiter *et al.*, 1979).

Scattering from electronic excitations in high-T_c superconductors leads to several phenomena (Thomsen, 1991). In some cases, it is thought to produce the broad, constant scattering background that is seen in some polarization configurations, which rolls off at low frequencies (Reznik *et al.*, 1992). Some phonon peaks have asymmetric profiles due to a Fano-type interference between phonon and electronic scattering, as seen in semiconductors. Both the softening and hardening, and the line broadening and narrowing of some phonon peaks that occurs when $T < T_c$ (the transition temperature), have been interpreted as evidence for a sharp superconducting gap (Thomsen, 1991; McCarty *et al.*, 1991). In the conventional superconductors Nb$_3$Sn and V$_3$Si, there is a peak at the superconducting gap due to coupling to superconducting pairs (Dierker *et al.*, 1983).

Raman scattering of free electrons in a magnetic field is quite different. The motion of free electrons in a magnetic field B (z direction) is quantized in the x-y plane, leading to Landau levels $\hbar\omega_c(l + \frac{1}{2})$ for $\omega_c \gg \omega_p$, where the cyclotron frequency $\omega_c = eB/m^*c$. More generally, the Landau levels are separated by the frequency of the collective magnetoplasmon mode $\omega_P(q,B) = [\omega_P^2(q) + \omega_c^2]^{1/2}$. Because of the coupling of the electron spin to B, each of the Landau levels is split by an energy $-g\mu_B B s_z$ ($s_z = \pm\frac{1}{2}$). In spin-flip Raman scattering, $\Delta s_z = 1$, $\Delta l = 0$, and the scattered light is Stokes shifted by $\omega_x = g\mu_B B/\hbar$. Spin-flip scattering occurs via spin–orbit coupling in intermediate levels, which is similar to the scattering of magnons. The scattered phonon frequency ω_s can be tuned by changing B, and the stimulated version of this process can be used to make a tunable spin-flip Raman laser. Because of the large values of g in some semiconductors, $g \sim -50$ in InSb, large shifts are possible, ~160 cm^{-1} for $B = 10$ T. With $\mathbf{q} \perp \mathbf{B}$, transitions involving inelastic scattering between the Landau levels, $\Delta l = 1, 2 \ldots$, can occur with frequency shifts at ω_c, $2\omega_c$, ...

5.3 Two-Dimensional Structures

As in vibrational Raman scattering, novel effects appear in electronic Raman scattering in two-dimensional structures, such as quantum wells (Abstreiter *et al.*, 1984; Pinczuk and Abstreiter, 1989). In two-dimensional electron gases, as in modulation-doped GaAs–Al$_x$Ga$_{1-x}$As heterostructures, there is quantized electron motion normal to the layer planes that produces subbands. In Raman scattering, there can be vertical intersubband transitions that involve electron motion only normal to the planes ($q_\parallel = 0$), and intersubband and intrasubband transitions that involve changes in electron wave vector parallel to the planes ($q_\parallel \neq 0$). Intrasubband transitions can involve single-particle excitations and plasmons. The plasma frequency ω_P depends on the details of the two-dimensional confinement.

These different transitions can be distinguished by the scattering geometry, and can be resonantly enhanced at photon energies near gaps for the electron bands that are involved. In a general backscattering geometry, with the laser incident at an angle ϕ_1 to the normal and the scattered light collected at an angle ϕ_2, $q_\perp \gg q_\parallel$. By changing ϕ_1 and ϕ_2, $q_\parallel$ can be varied. For $\phi_1 = -\phi_2 = 45°$, $q_\parallel = 0$ and only intersubband scattering is observed.

Figure 9 shows scattering in a modulation-doped GaAs quantum well. The depolarized $z(y',x')\bar{z}$ spectrum is due to single-particle spin-density intersubband excitations, while the polarized $z(x',x')\bar{z}$ spectrum is due to collective charge-density intersubband excitations. The polarized peaks are higher in energy because of the coupling of the macroscopic electric field with collective excitations (17.7 vs 11.3 meV, etc.), and the 34.7- and 42.4-meV polarized peaks come from the coupling of collective excitations and LO phonons, which is analogous to the $L_\pm$ modes in bulk semiconductors (Pinczuk and Worlock, 1982).

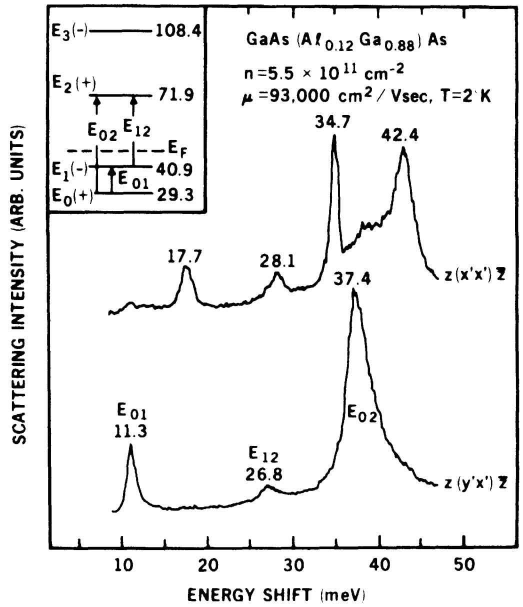

FIG. 9. Polarized (upper) and depolarized (lower) Raman spectra of modulation-doped GaAs-Ga$_{0.88}$Al$_{0.12}$As multiple quantum well, with 250-Å well thickness, due to vertical intersubband transitions (Pinczuk and Worlock, 1982).

With a magnetic field normal to the plane, motion in the plane is quantized. All transitions are discrete and are due to intersubband transitions, Landau-level transitions, and a combination of intersubband and Landau-level transitions. In-plane magnetic excitations between Landau levels that are associated with single-particle effects are called magnetic excitons, while those associated with collective modes are magnetoplasmons.

Analogous one-dimensional phenomena have been seen in quantum wires, where there is two-dimensional confinement.

5.4 Time-Resolved Studies

Pump/probe experiments with subpicosecond lasers can be used to study the dynamics of hot electrons, notably in semiconductors (Kash and Tsang, 1991). Equilibration of valence-band electrons occurs by coupling to optical phonons (~190 fs in GaAs), intervalley scattering, and carrier–carrier collisions. Hot conduction-band electrons, which are produced by a pump pulse, are relaxed by the formation of LO phonons. These phonons can be measured by monitoring the anti-Stokes Raman signal with a time-delayed pulse (von de Linde *et al.*, 1980).

6. RAMAN SCATTERING IN GASES AND LIQUIDS

Spontaneous Raman scattering in gases and liquids is a coherent two-step process, as from level a to level c in Fig. 1. In vibrational Raman scattering in gases and liquids, these two levels are different vibrational levels in the same electronic state. In gases, the rotational quantum numbers of a and c can also differ, leading to rotational–vibrational Raman scattering, or these two states can be different rotational states in the same vibrational level, which is called pure rotational Raman scattering. In vibrational and rotational scattering, the intermediate state b is in an excited electronic state. The states a and c can be different electronic states, as has been examined in atoms. Such electronic Raman scattering is relatively seldom studied.

Quantum mechanically, the term in the electric polarizability describing scattering from rotational–vibrational (rovibronic) states a to c in a molecule is

$$\alpha_{ij} = \frac{e^2}{\hbar}\sum_b\left(\frac{\langle c|r_j|b\rangle\langle b|r_i|a\rangle}{(\omega_{ab} - \omega_i - i\Gamma_b)} + \frac{\langle b|r_j|a\rangle\langle c|r_i|b\rangle}{(\omega_{bc} + \omega_i - i\Gamma_b)}\right), \qquad (7)$$

where r_i is the Cartesian component of the electron position operator, Γ_b is a damping term that describes the width of level b, and ω_{ab} is the frequency of the a–b transition (>0) (Rousseau *et al.*, 1979). The Born–Oppenheimer approximation allows factoring of each wave function, such as for state a, into three terms: a vibrational term $a_v(\mathbf{R})$, a rotational term $a_r(\mathbf{R})$, both of which are functions of the internuclear coordinate $\mathbf{R}$, and an electronic term $a_e(\mathbf{r},\mathbf{R})$, which is a function of the electron coordinate $\mathbf{r}$ and is parametrized by $\mathbf{R}$.

Integrating the rotational wave-function terms in the matrix elements over molecular orientation gives the dipole selection rules for the rotational quantum number. Integrating the electronic terms (a_e and c_e in the ground electronic state, and b_e in an excited electronic state) over the electronic coordinate gives an $\mathbf{R}$-dependent electronic dipole moment M that can be expanded about the equilibrium configuration ($\mathbf{R}_0$), as $\mathbf{R} = \mathbf{R}_0 + \mathbf{u}$, to give $M(R) = M(R_0) + [\partial M/\partial R|_{R_0}]u + \cdots$. Ignoring the nonresonant second term in Eq. (7) then gives

$$\begin{aligned}\alpha_{ij} = {} & |M(R_0)|^2\,\frac{1}{\hbar}\sum_b\frac{\langle c_v|b_v\rangle\langle b_v|a_v\rangle}{(\omega_{ab} - \omega_i - i\Gamma_b)} \\ & + M(R_0)\left.\frac{\partial M}{\partial R}\right|_{R_0}\frac{1}{\hbar} \\ & \times\sum_b\frac{\langle c_v|R|b_v\rangle\langle b_v|a_v\rangle + \langle c_v|b_v\rangle\langle b_v|R|a_v\rangle}{(\omega_{ab} - \omega_i - i\Gamma_b)} \\ & + \cdots, \qquad (8)\end{aligned}$$

where the remaining integration is over vibrational coordinates.

The first term in Eq. (8) involves the vibrational overlap Franck–Condon factors and is also known as the Albrecht A term. Its contribution to scattering is known as "Franck–Condon scattering." Far from resonance ($|\omega_{ab} - \omega_i| \gg 0$), the numerator sums to $\langle c_v|a_v\rangle$, which leads to no change in vibrational state, i.e., Rayleigh and pure rotational Raman scattering. The second term corresponds to the Albrecht B term and leads to "Herzberg–Teller scattering." Far from resonance, the numerator sums to $\langle c_v|R|a_v\rangle$, which means that the vibrational quantum number v changes by ± 1 (fundamental scattering). Overtone scattering ($|\Delta v| > 1$) is weak. Near resonance, the A term dominates vibrational Raman scattering, and both the fundamental and overtones can be strong (Rousseau *et al.*, 1979).

More generally, the separation of vibrational and rotational effects in Raman scattering can be seen by examining the electric polarizability in the space-fixed (laboratory) frame, where it depends on the vibrational and rotational coordinates, after transformation from the molecule-fixed frame, where it depends on only the vibrational coordinates.

Classically, pure rotational Raman scattering is due to the anisotropy in the static (or equilibrium) polarizability tensor, as given by $2\alpha_{zz} - \alpha_{xx} - \alpha_{yy}$. This is analogous to the requirement of a nonvanishing permanent electric dipole moment for allowed infrared transitions between rotational levels. Vibrational Raman scattering can occur if at least one of the derivatives of the polarizability tensor with respect to the normal coordinate, $\partial\alpha_{ij}/\partial u$, does not vanish when evaluated at the equilibrium position; then the dynamic polarizability, which is induced by vibration, is nonzero. Infrared vibrational transitions are allowed when at least one derivative of the dipole moment (transition dipole moment) does not vanish at the equilibrium position.

As with phonons in solids, symmetry arguments show that vibrational Raman scattering of a given mode is allowed if there is an α_{ij} that belongs to the same symmetry species, i.e., transforms the same way under symmetry operations, as does that mode (Long, 1977). Vibrations cannot be both Raman and IR active in molecules with a center of symmetry. The vibrational mode in homonuclear diatomic molecules, such as N_2, is Raman active and IR inactive. In linear symmetric triatomic molecules, like CO_2 (O–C–O), the symmetric stretch is Raman active and IR inactive, while the asymmetric stretch and the two degenerate bending modes are Raman inactive and IR active.

In molecules without a center of symmetry, modes can be both Raman and IR active. The vibrational mode in heteronuclear diatomic molecules, like HF, is both Raman and IR active, as are the three modes (asymmetric stretch, symmetric stretch, and bend) in nonlinear triatomic molecules, like H_2O. When the molecular symmetry is low, most or all modes may be both Raman and IR active, though the relative strengths of the Raman and IR modes may be very different for different modes.

In vibrational Raman scattering from a given mode of frequency ω_v with quantum number v, the Stokes spectrum corresponds to $\Delta v = 1$, as is seen for several different modes in liquid CCl_4 in the inset in Fig. 10(b), while the anti-Stokes spectrum corresponds to $\Delta v = -1$. Stokes transitions from $v = 0 \rightarrow 1$ dominate, but at higher temperatures Stokes scattering from higher v can occur. This scattering is weaker by $(v + 1) \times \exp(-v\hbar\omega_v/kT)$, and has slightly smaller shifts because of anharmonicity. Vibrational Raman cross sections have been compiled for many gases and liquids (Schrotter and Klockner, 1979). Typically, the vibrational Raman cross section per molecule is ~4× larger in a liquid than in a gas because of the effect of internal electric fields. Spontaneous and stimulated vibrational Raman scattering has been examined in numerous liquids (Fig. 10). Higher-order Stokes SRS peaks are also often seen. Thresholds for SRS are lower in liquid droplets because of morphology-dependent resonances (MDR) (Fig. 10) (Qian and Chang, 1986).

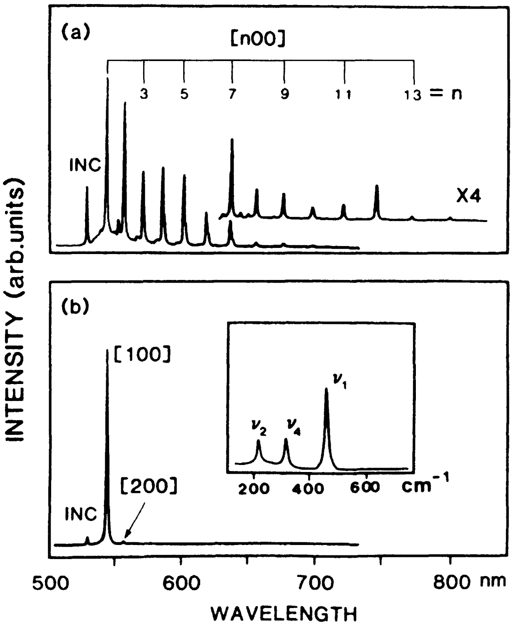

FIG. 10. Vibrational stimulated Raman scattering in (a) a CCl_4 droplet showing several higher-order Stokes lines for the ν_1 mode and in (b) liquid CCl_4 showing a strong first-order peak and a weak second-order peak. The inset shows spontaneous Raman scattering from several vibrational modes in liquid CCl_4 (Qian and Chang, 1986).

In gases, there is further structure due to changes in the rotational quantum numbers, giving rise to rotational–vibrational Raman scattering (Long, 1977). There is similar structure in pure rotational Raman scattering ($\Delta v = 0$), which has Stokes and anti-Stokes branches on either side of the Rayleigh-scattered peak as seen in Fig. 11. In linear molecules, such as N_2 and CO_2, where the rotational quantum number is J, the selection rules for rotational–vibrational scattering from totally symmetric vibrational species are $\Delta J = 0, \pm 2$; for pure rotational scattering, the selection rule is $\Delta J = 0, +2$. For degenerate vibrational species, $\Delta J = \pm 1$ is also allowed in rotational–vibrational scattering, and $\Delta J = +1$ for pure rotational scattering. The $\Delta J = -2, -1, 0, 1,$ and 2 branches are also called *O*, *P*, *Q*, *R*, and *S* branches, respectively.

In rigid-rotor approximation, the rotational energy of a linear molecule is $BJ(J + 1)$, where B is the rotational constant. In pure rotational scattering, the $\Delta J = +2$ selection rule gives rise to *S*-branch anti-Stokes lines at $\omega_i + (4J + 6)B$ [$J \geq 0$], which are upshifted in frequency by $6B$, $10B$, $14B$, ... relative to the laser line at ω_i, and *S*-band Stokes lines at $\omega_i - (4J - 2)B$ [$J \geq 2$], which are downshifted by $6B$, $10B$, $14B$, ... This is seen in Fig. 11 for N_2. These lines are equally spaced by $4B$, except for large J, where centrifugal deviations from the rigid-rotor model alter this spacing. Since ΔJ is often defined as $J' - J''$, where J' refers to the state with higher energy and J'' to that with lower energy, the selection rule for pure rotational scattering is formally $\Delta v = 0$, $\Delta J = +2$, for both Stokes and anti-Stokes scattering. The transition $\Delta v = 0$, $\Delta J = 0$ is actually Rayleigh scattering.

In rotational–vibrational Stokes scattering, the $\Delta J = \pm 2$ selection rule gives rise to a series of *S*-branch lines shifted down in frequency from the laser line ω_i by $\omega_v + 6B' + (5B' - B'')J + (B' - B'')J^2$ for $J \geq 0$ and *O*-branch lines shifted by $\omega_v + 2B' - (3B' + B'')J + (B' - B'')J^2$ for $J \geq 2$, where B' and B'' are the rotational constants for the upper and lower vibrational levels, respectively. (For Stokes scattering, these are the final and initial states, respectively.) These bands look qualitatively like those in pure rotational Raman scattering except that since usually $B' < B''$, the spacing of the *O*-branch lines increases with J, while the spacing of *S*-branch lines decreases with J. For large enough J, the shifts of *S*-branch lines may no longer increase with J but reverse sign to form a bandhead. The $\Delta J = 0$ selection rule gives *Q*-branch lines at $\omega_v + (B' - B'')J + (B' - B'')J^2$, which are closely spaced, sometimes overlapping to form a big peak, and are near but usually less than ω_v.

In symmetric-top molecules, such as H_2O

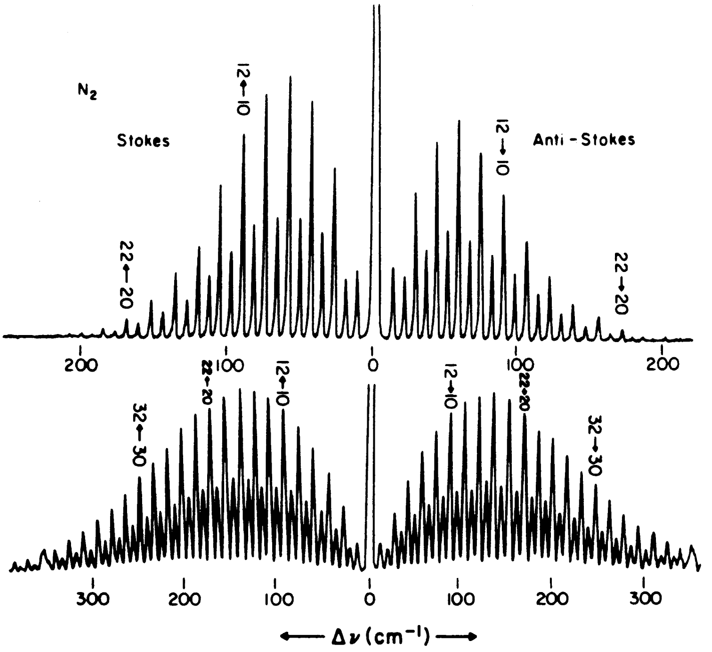

FIG. 11. Pure rotational Raman scattering in N_2 gas at 300 K (top) and at 1582 K in a H_2 diffusion flame (bottom), showing Stokes and anti-Stokes scattering (Drake, 1988).

and NH_3, there is additional rotational structure that results from the quantization of the projection of the rotational angular momentum J on the molecular axis, which is described by the quantum number K (Long, 1977). The selection rules for rotational–vibrational scattering from totally symmetric vibrational species are $\Delta J = 0, \pm 1, \pm 2$ and $\Delta K = 0$; for other vibrational species $\Delta K = \pm 1$ or ± 2 are sometimes allowed. The selection rule for rotational–vibrational scattering from totally symmetric vibrational species in spherical-top molecules, such as SF_6, is $\Delta J = 0$; for degenerate vibrational species $\Delta J = \pm 1, \pm 2$ are also allowed. In each case, the selection rules for pure rotational scattering are the same, except that negative ΔJ possibilities are excluded.

The relative strengths of the rotational lines depend on the product of the thermal population of the rotational state and the rotational matrix element (Long, 1977; Weber, 1979). The alternating line-intensity pattern sometimes seen in rotational Raman spectra is due to nuclear-spin statistics, such as the 2:1 ratio seen for N_2 in Fig. 11. The total scattering cross section of a rotational–vibrational Raman band is obtained by summing the rotational transitions, and is equal to the cross section of a space-fixed, nonrotating molecule integrated over all possible orientations (Schrotter and Klockner, 1979). High-resolution rotational–vibrational Raman spectroscopy (Broderson, 1979) and high-resolution rotational Raman spectroscopy (Weber, 1979) have been studied in many gases.

7. APPLICATIONS IN MATERIALS CHARACTERIZATION, PROCESS DIAGNOSTICS, AND LASER DEVELOPMENT

Vibrational and electronic Raman scattering are widely used in *ex situ* materials characterization, including that for semiconductors (Pollak, 1991), polymers (Bulkin, 1991), and catalysts (Stencel, 1990; Mehicic and Grasselli, 1991). Many properties of semiconductors can be probed, including damage resulting from processing such as ion implantation and reactive ion etching, strain, interface quality, grain size and orientation, and doping levels. In vibrational Raman scattering, substitutional dopant atoms can be detected by their local vibrational modes, when they are lighter than the host, and their effects on the host modes due to disorder. Disorder caused by doping or other types of damage can lead to mode softening and broadening, and the relaxation of symmetry and polarization selection rules. For example, in backscattering from a (001) surface of a zinc-blende semiconductor, TO modes may be seen in addition to the normally allowed LO modes, and disorder-activated modes, such as the DATA (disorder-activated TA) modes, may appear. Free carriers due to dopants can scatter by single-particle and collective effects, and sometimes couple to phonons, as discussed in Sec. 5.2. To see the bulk $L_\pm$ modes in n-type zinc-blende semiconductors, the Raman probe depth must exceed the width of the surface depletion layer, where only LO phonons are seen (Fig. 8). Electronic Raman scattering of intersubband transitions in semiconductor quantum wells can be used to determine band offsets (Menendez and Pinczuk, 1988).

Spontaneous vibrational Raman scattering can be used as a real-time diagnostic of the region near the surface during thin-film processing, as during molecular-beam epitaxy (MBE) (Nowak *et al.*, 1992) and laser-assisted chemical vapor deposition (CVD) (Magnotta and Herman, 1986). The gas above the substrate can be probed by vibrational and rotational Raman scattering; pure rotational Raman scattering can measure gas temperature by determining the thermal population of rotational levels as is seen in Fig. 11. Spontaneous Raman scattering is also used in the remote sensing of the atmosphere, which is called Raman lidar (light detection and ranging) (She, 1990). CARS has been used to monitor the gas phase during thin-film processing and, quite extensively, in combustion diagnostics (Nibler and Yang, 1987; Eckbreth, 1996). Stimulated Raman scattering can be used to determine the chemical concentration and size of fuel droplets in combustion (Acker *et al.*, 1990).

Stimulated Raman scattering in gases and liquids can produce coherent light at the Stokes and anti-Stokes wavelengths, as well as at higher-order Stokes and anti-Stokes wavelengths. Higher-order vibrational anti-Stokes scattering of ArF lasers (193 nm) in H_2 gas has produced vacuum ultraviolet radiation to 138 nm (Eimerl *et al.*, 1981; Dobele and Ruckle, 1984), while rotational (first Stokes) Raman scattering of CO_2 lasers (10.6 μm) in p-H_2 has efficiently produced radiation near 17 μm (Midorikawa *et al.*, 1985). Laser pulse compression can be achieved by stimulated backward Raman scattering in gases or liquids by amplifying a weak laser beam at the Stokes frequency by a counter-propagating pump beam. This can produce a pulsed laser at the Stokes wavelength that is much shorter than the pump beam (Murray *et al.*, 1979). Free-electron lasers (FEL) can be operated in the collective Raman mode (Raman FEL) where the laser wavelength is in the mm range, as well as in the single-particle, Compton regime where the laser wavelength is commonly 0.3–10 μm (Marshall, 1985).

GLOSSARY

Anti-Stokes Scattering: Inelastic scattering where the photon gains energy and deexcites the medium.

CARS: Coherent anti-Stokes Raman scattering, where two pulsed laser beams at ω_1 and ω_2 ($\omega_1 > \omega_2$) intersect in a material to produce coherent light at $\omega = 2\omega_1 - \omega_2$.

Hyper-Raman Scattering: Coherent process where a harmonic of the incident laser beam is produced, which interacts with the medium by a Stokes or anti-Stokes process.

Stimulated Raman Scattering: Coherent, nonlinear process where the Raman-scattering rate is proportional to the number of photons at the scattering frequency.

Stokes Scattering: Inelastic scattering where the photon loses energy and excites the medium.

INTRODUCTION

Our main theme is the random motion of a particle. A random process that involves a time variable is also called a stochastic process. A physical approach to this problem, pioneered by Langevin, is to write a Newtonian equation of motion $F = Ma$ for a particle. One can include additive random forces, as well as noisy parameters. A frictional force and a force derived from a potential can be included, as well. This approach allows one to investigate random motion in a potential, where the force is written as minus the gradient of the potential. The force can be linear or nonlinear. Random motion in the linear force field of a harmonic potential is called an Ornstein–Uhlenbeck process. In the Langevin approach the particle is always in motion. In the random-walk approach, discussed below, a particle can become trapped and not move for a random length of time.

The variables in a Langevin equation, such as position and velocity, are random variables because they are determined, in part, by the noise terms in the equation. We describe how to find the time dependence of moments of these random variables. When calculating moments, the simplest case arises when the noise is uncorrelated with itself in time or space. The effect of noise correlation can, however, be of overriding importance. We will see in the Kubo oscillator example how time-correlated noise dramatically changes the high-frequency behavior of the moments of a noisy oscillator. Moments, however, only give limited information about a random process. All the possible information about a random process is contained in probability distributions. We will discuss the Fokker–Planck method for deriving an equation for the probability distribution for random variables in Langevin equations. Over all the Langevin and Fokker–Planck equations are the approach of choice when the random process is best described by an equation of motion with noisy terms.

A different approach to random processes is to work with the probabilities that govern changes in a particle's position, and not to write directly an equation for random variables. This has been called a random-walk or master-equation approach. The focus is on the elemental transition probability for the step of a particle. This is a powerful method

because it allows many complicated situations and features to be directly incorporated and analyzed. For example, we start with the case of a random walk where a particle makes jumps of random lengths in random directions, but then add several important generalizations. We let the time between jumps, and the jump velocity, become random. This even includes fractal probability distributions with infinite mean jump lengths and infinite mean waiting times between jumps. We can account for the random walker being restricted to a fractal space or placed in a disordered environment. Reaction processes that annihilate random walkers are also introduced. Over all the random-walk methods are the approach of choice when one wishes to model the elemental transitions in a random process.

1. A BRIEF HISTORY OF RANDOM PROCESSES

Man's conscious deliberation with random processes is as least as old as the ancient game of throwing the bones (David, 1962). The bones in question, called astrogali, are the heel bones of animals including dogs and sheep. These bones fit nicely in the hand and are the forerunners of dice. In fact, the French expression "jeu d'hasard" (games of hazard or chance) comes from the Arabic for dice, "al-zar" (Székely, 1986). In reality, gambling (from dice to actuarial tables to risk-benefit analysis) has always been in the forefront of expanding the frontiers of probability theory. The bones in question have only four faces upon which they come to rest. The four-sided spinning dreidel is the most similar, in this respect, to throwing of the bones. In ancient times a mathematics of probability did not arise. Perhaps this was because the early dice did not have equally likely outcomes and the occurrence of a rare event (landing on a less probable face) was ascribed to luck rather than sparking the development of the idea of the permanence of statistical ratios. On the other hand, a mathematics of probability also did not arise from the ancient Chinese *I Ching,* which has 64 equally likely outcomes. The *I Ching* was used as an oracle and perhaps has too many outcomes to provide the insight to inaugurate a new field of mathematics.

Despite some early writings on dice games, probability got its recognized start with a correspondence between Pascal and Fermat (Todhunter, 1865) in 1654 that cleared up a misconception between the probability to win and the expected winnings. Specifically, the expected number of sixes in four throws of a die is 4/6, which equals the expected number of pairs of sixes in 24 throws of a pair of dice. The probability to throw at least one six in four throws is $1 - (5/6)^4 \cong 0.5177$, and the probability to get at least one pair of sixes in 24 throws of a pair of dice is $1 - (35/36)^{24} \cong 0.4914$. Equal expectations do not imply equal probabilities. Having easily settled this matter, Pascal and Fermat wrestled with other problems such as how to split up the ante in games of chance that are not completed. With more than two players considered, these problems would tax many modern practitioners.

The Pascal–Fermat letters stimulated Huygens to write a treatise on probability theory. This, in turn, piqued the interest of Jacob Bernoulli, who turned his attention to questions of combinations and permutations, and games of chance. His works were published posthumously, in 1713, under the title *Ars Conjectandi* (Art of Conjecture). He introduced the Bernoulli process where a player has a probability p to win in each trial of a game, and probability $q = 1 - p$ to lose. We would today equate this to a random walk on a lattice by keeping track of a player's status along a one-dimensional axis, with success equated to a jump of one unit to the right, and failure a jump of one unit to the left. The probability $p_n(k)$ of k successes in n trials is given by $[n!/(n - k)!k!]p^k q^{n-k}$. In the limit of large n, and for $p = q$, DeMoivre showed, in 1756, that the probability to get $2h$ more successes than failures (or vice versa) in n Bernoulli trials is $(2\pi n)^{-1/2} \exp(-h^2/2n)$. This can be seen by expanding the factorials in $p_n(k)$ with $k = n/2 \pm h$. This probability function is today called a Gaussian because Gauss showed, in 1809, that DeMoivre's result holds in a more general situation. An intimate connection (Einstein, 1905) with these types of random-walk processes and Gaussian probabilities was later made to the phenomenon of diffusion called Brownian motion. For example, in Bernoulli's game (process) consider two players each starting with $R/2$ coins and with equal probability to win or lose a coin in each trial. The mean number of trials, $\langle N(R)\rangle$, before one player loses his fortune can be calculated to be $R(R + 1)/6$, and for large R, $\langle N(R)\rangle \approx R^2$. In Brownian motion, the mean-square distance a particle moves after N steps satisfies $\langle R^2(N)\rangle \approx N$.

Poisson, in the 1830s, found another possible limit for the Bernoulli process; let $p \to 0$ and $n \to \infty$ such that $np \to \lambda$, a constant. Then $p_n(k) = n(n - 1) \cdots (n - k + 1)\, p^k(1 - p)^{n-k}/k! \approx (np)^k e^{-np} e^{pk}/k! \approx \lambda^k e^{-\lambda}/k!$. This is called a Poisson probability distribution. Poisson wrote a book on probability, but devoted to social problems, such as the probability of a jury reaching the correct verdict.

Over in London, Bernoulli's contemporary De Moivre wrote, in 1718, the first edition of his famous treatise on probability, *The Doctrine of Chances,* which provided explicit odds for popular card games and, more importantly, introduced new concepts, including the use of generating functions, Sterling's formula for $\log(n!)$, the derivation of the formula $(\cos\vartheta + i\sin\vartheta)^n = \cos n\vartheta + i \sin n\vartheta$, and the proof that the Gaussian is the many-trial limit of a Bernoulli process (in the 1756 3rd edition). The Gaussian (also called the normal) is the probability distribution for a *sum* of identically distributed random variables with finite second moments. It was not until 1879 that MacAlister introduced the distribution for a *product* of random variables called the log normal distribution, as it is a Gaussian in the logarithm of the variable. De Moivre's other probability book, *Annuities upon Lives,* inaugurated actuarial science. Laplace in his 1815 treatise *Theorie Analytique des Probabilites* continued the tradition of introducing new tools in applied mathematics through probability. Before Laplace, most work in probability focused on the discrete, where all the possible outcomes of a trial could be enumerated. Card and dice games are good examples of this genre. Laplace brought the integral and continuum mathematics to the fore of probability theory with questions like: If an urn contained an infinite number of black and white tickets and one chooses A tickets of which p turn out to be white and q are black, then what is the probability that if an additional B tickets are chosen, m are white and n are black. Laplace's solution,

$$\frac{\int_0^1 x^{p+m}(1 - x)^{q+n}dx}{\int_0^1 x^p(1 - x)^q dx}, \qquad (1)$$

led the way for calculating a wide variety of integrals, many of which are well known today.

Despite opposition to probability as a real mathematics, due to a number of seeming paradoxes, and prohibitions from church and state, due to its gambling connections, the ideas set in motion by the above-mentioned books would spread and be carried on by new generations. Poisson's book found its way to Russia where Chebyshev read it and did his 1846 Master's thesis on probability, and also started a school in this area. His star students were Markov and Lyapunov whose Markov chains and Lyapunov exponents are of great importance in modern work. Kolmogorov, in Russia, placed probability on a secure mathematical foundation. The early 1900s saw the introduction of Brownian motion by Einstein and Bachelier, and reaction kinetics by Smoluchowski. Langevin, in 1908, studied equations of motion with an additive random force. Jumping over potential barriers in noisy systems (Pontryagin *et al.,* 1933; Kramers, 1940) initiated the field of noise-induced transitions. Schottky (1922) studied the phenomenon of shot noise in diodes. Specifically, if electrons arrive at a detector with a rate ν and cause a decaying time-dependent current $i(t)$, then the total measured current is

$$I(t) = \sum_{j=1}^{\infty} i(t - T_j),$$

where T_j represents the past arrival time of the jth electron. This shot noise has an average value of $\nu\int_0^\infty i(t)dt$ and variance $\nu\int_0^\infty i^2(t)dt$. This is also known as Campbell's theorem to mathematicians, and it was introduced in 1909. Chandrasekhar's review of random processes (Chandrasekhar, 1943), including random walks, Brownian motion, escape over barriers, and stellar dynamics, dominated the field for many years. Rice (Wax, 1954) reviewed advances in analyzing noise in electrical devices. The analysis of telephone switching systems, by Fry at Bell Telephone in the 1920s and by Erlang in Denmark in the 1940s, produced advances in the statistical dynamics of congestion of networks. Fisher and Tippett (1928) introduced extreme-value theory to find the largest or the smallest value from a set of random variables. Statistical physics focused on noise, for its own intrinsic properties, and introduced the master equation, entropy, and fluctuation–dissipation theorems. Lévy, in the 1920s and 1930s, introduced scale-invariant random walks and distributions for random variables with infinite moments, which were an important precursor for the field of fractals. Such a wide variety of problems depend on probability that we cannot cover all the major topics and will omit many important problems including random-matrix theory, random fields, Ising-model dynamics, combinatorics, queuing theory, reliability theory, stochastic resonance, Monte Carlo techniques, signal processing, random-growth models, multifractals, and quantum probabilities.

2. GAUSSIAN RANDOM WALKS

Bernoulli's gambling problem allowed one's fortune to increase or decrease in discrete amounts. This is equivalent to a random walk on a lattice. Consider a random walk that starts at the origin of a lattice. We begin by choosing the probability $p(l)$ for the walker in one transition to change its position by l lattice spacings. All probabilities can be written in terms of $p(l)$ and the initial condition. The probability to be at site l after $n + 1$ steps is denoted by $P_{n+1}(l)$ (see Fig. 1 for a two-dimensional example), which we can write in one dimension as

$$P_{n+1}(l) = \sum_{l'} P_n(l - l')p(l'). \tag{2}$$

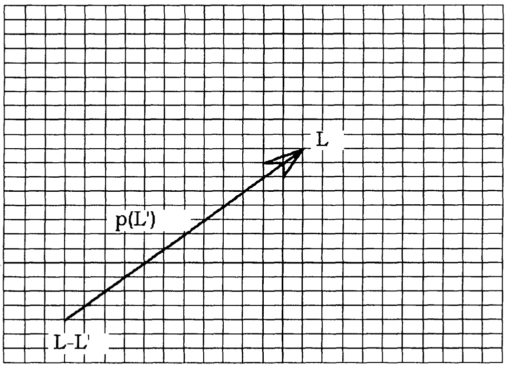

FIG. 1. A finite part of an infinite two-dimensional lattice. For a random walker on this lattice to reach site L after $n + 1$ steps, the walker first reaches some intermediate site $L - L'$ after n steps and then makes a transition with a displacement of L' at the next step with probability $p(L')$. A sum over all possible L' is necessary, as performed in Eq. (2), to obtain the probability to be at site L on the nth step.

Let us introduce the discrete Fourier transform $\tilde{p}(k)$ defined by

$$\tilde{p}(k) \equiv \sum_{l} \exp(ikl)p(l). \tag{3}$$

Fourier transforming $P_n(l)$ we have, since Eq. (2) is in the form of a convolution,

$$\tilde{P}_n(k) = [\tilde{p}(k)]^n$$

or

$$P_n(l) = \frac{1}{2\pi}\int_{-\pi}^{\pi} [\tilde{p}(k)]^n \exp(-ikl)dk. \tag{4}$$

For an unbiased random walk with no preferred direction, $\tilde{p}(k)$ is real and has a maximum value of 1 at $k = 0$. For example, a random walk with equal probabilities of $\frac{1}{2}$ to jump to the right or left one lattice site has $\tilde{p}(k) = \cos(k)$. For large n, $[\tilde{p}(k)]^n$ is small, except at and near $k = 0$. This implies that for large n (many jumps of a random walk) the integral in Eq. (4) is dominated by small values of k, and so we use a small-k expansion of $\tilde{p}(k)$ to calculate the large-n behavior of $\tilde{P}_n(k)$. We start by expanding the exponential in Eq. (4) for small k,

$$\begin{aligned}\tilde{p}(k) &= \sum_{l} [1 + ikl - \tfrac{1}{2}k^2l^2 + \cdots]p(l)\\ &= 1 + ik\langle l\rangle - \tfrac{1}{2}k^2\langle l^2\rangle + \cdots,\end{aligned} \tag{5}$$

where the moments of the jump distributions are defined as $\langle l^n\rangle \equiv \Sigma_l l^n p(l)$. For the sake of simplicity let us assume that jumps occur with equal probabilities to the right and left so that $\langle l\rangle = 0$, and that $\langle l^2\rangle$ is finite. Then, for small k values,

$$[\tilde{p}(k)]^n \approx \exp\left(-\frac{n}{2}\langle l^2\rangle k^2\right), \tag{6}$$

which is Gaussian in k. We can now extend the limits on the integral in Eq. (4) from $-\infty$ to $+\infty$ without significant error because the integrand, for large n, has a sharp maximum around $k = 0$. This yields the important result

$$P_n(l) = \frac{1}{\sqrt{2\pi\langle l^2\rangle n}} \exp\left(-\frac{l^2}{2\langle l^2\rangle n}\right) \tag{7}$$

for a many-step symmetric random walk with a finite $\langle l^2\rangle$ (see Fig. 2). This result of adding identically distributed random variables with finite second moments and arriving at a Gaussian distribution is known as the central limit theorem. This so impressed F. Galton that he wrote, "I know of scarcely anything so apt to impress the imagination as the wonderful form of cosmic order expressed by the Law of Frequency of Error. The law would have been personified by the Greeks and deified, if they had known of it. The larger the mob and the greater the apparent anarchy, the more perfect its sway." The Gaussian was originally applied to discuss errors in measurement, with its peak being the most probable value of the measurement and its variance related to typical errors in the measurement. The Maxwell–Boltzmann distribution is Gaussian in particle velocities, but the whole distribution has physical meaning, so that being away from the mean is not an error. In fact the whole distribution is a prediction. This was a major advance in thought.

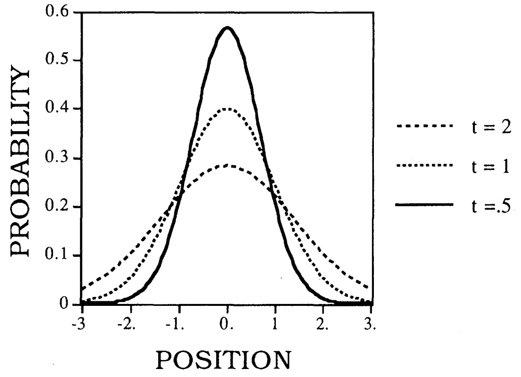

FIG. 2. Gaussian spreading. We let the number of steps become a continuous variable equivalent to the time and plot the spreading with time of a Gaussian probability. The variance of the distribution grows linearly with time.

It can be shown, via the Berry–Esséen theorem (Feller, 1971), that the value of n at which Gaussian behavior emerges is $n \approx (25/4)\langle |l^3| \rangle^2/\langle l^2\rangle^3$. The probability $P_n(l)$ satisfies the diffusion equation when we let the number of steps n and the distance l become continuous variables,

$$\frac{\partial P(l,n)}{\partial n} = D\frac{\partial^2 P(l,n)}{\partial l^2}, \tag{8}$$

with $D = \langle l^2\rangle/2\langle t\rangle$ where $1/\langle t\rangle$ is introduced as a jump rate. This is also known as the heat equation, and Bachelier, in 1900, was amazed to discover that probability could radiate in the same fashion as heat.

While the central limit theorem is very powerful, there are many situations where it does not apply. One can ask questions about the first time a random walk reaches a certain distance from its origin, or the maximum of a set of random variables, or the conditional probability for a random walker to be at a site now, given that it was at another site at an earlier time, or the probability distribution for a random walker whose mean jump distance is infinite, etc. This means that, although the Gaussian distribution plays a central role in probability theory connected to summing random variables, it is only one of many important limit theorems.

The above analysis was for a simple walk on a one-dimensional regular lattice. We began by writing down directly the transition probability for a single step. A different approach for investigating the random motion of a particle is to employ a stochastic differential equation of motion for a particle's position or velocity (the Langevin approach) and then calculate via a partial differential equation (the Fokker–Planck equation) the probability for the particle being at position x at time t. We turn to the Langevin approach now, before returning to more complex random-walk models.

3. LANGEVIN EQUATIONS

One of the major themes in probability is the mathematics of Brownian motion and its variants. The original work of Einstein involved a large Brownian particle in a fluid being buffeted continuously by smaller fluid particles. If the Brownian particle has mass M and random velocity, denoted by v, then the equation of motion for the Brownian particle's dynamics is

$$M\frac{dv}{dt} = -fv + F(t), \tag{9}$$

where mass times acceleration is on the left-hand side (LHS) and the forces are on the right-hand side (RHS). The term f is the friction coefficient and $F(t)$ is a random force representing random collisions of the Brownian particle with the smaller fluid particles. An $F = Ma$ equation that involves random forces and/or parameters is called a Langevin equation. Although, one can readily solve for $v(t)$ as

$$v(t) = v(0)e^{-\beta t} + e^{-\beta t}\int_0^t e^{\beta\tau}A(\tau)d\tau, \tag{10}$$

where $\beta = f/M$ and $A = F/M$, one cannot directly evaluate $v(t)$ because it is a random variable, which is written in terms of $A(t)$, the random force per mass. One can, however, determine the probability distribution for values of v, or of related random variables such as the position $r(t)$, which is related by $v(t) = dr(t)/dt$. To proceed further, one must consider the statistical properties of the noise. A straightforward case, called white noise, is uncorrelated noise. A white-noise random force has the properties, where the brackets indicate a time average,

$$\begin{aligned}&\langle F(t)\rangle = 0,\\ &\langle F(t=0)F(t)\rangle = 2D\delta(t).\end{aligned} \tag{11}$$

The choice of white noise yields $\langle v(t)\rangle = v(0)e^{-\beta\tau}$, and $\langle v^2(t)\rangle = \beta D + [v(0)^2 - \beta D] \times \exp(-2\beta t))$. In the long-time (equilibrium) limit $\frac{1}{2}M\langle v^2\rangle$ must be equal to $k_BT/2$, the energy of the system. Thus the choice of D is not arbitrary, but must be $D = k_BT/\beta M$. One can also solve for the moments of $r(t)$. Integrating Eq. (10) one obtains

$$\begin{aligned}r(t) = r(0) + \frac{v(0)}{\beta}(1 - e^{-\beta t})\\ - \frac{1}{\beta}e^{-\beta t}\int_0^t e^{+\beta\xi}A(\xi)d\xi + \frac{1}{\beta}\int_0^t A(\xi)d\xi.\end{aligned} \tag{12}$$

Taking averages over values of A and initial velocities $v(0)$ one obtains $\langle r(t)\rangle = r(0)$. Squaring Eq. (12) and again taking double averages over the random forces and initial velocities one obtains the classic Brownian-motion result,

$$\langle r^2(t)\rangle = \frac{2k_BT}{M\beta}t = \frac{2k_BT}{f}t = 2Dt, \tag{13}$$

plus terms that decay exponentially with time. In his theory of Brownian motion, Einstein wrote specifically $\beta = 6\pi a\eta/M$, which is Stokes's law for a spherical particle of radius a and mass M, in a fluid with viscosity η.

The next challenge is to find the probability distribution of these stochastic variables, not just their moments. Before we address this matter, we mention that Eq. (9) can be easily generalized to govern Brownian motion in a potential by adding the force term $K(x)/M$ to the RHS. For a harmonic potential (the Ornstein–Uhlenbeck problem) $K(x)/M = -\omega^2x$, and this produces an oscillatory decay to the equilibrium value of zero for the mean position (and also the mean velocity), i.e.,

$$\begin{aligned}\langle r(t)\rangle = \frac{Mv(0)}{\omega}e^{-(1/2)\beta t}\sin\omega t\\ + \frac{r(0)}{\omega}e^{-(1/2)\beta t}\left(\omega\cos\omega t + \frac{\beta}{2}\sin\omega t\right).\end{aligned} \tag{14}$$

Expressions can be similarly calculated for the second spatial and velocity moments with oscillatory decays to equilibrium values, as opposed to the exponential decays when only the frictional force is present.

3.1 Kubo Oscillator

Consider randomness entering through a multiplicative factor in a stochastic differential equation. A classic problem is an oscillator (Kubo, 1962) with amplitude $x(t)$ and fluctuating frequency $\omega(t)$. This process satisfies the equation

$$\frac{dx(t)}{dt} = i\omega(t)x(t),$$

with the first moment given by

$$\langle x(t)\rangle = \left\langle \exp\left(i \int^{t} \omega(t')dt'\right)\right\rangle. \tag{15}$$

Because $\omega(t)$ is fluctuating, $x(t)$ is a random variable. We will not calculate the probability distribution for x, but will only concentrate on its first moment here, and the effect of colored noise on this behavior. For $\omega(t) = \omega_0 + \delta\omega(t)$, with $\langle\delta\omega(t)\rangle = 0$, the frequency fluctuates around the mean value ω_0. If $\delta\omega(t)$ possesses Gaussian statistics, then

$$\begin{aligned}\langle x(t)\rangle &= e^{i\omega_0 t}\exp\left(-\tfrac{1}{2}\int_0^t dt' \int_0^t dt''\langle\delta\omega(t')\delta\omega(t'')\rangle\right)\\ &= e^{i\omega_0 t}\exp\left(-\int_0^t (t - t')\langle\delta\omega(t')\delta\omega(0)\rangle dt'\right).\end{aligned} \tag{16}$$

If $\langle\delta\omega(t)\delta\omega(0)\rangle = 2\lambda\delta(t)$, then it follows that

$$\langle x(t)\rangle = e^{i\omega_0 t}e^{-\lambda t}. \tag{17}$$

The relaxation function, defined by $\Phi(t) = \exp(-\lambda t)$, leads to the line-shape spectrum $I(\omega)$, defined as

$$\begin{aligned}I(\omega - \omega_0) &= \frac{\mathrm{Re}}{2\pi}\int_{-\infty}^{\infty} \exp[i(\omega - \omega_0)]\Phi(t)dt\\ &= \frac{1}{\pi}\frac{\lambda^2}{(\omega - \omega_0)^2 + \lambda^2}.\end{aligned} \tag{18}$$

The effect of the noisy frequency was to broaden the line shape around the peak at ω_0.

Temporally correlated "colored" noise can lead to other line shapes. If $\langle\delta\omega(t)\delta\omega(0)\rangle = (D/\tau)\exp(-|t|/\tau)$, then for $t \ll \tau$, $(\tau/D) \times \langle\delta\omega(t)\delta\omega(0)\rangle \approx 1$, and so Eq. (16) yields, for short times,

$$\langle x(t)\rangle = e^{i\omega_0 t}\exp\left(-\frac{D}{2\tau}t^2\right) \quad \text{for } t \ll \tau. \tag{19}$$

The line shape generated by this Gaussian relaxation at short times is a Gaussian at large frequencies. For long times $t \gg \tau$, $\langle\delta\omega(t)\delta\omega(0)\rangle \approx 0$, i.e., the correlation has decayed away, and so one can replace the upper limit in the last integral in Eq. (16) by infinity and recover the exponential decay of the delta-correlated noise case (effectively the $\tau = 0$ case) and Lorentzian line shape of Eq. (18) at low frequencies. This crossover from a Lorentzian to a Gaussian line shape at $\omega = 1/\tau$ illustrates the crucial role that correlated "colored" noise can play in random processes.

Equation (18) is also called a power spectrum. In general, take a random time series $h(t)$ whose mean is zero. Let $h(t)$ be zero outside a time interval T and represent $h(t)$ in terms of its Fourier transform

$$h(t) = \int_{-\infty}^{\infty} \exp(2\pi i f t)g(f)df.$$

The power spectrum $S(f)$ can be defined as

$$S(f) = \lim_{T\to\infty}\frac{2}{T}|g(f)|^2. \tag{20}$$

That also

$$4\mathrm{Re}\int_{-\infty}^{\infty}\langle h(t + \tau)h(t)\rangle \exp(2\pi i f\tau)d\tau = S(f)$$

is called the Wiener–Khintchine theorem. If the correlation function is the product of an electrical current at two different times, then its power spectrum reflects the electric power as a function of frequency; hence the appellation of power. The Lorentzian power spectrum of Eq. (18) arises from a correlation function that decays exponentially. In many complex systems one finds a noise power spectrum, for low frequencies, of the form $S(f) \approx 1/f^{\alpha}$ where α is close to unity. This is called one-over-f noise. One method to derive $1/f$ noise is to have an exponentially decaying correlation $\exp(-t/\tau)$ with a distribution of correlation times $\rho(\tau) \approx \tau^{-1-\alpha}$. This produces $S(f) \approx 1/f^{1-\alpha}$. It is still an open question to determine the physics underlying $1/f$ noise in many complex systems (Weissman, 1988).

4. PROBABILITY EQUATIONS

4.1 The Chain Equation and the Master Equation

To describe fully a stochastic process $X(t)$ one must know all the joint probabilities,

$$P_n(x_1,t_1;\cdots;x_n,t_n) \quad \text{for all } n,$$

i.e., that at time t_i, the variable $X(t)$ has the value x_i, for $i = 1, \ldots, n$. Alternatively, one can describe $X(t)$ by defining joint conditional probabilities W_n for $X(t)$ to have the value x_n at time t_n when the earlier values x_i at t_i are given for $i = 1, \ldots, n - 1$. The probability P_n can be written as

$$P_n(x_1,t_1;\cdots;x_n,t_n) = W_n(x_n,t_n|x_1,t_1;\cdots;x_{n-1},t_{n-1}) \times P_{n-1}(x_1,t_1;\cdots;x_{n-1},t_{n-1}). \tag{21}$$

Knowing P_1 and all the W_n also completely specifies $X(t)$. A Markov process is defined by

$$W_n(x_n,t_n|x_1,t_1;\cdots;x_{n-1},t_{n-1}) = W_2(x_n,t_n|x_{n-1},t_{n-1}),$$

where the value of x_n depends only on x_{n-1} and the probability of transitioning from x_{n-1} to x_n. The earlier information of the x_{n-i} does not affect the outcome of the next step in a Markov process. For a Markov process the conditional probabilities satisfy the famous Bachelier–Smoluchowski–Chapman–Kolmogorov chain equation

$$W_2(x,t|x_0,t_0) = \int W_2(x,t|x',\tau)W_2(x',\tau|x_0,t_0)dx', \tag{22a}$$

where we considered going from x_0 to x in two steps, and we have integrated over all possible intermediate states x'. One can also write the chain equation as

$$\frac{\partial P(x,t)}{\partial t} = \int [K(x,x')P(x',t) - K(x',x)P(x,t)]dx', \tag{22b}$$

which is called a master equation (Oppenheim *et al.*, 1977). To derive the master equation from the chain equation all the initial conditions have been integrated out, so that $P(x,t)$ is the probability to be at state x at time t independent of the initial condition. The quantity $K(x,x')$ is the transition rate (it has the dimension of a frequency) for the system to change from state x' to state x. The derivative measures the rate of change with time of the probability to be in state x. The first term in the integral gives the rate of the system moving into state x from state x' (integrated over all x') times the probability that the system is in state x', while the second term calculates the rate for leaving state x times the probability that the system is in state x. In our discussion of continuous-time random walks we will study semi-Markovian (temporal, but no spatial, memory) processes where a trapping of a random walker occurs between each of its jumps. For these random-walk processes, an integro-differential master equation arises with an integral over all possible waiting times in a trap [see Eq. (52)].

4.2 Fokker–Planck Equations

From the chain equation, for only small transitions in x allowed, we can derive a second-order differential equation for $P(x,t)$. Let us denote W_2 in Eq. (22a) as P and look, following Wang and Uhlenbeck (Wax, 1954), at

$$\int dyR(y)\frac{\partial P(y,t|x,0)}{\partial t},$$

where $R(y)$ is an arbitrary function that asymptotically goes to zero at infinity. We can write the above derivative as

$$\lim_{\Delta t\to 0}\frac{1}{\Delta t}[P(y,t+\Delta t|x,t) - P(y,t|x,t)] = \lim_{\Delta t\to 0}\frac{1}{\Delta t} \times \left[\int [P(y,t+\Delta t|z,t')P(z,t'|x,t)dz - P(y,t|x,y)\right], \tag{23}$$

where we have used the chain equation (22a). Expanding $R(y)$ in a Taylor series up to the second derivative and using Eq. (23) for the derivative produces the following equation for $P(x,t)$, called the Fokker–Planck equation:

$$\frac{\partial P(x,t)}{\partial t} = -\frac{\partial}{\partial x}[A(x)P(x,t)] + \tfrac{1}{2}\frac{\partial^2}{\partial x^2}[B(x)P(x,t)], \tag{24}$$

where $A(x)$ is related to the first moment of $P(x,t)$ as

$$A(x) = \lim_{\Delta t\to 0}\frac{1}{\Delta t}\int P(y,\Delta t|x,t=0)(x-y)dy$$

and $B(x)$ is the same expression as above, except that the second moment of P appears through $(x - y)^2$ replacing $(x - y)$. These two terms on the RHS of Eq. (24) represent drift and diffusion in a force field. Although the expansion for $R(y)$ can be carried out to higher-order terms, they are usually small unless large jumps occur. In that case the full master equation should be used, as we do in our discussion of fractal processes. Setting the time derivative equal to zero, in Eq. (24), one has the following steady-state solution:

$$\lim_{t\to\infty} P(x,t) = \frac{\text{const.}}{B(x)} \exp\left(\int^x \frac{A(x')}{B(x')}\,dx'\right), \tag{25}$$

where the constant is chosen to insure normalization. When the first moment vanishes because there is no preferred direction, and the second moment is a constant, denoted by D, the Fokker–Planck equation reduces to the familiar diffusion equation.

The Ornstein–Uhlenbeck process for random motion in a harmonic potential has $A(x) = -\omega^2 x$, $B =$ constant. The solution of the Fokker–Planck equation for $P(x,t)$ is then

$$P(x,t) = \frac{1}{\sqrt{2\pi\sigma^2(t)}} \exp\left\{-\frac{x^2}{2\sigma^2(t)}\right\}, \tag{26a}$$

where

$$\sigma^2(t) = \frac{D}{\omega^2}[1 - \exp(-2\omega^2 t)]. \tag{26b}$$

In the long-time, steady-state limit $\omega \to 0$, $\sigma^2(t) \to 2Dt$, which brings us back to the Brownian-motion limit.

In general, a Langevin equation of the form

$$\frac{dx(t)}{dt} = F(x(t)) + G(x(t))\eta(t), \tag{27}$$

with

$$\langle \eta(t)\eta(t')\rangle = 2D\delta(t - t'),$$

has the probability $P(x,t)$ governed by the Fokker–Planck equation

$$\frac{\partial P(x,t)}{\partial t} = -\frac{\partial F(x)P(x,t)}{\partial x} + D\frac{\partial}{\partial x} G(x)\frac{\partial G(x)P(x,t)}{\partial x}. \tag{28}$$

However, when a finite-correlation-time "colored" noise, e.g.,

$$\langle \eta(t)\eta(0)\rangle = (D/\tau)\exp(-|t|/\tau), \tag{29}$$

is required, a more complicated situation arises. Many techniques (Moss *et al.*, 1990) have been derived to treat stochastic differential equations with colored noise using expansions and infinite resummation in powers of D or τ.

5. RANDOM WALKS

5.1 Discrete-Time

Let us return to Eq. (2) for $P_n(l)$ and define the *generating function* $G(l;z)$ as

$$G(l;z) \equiv \sum_{n=0}^{\infty} P_n(l) z^n. \tag{30}$$

Multiplying both sides of Eq. (2) by z^{n+1} and summing over all n yields, for a walker that starts at the origin,

$$G(l;z) - z\sum_{l'} G(l - l';z)p(l') = \delta_{l,0}, \tag{31}$$

i.e., the random-walk generating function satisfies a Green's-function equation. Fourier transforming Eq. (31) gives an algebraic equation for $\tilde{G}(k;z)$, with the solution

$$\tilde{G}(k;z) \equiv \sum_{l} \exp(ikl) G(l;z) = \frac{1}{1 - z\tilde{p}(k)}. \tag{32}$$

For the case of nearest-neighbor transitions $p(l) = \frac{1}{2}[\delta_{l,-1} + \delta_{l,+1}]$, we have

$$\tilde{p}(k) = \cos(k) \tag{33}$$

and

$$P_n(l) = \frac{n!}{[\frac{1}{2}(n + l)]![\frac{1}{2}(n - l)]!} 2^{-n}. \tag{34}$$

This is the expression DeMoivre analyzed for $n/2 + l/2$ successes (jumps to the right) and $n/2 - l/2$ failures (jumps to the left) in n Bernoulli trials. He showed that $P_n(l)$ is Gaussian in the large-n limit. This is true for any symmetric random-walk process with finite mean squared jump lengths, as Gauss proved in 1809 in his central limit theorem.

The generating-function formalism is also good for calculating first-passage times. The probability $F_n(l)$ that a walker reaches site l for the first time on the nth step enters the following equation:

$$P_n(l) = \sum_{j=1}^{n} F_j(l)P_{n-j}(0) + \delta_{n,0}\delta_{l,0}, \tag{35}$$

which accounts for being at l after n steps by first reaching l after j steps and then leaving and returning to l in $n - j$ steps (for all possible j values). Multiplying Eq. (35) by z^n, and summing over all n, gives the generating-function equation

$$G(l;z) = \delta_{l,0} + F(l;z)G(l = 0;z), \tag{36}$$

where

$$F(l;z) \equiv \sum_{j=0}^{\infty} F_j(l)z^j.$$

This shows that knowledge of $G(l;z)$ allows the calculation of the first-passage-time generating function. The Green's function for return to the origin, which appears on the RHS of Eq. (36), has been calculated, for nearest-neighbor jumps, for z close to 1:

$$G(l = 0;z) = \left(\frac{1}{2\pi}\right)^D \int_0^{2\pi} \cdots \int_0^{2\pi} \frac{d^Dk}{1 - \frac{z}{D}[\cos(k_1) + \cdots + \cos(k_D)]}$$
$$= \begin{cases} (1 - z^2)^{-1/2} & \text{for } D = 1, \\ \approx -\frac{1}{\pi}\log(1 - z) & \text{for } D = 2, \\ \approx 1.516 - \frac{3}{\pi}\sqrt{\frac{3}{2}(1 - z)} & \text{for } D = 3. \end{cases} \tag{37}$$

The 2D result is for a square lattice and the 3D result is for a cubic lattice. The manner in which $G(l = 0;z)$ diverges near $z = 1$ is important for calculating first–passage-time probabilities. Consider Polya's question of what is the probability for a symmetric random walker with $\langle l \rangle = 0$, on a regular lattice, to return to its origin. This probability of return, R, is given as

$$R = \sum_{n=0}^{\infty} f_n(0) = F(l = 0;z = 1) = 1 - \frac{1}{G(0;1)}, \tag{38}$$

where we have used Eq. (36). We see from Eq. (37) that $G(0;1)$ diverges in one and two dimensions, and is finite in higher dimensions, yielding Polya's famous result that return to the origin is assured with probability 1 in one and two dimensions, but not in higher dimensions. The square-root divergence of the one-dimensional $G(0;1)$ in Eq. (37) implies that the probability that the walker has not returned by step n is

$$F_n(0) = \sum_{j=n+1}^{\infty} f_j(0) \approx \left(\frac{1}{n}\right)^{1/2}, \tag{39}$$

causing, in one dimension, that the mean number of steps

$$\langle n \rangle = \sum_{n=0}^{\infty} nf_n(0)$$

for the first return of a random walker to the origin is infinite. The walker returns with probability 1, but the mean time to do this is infinite.

What if N walkers start at the origin? Is the mean time for any one of this set to return to the origin also infinite (Lindenberg *et al.*, 1980)? The probability $f_{N,n}(0)$ that any walker from a group of N walkers returns on the nth step is, using Eq. (39),

$$f_{N,n}(0) = F^N_{n-1}(0) - F^N_n(0), \tag{40}$$

where the N on the LHS denotes the number of walkers and N is a power on the RHS.

The RHS is the difference between the probabilities that none of the walkers has returned by the $(n - 1)$st and the nth step. This difference is the probability that at least one walker returned on the nth step. The mean first time for a return to the origin from the set of N walkers is

$$\langle T_N \rangle = \sum_{n=1}^{\infty} n f_{N,n}(0) = \sum_{n=0}^{\infty} F_n^N(0). \qquad (41)$$

In one dimension $F_n(0) \approx \sqrt{1/n}$, and so the divergence of the mean return time for the set of N walkers depends on the series

$$\sum_{n=1}^{\infty} \left(\frac{1}{n}\right)^{N/2}. \qquad (42)$$

For three (or more) walkers, Eq. (42) determines that the mean time for return to the origin is finite. This further explores Polya's classic study of the effect of dimensionality on random-walk quantities.

There are several directions in which the generating-function approach to random walks can be naturally extended. One is to include finite memory of the walker's jump history. This can be accomplished through the use of internal states at each lattice site, say to keep track of whether a random walker came from the left or right. In one dimension if the probability for a walker to continue in the same direction is $p < 1$, and to change direction is $q = 1 - p$, then the generating-function method finds after many jumps that the probability density for the walker's position is Gaussian, as in Eq. (7), but with the extra factor p/q in the diffusion constant D.

Restricted reversal correlation can also be handled in terms of internal states. Suppose, in two dimensions, that a walker is not allowed to reverse its direction to go back immediately to its previous position. This is handled by having four states in a unit cell representing the four directions a walker could have come from, and not having a connecting path back to the reversed position. The mean squared displacement is doubled from the unrestricted walk, and for a periodic lattice with coordination number q, the mean squared displacement is enhanced by the factor $q/(q - 2)$ (Domb and Fisher, 1958). Correlation over a finite number of steps (Montroll, 1950) will only modify the diffusion constant, and not change the simple linear dependence on n (the number of steps) of the mean square displacement. One needs infinite correlation to go beyond simple asymptotic Gaussian probabilities for random walks with simple steps on a regular lattice. The self-avoiding random walk is one such example. This model forbids the walker to cross its own trajectory at any point. For a self-avoiding random walk on a three-dimensional cubic lattice one finds $\langle l^2(n) \rangle \approx n^{\gamma}$ with $\gamma \approx 6/5$.

5.2 Continuous-Time

So far we have treated random walks with steps taken at regular time intervals τ, 2τ, 3τ, ... We can generalize this by introducing a probability $\psi(t)dt$ for the interval between jumps to be between t and $t + dt$. The quantity $\psi(t)$ is called a waiting-time probability density, and it must be integrated over t to yield a probability. A quantity that we will find useful is $\Phi(t)$, the probability that a jump has not occurred by time t, since the previous jump. This is given by

$$\Phi(t) = 1 - \int_0^t \psi(\tau)d\tau. \qquad (43)$$

The probability density $\psi_2(t)$ that the interval between two consecutive jumps is t is given by

$$\psi_2(t) = \int_0^t \psi(t - \tau)\psi(\tau)d\tau. \qquad (44)$$

Similarly, we introduce $\psi_n(t) = \int_0^t \psi_{n-1}(t - \tau)\psi(\tau)d\tau$, and the Laplace transform of $\psi_n(t)$,

$$\psi_n^*(s) \equiv \int_0^{\infty} \psi_n(t) \exp(-st)dt = [\psi^*(s)]^n. \qquad (45)$$

If $\psi(t) = \lambda \exp(-\lambda t)$ then $\Phi(t) = \exp(-\lambda t)$. This represents a pure random process with a constant jump rate λ. By a pure process it is meant that the next jump of a walker is independent of whether you start the random walker at $t = 0$ or observe it at a random time and do not know how much time has elapsed since the last jump of the walker. This is equivalent to waiting for a bus that goes in a loop. Do you have to wait longer for the bus to return if you see that the bus just left, or if you come and no bus is present? If the time between returns to your stop is governed by an exponential $\psi(t)$ then both cases have the same result. This is only true for the exponential $\psi(t)$, and for this case the probability $N_n(t)$ that n jumps have occurred by time t is $N_n(t) = \int_0^t \psi_n(t - \tau)\Phi(\tau)d\tau$. In Laplace space,

$$N_n^*(s) = [\psi^*(s)]^n \frac{1}{1 - \psi^*(s)} = \frac{\lambda^n}{(s + \lambda)^{n+1}}. \tag{46a}$$

Taking the inverse Laplace transform we find for $N(t)$ that

$$N_n(t) = \frac{(\lambda t)^n \exp(-\lambda t)}{n!}, \tag{46b}$$

which is the Poisson distribution.

It is useful to define the moments of $\psi(t)$,

$$\langle t^n \rangle \equiv \int_0^\infty t^n \psi(t)dt. \tag{47}$$

With these preliminaries, we can now write the probability density $Q(l,t)$ to reach site l *exactly* at time t, via the relationship

$$Q(l,t) = \sum_{l'} \int_0^t Q(l - l',t - \tau)p(l')\psi(\tau)d\tau + \delta_{l,0}\delta(t). \tag{48}$$

The RHS accounts for the walker reaching the site $l - l'$ at time $t - \tau$ and then a time τ later performing a jump of displacement l' that brings the walker to site l exactly at time t. The delta functions on the RHS take into account the initial condition of the walker being at the origin. In Laplace–Fourier space, Eq. (48) has the form

$$\tilde{Q}^*(k,s) = \frac{1}{1 - \tilde{p}(k)\psi^*(s)}, \tag{49}$$

which is equivalent to the Green's function for the discrete-time random walk when in Eq. (32) we set $z = \psi^*(s)$. The Green's function acting for a time t gives the probability evolution for that time interval. It is also called a propagator. The probability $P(l,t)$ to be at site l at time t is different from $Q(l,t)$ because the walker may have reached site l at an earlier time $t - \tau$, and then no jump occurs during the interval $t - \tau$ to t. We can write $P(l,t)$ as

$$P(l,t) = \int_0^t Q(l,t - \tau)\Phi(\tau)d\tau. \tag{50}$$

In Fourier–Laplace space the probability is

$$\tilde{P}^*(k,s) = \tilde{Q}^*(k,s)\frac{1 - \psi^*(s)}{s} = \frac{1}{1 - \tilde{p}(k)\psi^*(s)} \frac{1 - \psi^*(s)}{s}. \tag{51}$$

The above analysis describes a continuous-time random walk (CTRW) (Montroll and Weiss, 1965) (see Fig. 3).

We can write the probability in Eq. (51) in terms of a nonlocal-time master equation with a transition rate $p(r)K(t)$, i.e., which generalizes Eq. (22b) for the master equation:

$$\frac{\partial P(r,t)}{\partial t} = \int_0^t \left[-P(r,t) + \sum_{r'} P(r',t)p(r - r') \right] \times K(t - \tau)d\tau, \tag{52}$$

if we set in Laplace space

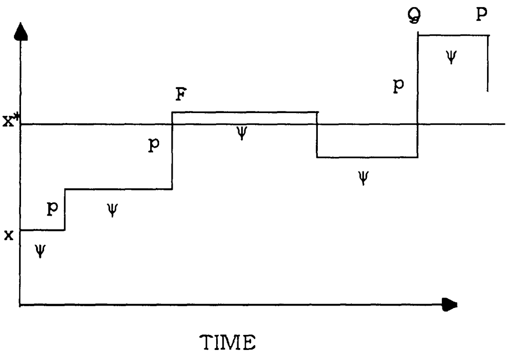

FIG. 3. A schematic plot of position x vs time t for a continuous-time random walk. The walker first waits with no movement for a time governed by $\psi(t)$, the waiting-time density. Next the walker jumps a distance r, governed by $p(r)$, then the walker again waits a random time. We choose a certain level x^*, and $F(x^*,t)$ denotes the first-passage time to this level. $Q(x,t)$ represents reaching position x exactly at time t, and $P(x,t + \tau)$ represents the probability of being at x at time $t + \tau$, which includes having arrived at an earlier time and not having left by time $t + \tau$.

$$K^*(s) = s\psi^*(s)/[1 - \psi^*(s)]. \tag{53}$$

An analysis can show that Eqs. (52) with (53) (the master equation) and (51) (the continuous-time random walk) are equivalent. The temporal memory relates how transitions (jumps) of the random walker at time t are related to the previous history of the random process. The case of $\psi(t) = \lambda \exp(-\lambda t)$ implies $K(t) = \lambda\delta(t)$. This $K(t)$, coupled with choosing $p(r)$ connecting only nearest neighbors on a one-dimensional lattice with equal probability, has the solution $P(l,t) = e^{-\lambda t}I_l(\lambda t)$, where I_l is the modified Bessel function. An analysis of the long-time behavior of the Bessel function demonstrates, in accord with the central limit theorem, that this probability asymptotically becomes Gaussian at long times.

Moments of $P(l,t)$ can be directly calculated from $\tilde{P}^*(k,s)$, e.g.,

$$\begin{aligned}\langle l(t)\rangle &= \sum_l lP(l,t) = \lim_{k\to 0}\left[-i\frac{\partial}{\partial k}\sum_l \exp(ikl)P(l,t)\right]\\ &= \lim_{k\to 0}\left[-i\frac{\partial}{\partial k}\mathscr{L}^{-1}\tilde{P}^*(k,s)\right]\\ &= \bar{l}\mathscr{L}^{-1}\left\{\frac{\psi^*(s)}{s[1-\psi^*(s)]}\right\},\end{aligned} \tag{54}$$

where the mean distance per jump is

$$\bar{l} = -i\frac{\partial}{\partial k}\tilde{p}(k=0)$$

At long times if $\bar{l}$ is not zero, and $\bar{t}$ is finite, the walker has a drift,

$$\langle l(t)\rangle \approx (\bar{l}/\bar{t})t. \tag{55}$$

The variance, $\sigma^2(t) = \langle l^2(t) - \langle l(t)\rangle^2\rangle$, can be shown to behave asymptotically as

$$\sigma^2(t) \approx \left\{\frac{\overline{l^2}}{\langle t\rangle} + \left(\frac{2\bar{l}^2}{\langle t\rangle}\right)\left[\frac{1}{2}\frac{\langle t^2\rangle}{\langle t\rangle^2} - 1\right]\right\}t. \tag{56}$$

In the later sections we will explore ways in which this result can be modified either through infinitely long jumps or waiting times, or through walks on fractal lattices.

One of the strengths of the generating-function formalism is that many quantities can be expressed in terms of the Green's function. We now show how to calculate the first-passage time within the CTRW formalism. Let $F(l,t)$ be the probability density to reach site l for the first time at time t. This is related to the first passage in n steps (with a sum over all n) times the probability density for the nth step to occur at time t,

$$F(l,t) = \sum_{n=0}^{\infty} F_n(l)\psi_n(t). \tag{57}$$

In Laplace space, we can write $F^*(l,s)$ in terms of the first–passage-time generating function $\mathscr{F}$ as

$$\begin{aligned}F^*(l,s) &= \int_0^{\infty} F(l,t)\exp(-st)dt\\ &= \sum_{n=0}^{\infty} F_n(l)[\psi^*(s)]^n = \mathscr{F}(l;\psi^*(s)).\end{aligned} \tag{58}$$

From Eq. (36) we write

$$\mathscr{F}(l,\psi^*(s)) = \frac{G(l,\psi^*(s)) - \delta_{l,0}}{G(l = 0,\psi^*(s))} \tag{59}$$

or in Fourier space,

$$\tilde{\mathscr{F}}(k,\psi^*(s)) = \frac{[1 - \tilde{p}(k)\psi^*(s)]^{-1} - 1}{G(l = 0,\psi^*(s))}. \tag{60}$$

In one dimension, using Eq. (37) for $G(l = 0;z)$, we have for s, $k \to 0$

$$\tilde{F}^*(k,s) \approx \frac{1}{\sqrt{2\langle t\rangle s}\,(\frac{1}{2}k^2\overline{l^2} + s\langle t\rangle)}. \tag{61}$$

Taking the inverse Laplace and then the Fourier transform yields, for the long-time, large-distance limit,

$$F(l,t) = \frac{|l|}{\sqrt{4\pi D}}t^{-3/2}\exp\left(-\frac{l^2}{4Dt}\right), \tag{62}$$

where $D = \overline{l^2}/2\langle t\rangle$. The function $F(l,t)$ is a one-dimensional probability density and must be integrated over time to calculate a probability. This probability may superficially look similar to a Gaussian probability (except for the $|l|$ term), but for fixed time t, a Gaussian has a maximum at $l = 0$, while $F(l,t)$ has a maximum when $l^2 = 2Dt$. In fact, $F(l,t)$ is zero at $l = 0$. An important fact to notice is that the mean first-passage time, on an infinite lattice, to any lattice site is infinite. This is because the walker can drift out to infinity in a direction away from the chosen site to which the first passage is calculated. However, the average time $\langle T(R)\rangle$ to leave a region of length scale R (e.g., a circle of radius R) is finite because we then sum over all l on the boundary of the region. Since a Gaussian probability density spreads as $\langle R^2(T)\rangle \approx T$, one might suspect that $\langle T(R)\rangle \approx R^2$, and this is correct, as we show in Sec. 5.3.

An important quantity is $S(t)$, the number of distinct sites visited on a lattice in a time t. In the field of reactions it is important to know how much territory a diffusing reactant explores in a time t. This is related to $S(t)$. We begin with the quantity S_n, the number of distinct sites visited in n steps (and we count the origin as the first new site). We can write

$$S_n = 1 + \sum_l [F_1(l) + \cdots + F_n(l)]. \qquad (63)$$

In continuous time the number of distinct sites visited in a time t is

$$S(t) = \sum_{n=0}^{\infty} S_n \int_0^t \psi_n(t - \tau)\Phi(\tau)d\tau, \qquad (64)$$

where the integral accounts for the nth jump occurring at time $t - \tau$, and then no jump occurring from time $t - \tau$ to t. Using generating-function techniques one finds for the Laplace transform of $S(t)$ the form $\psi^*(s)/sG(l = 0;\psi^*(s))$. Using the explicit form of the Green's function, we find (assuming $\langle t\rangle$ is finite) that

$$S(t) \approx \begin{cases} t/\langle t\rangle G(0;1) & \text{for } D = 3, \\ \pi t/\langle t\rangle \log(t/\langle t\rangle) & \text{for } D = 2, \\ \sqrt{8t/\pi\langle t\rangle} & \text{for } D = 1. \end{cases} \qquad (65)$$

Consider the number of distinct points visited in a set other than the entire lattice. The generating-function formalism still holds, with a sum over points in the set instead of over every lattice point. For the set being a plane in a three-dimensional cubic lattice $\langle S(t)\rangle \approx t^{1/2}$, so that after a time t the number of points in the plane visited by the walker (which can go anywhere in three dimensions) scales as $t^{1/2}$. For the special set being a line in three dimensions, $\langle S(t)\rangle \approx \log(t)$. The calculation of the probability distribution of $S(t)$, as opposed to its first moment, requires techniques beyond the generating-function approach.

5.3 Many Walkers

There are several ways to obtain noninteger exponents in random walks. We will later address the concepts of fractal space and time where fractional exponents reflect fractal properties. Here, we treat the case of more than one random walker. We consider N random walkers inside a sphere (see Fig. 4) of radius R, and ask the question for the mean first-passage time for the sphere to be empty of random walkers. This problem was posed in the context of the disentanglement time for N entangled polymer chains (Weiss *et al.*, 1988). If the walkers undergo Brownian motion we have, for the probability $p(\mathbf{r},t|\mathbf{r}_0,t = 0)$ for the walker to go between $\mathbf{r}_0$ and $\mathbf{r}$ in a time t,

$$p(\mathbf{r},t|\mathbf{r}_0,t = 0) = 4\pi\left(\frac{3}{4\pi Dt}\right)^{3/2} \exp\left[-\frac{3(\mathbf{r} - \mathbf{r}_0)^2}{4Dt}\right], \qquad (66)$$

where D is the diffusion constant. Let $E(t)$ be the probability that a particle initially in the sphere is in the sphere at time t. We can express $E(t)$ as the integral of Eq. (66) over $\mathbf{r}$ and $\mathbf{r}_0$ for all points in the sphere. For N

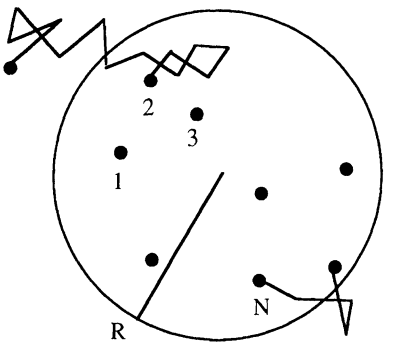

FIG. 4. *N* random walkers, denoted by ●, and labeled 1,2,3, . . ., *N*, start in random initial conditions inside a sphere of radius *R*. Each walker undergoes Brownian motion. A possible trajectory for walker 2 is shown. We are interested in the mean first-passage time for the sphere to be empty of walkers. Note that walker *N* left the circle, but reentered. This possibility complicates the calculation for the circle being empty of walkers.

noninteracting walkers the probability that at least one of them is in the sphere is given by $\Lambda(t) = \{1 - [1 - E(t)]^N\}$. The rate of change of $\Lambda(t)$ is the probability for the sphere to be empty. The first moment $\langle T_N \rangle$ for the sphere to be empty of N walkers (but not necessarily for the first time, although this is a good approximation in 3D for the first-time probability) is

$$\langle T_n \rangle = \int_0^\infty t \frac{d\Lambda(t)}{dt} dt = \int_0^\infty \Lambda(t) dt. \tag{67}$$

Now for t sufficiently large that $Dt \gg R^2$, then

$$E(t) \approx \sqrt{2\pi}\,(R^2/Dt)^{3/2}. \tag{68}$$

When N is large,

$$\begin{aligned} \langle T_N \rangle &\approx \int_0^\infty (1 - e^{-NE(t)}) dt \\ &\approx \int_0^\infty [1 - \exp[-N(T/t)^{3/2}]] dt \\ &\approx TN^{2/3} \int_0^\infty [1 - \exp(-x^{3/2})] dx, \end{aligned} \tag{69}$$

where $T = cR^2/D$, with c a constant. If N, the number of walkers, is a function of R, say $N(R) = R$, then a fractional exponent results, i.e., $\langle T_N \rangle \approx R^{8/3}$ as opposed to the single-particle result of $\langle T_1 \rangle \approx R^2$.

Another example of a fractional exponent entering a many-random-walker problem deals with interacting walkers that annihilate upon contact. In one dimension, the probability that p walkers starting near each other survive for n steps scales as $n^{-p(p-1)/4}$ (Fisher, 1984). Fractional exponents also enter naturally in trapping and reaction problems, as discussed in Sec. 6.

6. REACTION KINETICS

6.1 Trapping

Consider Brownian motion of randomly spaced particles in the presence of randomly spaced trapping regions. One might as a first-order guess consider space to be broken up into cells of length R, each with a particle and a number of traps. The mean trapping time would be proportional to R^2/D, where R is the average distance to a trap and D is the particle's diffusion constant. The probability that a particle is not trapped would then be $\Phi(t) = \exp(-2nDT/R^2)$ where n is the dimension. This expression is, in fact, a good approximation for all but asymptotic times. On a finite lattice the survival time is always exponential (den Hollander, 1985).

The problem with this approach is that it ignores spatial fluctuations in the trap positions. Let us consider a particle that starts in a region of radius R without any traps. We must now average the lifetime of a particle over the probability of being in such a region of radius R (Donsker and Varadhan, 1979). If we assume a Poisson distribution for a region of volume V to be void of traps, i.e., $P(V) = (1/V)\exp(-V/V_0)$, with volume $V \sim R^d$ then the lifetime distribution of a walker is given by

$$\begin{aligned} \Phi(t) &\approx \int_0^\infty \exp\left(-\left[\frac{R}{R_0}\right]^d\right) \exp\left(-\frac{2dDt}{R^2}\right) dR \\ &\approx \exp(-\text{const.}\, t^{d/(d+2)}). \end{aligned} \tag{70}$$

This behavior is dominated by that small fraction of walks that start very far away from any traps, and Eq. (70) is only valid at very long times.

6.2 First- and Second-Order Kinetics

We now consider various reaction–diffusion schemes. In all cases we consider diffusion to be the rate-limiting step. This means the reactions are diffusion limited and not rate limited. In bimolecular reactions, if one species is unlimited in number, the population of the other species is said to follow a pseudo-unimolecular reaction.

For a unimolecular reaction if we start with N_0 reactants, we can write an equation for the probability $P(N,t)$ of having N reactants left at time t, where $K(t)$ is the reaction rate:

$$\frac{dP(N,t)}{dt} = K(t)[(N+1)P(N+1,t) - NP(N,t)]. \tag{71}$$

The equation for the average number of reactants $\langle N(t) \rangle$ is

$$\frac{d\langle N(t) \rangle}{dt} = -K(t)\langle N(t) \rangle, \tag{72}$$

with the solution

$$\langle N(t)\rangle = N_0 \exp\left(-\int_0^t K(\tau)d\tau \right). \tag{73}$$

Usually $K(t)$ is treated as a constant.

For a bimolecular reaction with species A and B annihilating upon contact, one writes for the average populations $A(t)$ and $B(t)$ the following rate equation:

$$\frac{dA(t)}{dt} = -kA(t)B(t) = \frac{dB(t)}{dt}, \tag{74}$$

with the solution

$$\frac{1 + C/A(t)}{1 + C/A(0)} = \exp(Ckt), \tag{75}$$

where $C = B(0) - A(0)$. If $B(0) \gg A(0)$ then $C \approx B(0)$ and

$$A(t) \approx A(0) \exp[-kB(0)t]. \tag{76}$$

If, however, $A(0) = B(0)$, then expanding Eq. (75) for small C yields

$$A(t) = \frac{A(0)}{1 + A(0)kt} \approx \frac{1}{kt}. \tag{77}$$

This solution is in fact not valid for dimensions $d \leq 2$ because it assumes that the rate constant *is* a constant. Actually, k is proportional to $dS(t)/dt$, where $S(t)$ is the number of new sites visited. Since $S(t) \approx \sqrt{t}$ and $t/\ln(t)$ in 1D and 2D, k is time dependent. A more serious matter involves spatial fluctuations. In the $A + B \rightarrow 0$ case, with $A = B$, fluctuations in the density will create regions with $A > B$ and vice versa. The number of particles in a region of radius R is proportional to R^d, with fluctuations of order $R^{d/2}$. After a time $t = R^2/D$, most particles of the lower density in a region have reacted, leaving mostly the excess majority species. So an A-rich region will have about $N(A) \sim R^{d/2} \sim (Dt)^{d/4}$ particles in a volume $V \sim (Dt)^{d/2}$. The density thus decays at long times as $N/V \sim (Dt)^{-d/4}$ for $d \leq 4$, and not $1/t$ as in Eq. (77). We derive this result in the next section.

6.3 Reaction–Diffusion Equations

The above rate-equation approach for average populations and constant reaction rates is useful and holds well at early times, but it lacks spatial information about the reactants, especially the segregation into A- and B-rich regions. This segregation phenomenon will slow down the reaction rate relative to the prediction of the rate equation. It is more accurate and interesting to start with a reaction–diffusion equation, where $P_A(r,t)$ is the probability that a particle of type A is at position $\mathbf{r}$ at time t (and similarly for particles of type B), and D is the diffusion constant for type A and type B particles. Type A and type B particles annihilate upon meeting with reaction rate k:

$$\begin{aligned} \frac{\partial P_A(\mathbf{r},t)}{\partial t} &= D\nabla^2 P_A(\mathbf{r},t) - kP_A(\mathbf{r},t)P_B(\mathbf{r},t), \\ \frac{\partial P_B(\mathbf{r},t)}{\partial t} &= DP_B\nabla^2(\mathbf{r},t) - kP_A(\mathbf{r},t)P_B(\mathbf{r},t). \end{aligned} \tag{78}$$

Source and sink terms, plus boundary conditions, can also be added to the above equations. Further analysis proceeds by introducing two new variables (Ovchinnikov and Zeldovich, 1978),

$$\begin{aligned} s(\mathbf{r},t) &\equiv \tfrac{1}{2}[P_A(\mathbf{r},t) + P_B(\mathbf{r},t)], \\ \delta(\mathbf{r},t) &\equiv \tfrac{1}{2}[P_A(\mathbf{r},t) - P_B(\mathbf{r},t)]. \end{aligned} \tag{79}$$

This method immediately produces the linear diffusion equation for the difference variable,

$$\frac{d\delta(\mathbf{r},t)}{dt} = D\nabla^2\delta(\mathbf{r},t). \tag{80}$$

We will treat the case of equal numbers of A and B particles, which are randomly distributed in an uncorrelated fashion. The average of δ vanishes identically. We need to calculate the second moment,

$$\begin{aligned} \Gamma(\mathbf{r} - \mathbf{r}',t) &\equiv \langle \delta(\mathbf{r},t)\delta(\mathbf{r}',t)\rangle \\ &= \frac{\rho(t = 0)}{2(8\pi Dt)^{d/2}} \exp\left(-\frac{[\mathbf{r} - \mathbf{r}']^2}{8Dt} \right), \end{aligned} \tag{81}$$

which is the d-dimensional form of the Gaussian, and $\rho(t = 0)$ is the initial particle density. The form for Γ follows from the Gaussian form for δ when the A and B initial positions are random and uncorrelated. For $\mathbf{r} = \mathbf{r}'$ we obtain the scaling $\delta(\mathbf{r},t) \sim t^{-d/4}$ for $d < 4$ and t^{-1} for $d \geq 4$. The bimolecular reaction–diffusion equation can produce other results for other conditions. For example, Lindenberg *et al.* (1990) find for geminate recombination with A's and B's created in initially close pairs (say, e.g., in electron–hole creation) that $\delta(\mathbf{r},t) \sim t^{-(d+2)/4}$.

7. FRACTAL-TIME PROCESSES

7.1 Fractal Waiting Times

In the continuous-time random walk let us now consider the Laplace transform of the waiting-time density, as this quantity appears in calculating many properties of a random walk, such as in determining the number $S(t)$ of distinct sites visited in a time t:

$$\psi^*(s) \equiv \int_0^\infty \psi(t)\exp(-st)dt = \sum_{n=0}^{\infty} (-1)^n s^n \langle t^n \rangle. \tag{82}$$

This expansion only holds if all the moments of $\psi(t)$ are finite. Let us consider a case where this does not occur. Choose $\psi(t)$ as

$$\psi(t) = \frac{1-q}{q}\sum_{j=1}^{\infty} q^j\lambda^j \exp(-\lambda^j t) \quad (\lambda < q < 1). \tag{83}$$

This has a scaling form, with an order-of-magnitude longer waiting time (in base $1/\lambda$) occurring an order of magnitude less often (in base $1/q$). This is like intervals in the triadic Cantor set where longer lengths (in base 3) occur two times less often. Our waiting-time distribution is easily checked to be normalized to 1, but the condition that $\lambda < q < 1$ leads to $\langle t \rangle$ being infinite, i.e.,

$$\langle t \rangle = \frac{1-q}{q}\sum_{j=1}^{\infty}\left(\frac{q}{\lambda}\right)^j = \infty, \tag{84}$$

and so the straightforward use of the moment expansion in Eq. (82) is invalid. How then can one proceed with a power-series expansion of $\psi^*(s)$ to determine its dominant behavior? We can write $\psi^*(s)$ as

$$\psi^*(s) = \frac{1-q}{q}\sum_{j=1}^{\infty}\frac{(q\lambda)^j}{[s+\lambda^j]}. \tag{85}$$

The scaling relation

$$\psi^*(s) = q\psi^*\left(\frac{s}{\lambda}\right) + \frac{\lambda(1-q)}{(s+\lambda)} \tag{86}$$

allows one to determine the noninteger exponent in the expansion of $\psi^*(s)$ in terms of powers of s. The inhomogeneous term in Eq. (86) involves only integer powers of s, and so any noninteger exponent must come from the homogeneous part of the equation $\psi^*(s) = q\psi^*(s/\lambda)$, which has a solution of the form

$$\psi^*(s) \approx s^\beta, \quad \text{with } \beta = \frac{\ln(q)}{\ln(\lambda)}. \tag{87}$$

This term is missing from the series expansion in Eq. (82) because that expansion assumed that all the moments of $\psi(t)$ were finite. Adding to Eq. (82) this missing term with its noninteger exponent yields (if β is less than 1)

$$\psi^*(s) \approx 1 - s^\beta + O(s), \quad \text{as } s \to 0,$$

and

$$\psi(t) \approx t^{-1-\beta}, \quad \text{as } t \to \infty. \tag{88}$$

If β is greater than unity, then for small s, the s term will dominate the s^β term in Eq. (82), and $\psi(t)$ will decay fast enough so that $\langle t \rangle$, the average time between transitions in the random process, is finite. This implies that Poisson statistics will asymptotically govern the number of transitions in the random process, i.e., the mean number of transitions will grow linearly with time as $t/\langle t \rangle$. This is similar to the central limit theorem where the important spatial quantity was $\langle r^2 \rangle$. If this was finite, Gaussian behavior ensued. The condition $\lambda < q < 1$, which makes $\langle t \rangle$ infinite, also keeps $\beta < 1$. When β equals 1, jumps occur at a well-defined constant rate and time flows forward (as measured by the number of jumps) as a one-dimensional process. The above $\psi(t)$, with β less than 1, is called a *fractal-time* random process because the mean number of jumps in a time t grows as t^β when $\beta < 1$, as opposed to linearly with t when $\beta > 1$. Time can be described as being β-dimensional for a fractal-time random process.

7.2 Stretched-Exponential Relaxation

A random process is said to be subordinated to a second random process if an event occurring in the first process depends on the probability of an event occurring in the second random process. We consider, specifically, the first random process to be a reaction that is subordinated to a second random process of random walkers reaching the reaction site. In this scenario, when the second process involves random walks moving in fractal time, the second process will be shown to be a stretched-exponential relaxation.

Consider the problem of dielectric relaxation of glasses involving a frozen-in dipole that can be relaxed only when it is hit by a mobile defect. This problem involves the first-passage time of random walkers (defects) to reach the origin (frozen-in dipole). The mathematical analysis of the problem is in the form of letting there be V lattice sites and letting N walkers be initially randomly distributed among these sites, not including the origin. The probability $\Phi(t)$ that none of the walkers has reached the origin by time t is given by

$$\Phi(t) = \left[1 - \frac{1}{V}\sum_{r}\int_0^t F(\mathbf{r},\tau)d\tau\right]^N, \tag{89}$$

where $F(\mathbf{r},\tau)$ is the probability density that a walker starting at site $\mathbf{r}$ will reach the origin for the first time at time τ. The integral allows for a first passage of a walker to the origin in the interval $(0,t)$. The $1/V$ enters as the probability of a walker starting at a site, and a sum over all possible starting points for a walker is performed. The quantity in brackets gives the probability that a particular walker has not reached the origin, and it is raised to the Nth power for the probability that none of the walkers has yet reached the origin. The problem is easier in the limit $N \to \infty$, $V \to \infty$, but with the ratio remaining constant, $N/V = c$. In this limit,

$$\Phi(t) = \exp\left[-c\sum_{\mathbf{r}}\int_0^t F(\mathbf{r},\tau)d\tau\right] = \exp[-cS(t)]. \tag{90}$$

The term in brackets was simplified by noting that any of the sites from which a walk can reach the origin in a time t are exactly the same sites a walker starting at the origin can reach in a time t. This is exactly $S(t)$, the number of distinct sites that a walker visits in a time t, as discussed in Sec. 5.3. Equation (90) has the following form for the random-walk jumps governed by finite and infinite $\langle t\rangle$ (see Fig. 5):

$$\Phi(t) \approx \begin{cases}\exp(-\text{const.}t/\langle t\rangle) & \text{for}\,\langle t\rangle\,\text{finite},\\ \exp(-\text{const.}t^{\beta}),\ \beta<1, & \text{for}\,\langle t\rangle\,\text{infinite}.\end{cases} \tag{91}$$

In addition to introducing subordination processes, we have found that the stretched exponential is a probability limit distribution. This means that the form of $\Phi(t)$ does not depend on the details of the underlying random process, but only on whether $\langle t\rangle$ for the time between jumps is finite or infinite.

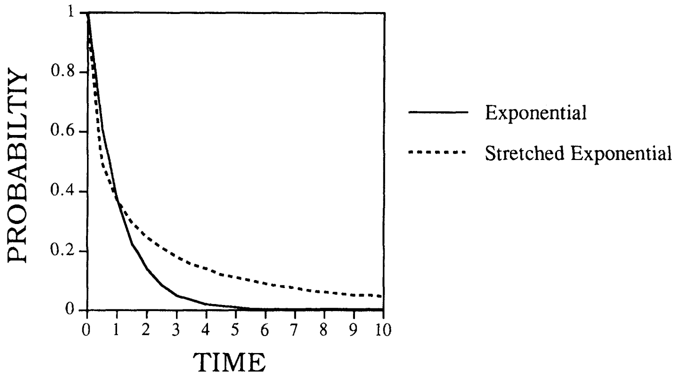

FIG. 5. The exponential decay (single time scale) compared to a stretched-exponential decay. The stretched-exponential decay is initially faster, but is slower after the $1/e$ decay of the exponential.

8. FRACTAL-SPACE PROCESSES

8.1 Lévy Flights

There are many ideas that have been introduced for generalizing Brownian motion, including fractional Brownian motion (Mandelbrot and van Ness, 1968). A fractional Brownian-motion time series would have a Gaussian distribution of values, but the variance would grow, in time t, as t^H with $0 < H < 1$. If $H > \frac{1}{2}$ the motion is called persistent and the variance grows at least as t^2, which is faster than Brownian motion, while the opposite is true for the antipersistent case of $H < \frac{1}{2}$.

A random-walk process that does not fall into the Brownian-motion class occurs when the variance of the jump lengths is infinite (Lévy, 1937). If the variance of each jump is infinite, then the variance of N jumps is also infinite. This in turn implies that the distribution of the sum of N steps should have similar properties to that of a single step. This is basically the question of fractals: When does the whole (the sum of N steps) look like its parts? Lévy found the answer that asymptotically for small k, the Fourier transform $\tilde{p}(k)$ of the probability $p(x)$ to make a jump of displacement x was of the form $\tilde{p}(k) = \exp(-|k|^\beta)$ with $\beta \leq 2$. The Gaussian is the case $\beta = 2$. The Cauchy is the case $\beta = 1$ (see Fig. 6). This is reminiscent of our analysis of fractal time where noninteger exponents entered and signaled self-similar behavior and infinite moments of a probability distribution. This time the moments are spatial, instead of temporal. Let us look at a particular pedagogical case, called the Weierstrass random walk, which illuminates the above discussion.

Begin with a random walk on a lattice with the following probabilities for jumps of length r:

$$p(r) = \frac{q-1}{2q} \sum_{j=0}^{\infty} q^{-j}[\delta_{r,b^j} + \delta_{r,-b^j}]. \tag{92}$$

In this scheme jumps an order of magnitude farther (in base q) occur an order of magnitude less often (in base b). About q jumps of size unity are made, and form a cluster of q sites, before a jump of length b occurs, and about q such clusters of visited sites are formed before a jump of length b^2 occurs, and so on until an infinite fractal hierarchy of clusters is formed. To see the mathematical condition necessary for this to occur, examine the Fourier transform of $p(r)$ to obtain

$$\tilde{p}(k) = \frac{q-1}{q} \sum_{j=0}^{\infty} q^{-j} \cos(kb^j). \tag{93}$$

This is the famous Weierstrass function, which is everywhere continuous, but nowhere differentiable, when $b > q$. Note that

$$\begin{aligned} \langle r^2 \rangle &= \sum_{r=-\infty}^{\infty} r^2 p(r) = \frac{q-1}{q} \sum_{j=0}^{\infty} \left(\frac{b^2}{q}\right)^j \\ &= -\frac{\partial^2}{\partial k^2} \tilde{p}(k=0) = \infty \end{aligned} \tag{94}$$

when $b^2 > q$. This divergence of the second moment (absence of a scale) is a sign of fractal self-similar properties. We have numerically graphed a two-dimensional version

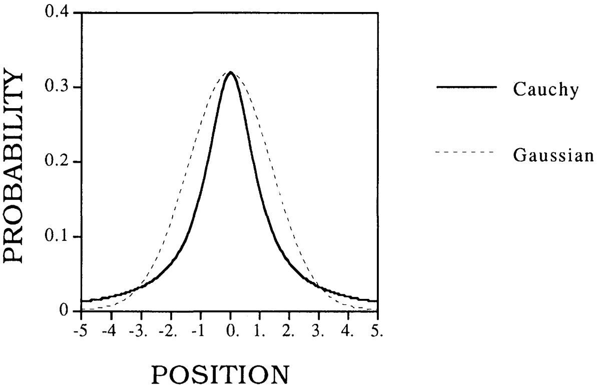

FIG. 6. A Gaussian distribution falls off rapidly enough that all of its positive moments are finite. The Cauchy distribution falls off slowly enough that its second and all higher moments are infinite. The probability in the tail is sufficiently strong to induce events far away from the typical Gaussian behavior. A random walker whose jumps are governed by a Cauchy distribution will visit in two or higher dimensions a fractal set of points with fractal dimension of 1. The traditional approach when encountering Cauchy distributions was to characterize them by their full width at half maximum, and to ignore the fractal consequences of a probability distribution with infinite moments.

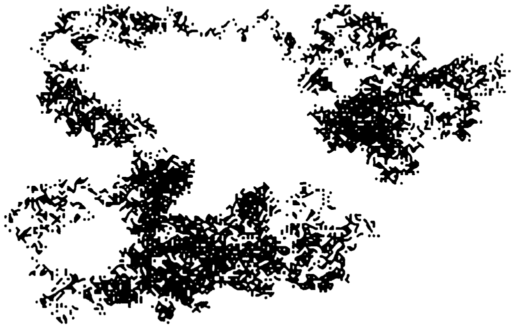

FIG. 7. A 10 000-step random walk with nearest-neighbor transitions. Eventually an infinite-step walk would fill every site in the plane and achieve a trivial self-similarity of looking the same on every scale.

of a Gaussian random walk and a Weierstrass random walk in Figs. 7 and 8 to emphasize the difference between a Gaussian and a Lévy process. We cannot write a power-series expansion of $\tilde{p}(k)$, since the coefficient of the $\langle r^2 \rangle$ term is infinite. However, as in the case of the fractal-time distribution, a scaling equation can be employed to determine the small-k behavior of $\tilde{p}(k)$,

$$\tilde{p}(k) = \frac{1}{q}\tilde{p}(bk) + \frac{q-1}{q}\cos(k). \tag{95}$$

The inhomogeneous term has no noninteger powers, and so we focus on a solution to the homogeneous part of the equation, $\tilde{p}(k) = (1/q)\tilde{p}(bk)$, which has a solution of the form k^β with $\beta = \ln(q)/\ln(b)$. When $\beta < 2$ the small-k (large distances r) behavior of $\tilde{p}(k)$ involves the exponent β, while for $\beta > 2$ the moment $\langle r^2 \rangle$ is finite and a Taylor-series expansion of $\tilde{p}(k)$ will exist, i.e.,

$$\tilde{p}(k) \approx \begin{cases} 1 - \text{const.}|k|^\beta + O(k^2) \approx \exp(-|k|^\beta) & \text{for } \beta < 2, \\ 1 - \frac{1}{2}\langle r^2 \rangle k^2 \approx \exp(-|k|^2) & \text{for } \beta > 2. \end{cases} \tag{96}$$

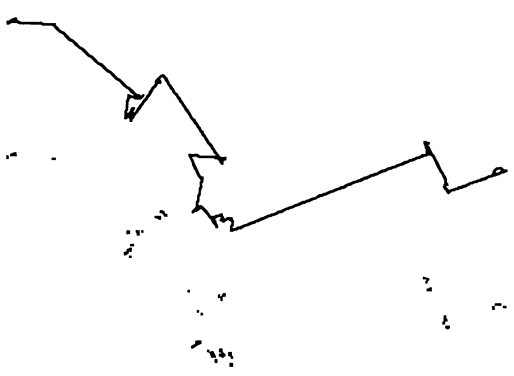

FIG. 8. A Weierstrass random walk of 1000 steps is shown with both the flight segments and the turning points (projected below) Note the self-similar nature of the cluster patterns. The more steps that are taken, the larger would be the probability that longer jumps would be made, thus starting new clusters at order-of-magnitude greater distances from the existing clusters. In this manner self-similar fractal clusters are generated.

One can calculate $P_n(r)$, following Eq. (4), in terms of the inverse Fourier transform of $[\tilde{p}(k)]^n$. For large n, $[\tilde{p}(k)]^n$ will be dominated by small k values, which are what we have calculated in Eq. (96). For the case $\beta = 1$, $P_n(r)$, in the large-n limit, has the Cauchy form $n/[\pi(n^2 + r^2)]$. Lévy's work treats a more general case allowing for a bias and additional parameters, but the above discussion captures the general spirit.

8.2 Lévy Walks

Despite the beauty of Lévy flights, they have been largely ignored in the physics literature because of their infinite moments. This infinity can be tamed by associating a velocity with each flight-trajectory segment (Shlesinger *et al.* 1987). Still in the continuous-time random-walk framework, we consider $\Psi(r,t)$ to be the probability density to make a jump of displacement r in a time t. We write

$$\Psi(r,t) = \psi(t|r)p(r)$$

or

$$\Psi(r,t) = p(r|t)\psi(t), \tag{97}$$

where $p(r)$ and $\psi(t)$ have the same meaning as before and $\psi(t|r)$ and $p(r|t)$ are conditional probabilities for a jump taking a time t given it is of distance r, and for a jump being of distance r, given it took a time t. A simple choice is

$$\psi(t|r) = \delta(t - r/V(r)). \tag{98}$$

In the study of turbulent diffusion Kolmogorov assumed a scaling law implying $V(r) \sim r^{1/3}$. If we furthermore choose

$$p(r) \approx |r|^{1+\beta}, \tag{99}$$

which for small enough values of β produces a Lévy flight with $\langle r^2 \rangle = \infty$, one finds for the mean square displacement

$$\langle r(t) \rangle^2 = \begin{cases} t^3 & \text{for } \beta \leq \frac{1}{3}, \\ t^{2+(3/2)(1-\beta)} & \text{for } \frac{1}{3} \leq \beta \leq \frac{5}{3}, \\ t & \text{for } \beta \geq \frac{1}{3}. \end{cases} \tag{100}$$

The t^3 case is called Richardson's law of turbulent diffusion. It corresponds to a Lévy walk with Kolmogorov scaling for $V(r)$ combined with a β such that the mean time spent in a segment of the trajectory is infinite. The reason we did not obtain the usual Lévy flight result of $\langle r^2(t) \rangle = \infty$ is that with the coupled space-time memory $\Psi(r,t)$ one does not calculate $\langle r^2 \rangle = -\partial^2 \tilde{p}(k = 0)/\partial k^2$, which would be infinite, but one uses $\int \exp(ikr)\psi(s|r)p(r)dr$ instead of $\tilde{p}(k)$. In effect, one is asking how far a walker has gone in a time t, instead of how long is the flight segment.

8.3 Random Walks on Fractals

Consider a random walk that is simple in the sense that it makes all of its jumps at a constant rate to a nearest neighbor. This can still lead to complex behavior if the set of sites is fractally distributed. One example is a random walk on a percolation cluster. The percolation cluster can be formed by connecting, with probability p, neighboring sites on a regular lattice. For low p values only finite-sized islands of connected sites are found. As p is increased there is a critical value when an infinite cluster of connected sites appears. Consider the two-dimensional case (see Fig. 9). If one draws a circle with radius R, then the number of sites on the connected cluster inside this circle grows as R^{d_f}, where d_f is the fractal dimension of the cluster. On a square lattice, with all sites accessible, $d_f = 2$, while on the critical percolation cluster $d_f \approx 1.89$. The cluster has many dead ends, which do not contribute to the mean square displacement, and so one may expect that $\langle R^2(t) \rangle$ grows more slowly in time than for Brownian motion in the plane.

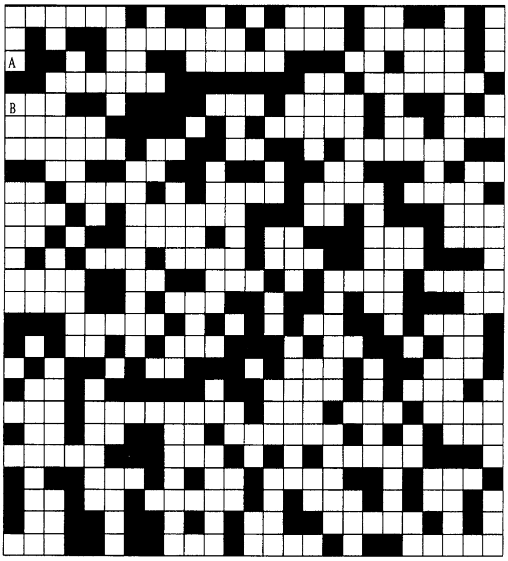

FIG. 9. The white squares represent a lattice that percolates (has continuous pathways for nearest-neighbor transitions) through the full square lattice. Many of the pathways, however, present an inefficient means for connecting two points, e.g., the nearby points A and B. A random walker on this tortuous percolation lattice only visits about $N^{2/3}$ new sites in an N-step random walk vs $N/\log(N)$ new sites on a perfect square lattice.

However, even if all the dead ends are excised and the random walk is restricted to the backbone of the percolation cluster, one still finds slower than linear growth of $\langle R^2(t) \rangle$.

For walks on fractal objects one defines the dimension of the walk, d_w, by

$$\langle R^2(t) \rangle \approx t^{2/d_w}. \tag{101}$$

Random walks on regular infinite lattices have $d_w = 2$. This is because by Polya's theorem a random walk will visit every site in two or fewer dimensions with probability 1, and so the walk trajectory dimension equals 2. Another dimension, called the spectral or harmonic dimension (Alexander and Orbach, 1982), associated with a random walker is defined via the equation for the number $S(t)$ of distinct sites visited, by

$$S(t) \approx t^{d_s/2}. \tag{102}$$

For a regular three-dimensional lattice, $d_s =$

$d_w = 2$. Using Eq. (101) for $\langle R^2(t)\rangle$ we see the scaling $R \approx t^{1/d_w}$. We can also write that after a time t the walker has explored a volume scaling as R^{d_f} that we can write as t^{d_f/d_w}. Equating the volume explored to the number of sites visited gives the following relationship between exponents:

$$d_s = 2d_f/d_w. \qquad (103)$$

In general, d_w is not necessarily equal to d_f. For a percolation lattice $d_s \approx 4/3$. One can further write d_w in terms of scaling exponents of the percolation lattice (Gefen *et al.*, 1982) For percolation the probability P_∞ that any given lattice site belongs to the infinite cluster is $(p - p_c)^\beta$, and the linear size ξ of the cluster scales as $(p - p_c)^{-\nu}$. We rewrite P_∞ as $\xi^{-\beta/\nu}$, so that the fractal dimension is $d_f = d - \beta/\nu$. By the Einstein relation, the dc conductivity σ and diffusion D are linked by $\sigma = e^2nD/kT$, where e is the charge on an electron, n is the number of electrons, k is the Boltzmann constant, and T is the temperature in kelvins. The conductivity scales as $\sigma \approx (p - p_c)^\mu \approx \xi^{-\mu/\nu}$. Using that $n \approx P_\infty$, we have $D \propto \sigma/n \propto \xi^{-\mu/\nu+\beta/\nu}$. For $p < p_c$ the largest cluster is of size ξ, so that at long times $\langle R^2(t)\rangle \approx \xi^2 \approx t^{2/d_w}$, and so $\xi \approx t^{1/d_w}$. We also write $\langle R^2(t)\rangle \approx Dt$, which implies $D \approx t^{2/d_w-1} \approx \xi^{2-d_w}$. Now using the expression for D in terms of μ, ν, and β, we have

$$d_w = 2 + (\mu - \beta)/\nu. \qquad (104)$$

The percolation lattice is a random fractal and only estimates of the various exponents governing random walks on this lattice have been achieved. For regular fractals, exact calculations of d_f, d_w, and d_s are possible. For example, on the Sierpinski gasket in d dimensions $d_w = \ln(d + 3)/\ln(2)$. For the 2D Sierpinski gasket (see Fig. 10), $2/d_w = 2 \times \ln(2)/\ln(5) = 0.862$, which is the exponent that describes the mean square displacement.

9. DISORDERED SYSTEMS

Consider a random walk of N steps on a straight line with only nearest-neighbor jumps allowed. The mean square displacement in this one-dimensional problem is the familiar $\langle r^2(N)\rangle \sim N$. Now take the straight line and deform it to follow a three-dimensional random-walk path. N units of the deformed line are separated from each other on the average only a distance of $N^{1/2}$, instead of the N units separating them on the straight line. The random walk of N steps on the deformed line has $\langle r^2(N)\rangle \sim N^{1/2}$ (Haus and Kehr, 1987). This is a simple example that provides results different from the standard random walk.

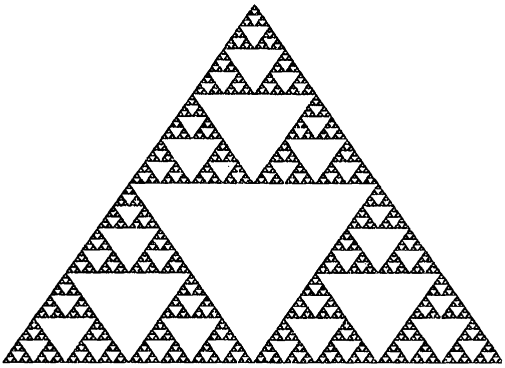

FIG. 10. A Sierpinski gasket. One performs a random walk on this structure by moving along the edges of the triangles. The jump length is the size of the side of the smallest triangle. The hierarchy of vacant triangular regions, in this fractal object, makes diffusion between widely separated sites more complicated and difficult than for a random walk on a regular square lattice. The mean square displacement of a random walker on the Sierpinski lattice grows with time as t^β with $\beta = 2 \ln(2)/\ln(5) = 0.862$. On a regular lattice $\beta = 1$.

Sinai (1982) investigated the properties of a random walk on a one-dimensional lattice with fixed probabilities to move to the right and left at each lattice site. Although these probabilities are fixed, their values are chosen from a probability distribution such that there is a strong bias at each site for the walker to go in a preferred direction. Sinai found that the walker spends many jumps going between two sites: a leftmost site that when approached from the right sends the walker back toward the right with high probability, and similarly a rightmost site that sends the walker back to the left. Many such pairs of sites can exist, especially in a nested configuration. Sinai finds $\langle r^2(t)\rangle \sim [\ln(t)]^4$ for this random-walk process. A more complicated example involves a random walker in one dimension with a random distribution of symmetric transition rates to the right and left. [See the traps in Fig. 11(b)]. For this problem, one can find (Alexander *et al.*, 1982) the anomalous statistics $\langle r^2(t)\rangle \sim t^{2(1-\beta)/(2-\beta)}$ for a distribution $g(w) \approx w^{-\beta}$ of transition rates, between neighboring sites, for small w when $\beta \leq 1$. The difficulty in generalizing the above calculations beyond one dimension has led to other approaches for random walks on disordered lattices.

Consider a random walker faced with a distribution of transition rates $g(W)$. Effective-medium theory postulates an *unknown* time-dependent rate, $W(t)$, which represents the average behavior of all the possible transitions in the random system. One determines $W(t)$ through a self-consistency argument. Change one transition between two neighboring sites in the system from $W(t)$ to a random value chosen from the distribution $g(W)$. Next calculate the Green's function $G = \langle G\rangle + \delta G$, where $\langle G\rangle$ is the random-lattice–walk Green's function for the perfect lattice where all transitions are governed by $W(t)$, and δG involves transitions T that encounter the altered bond. The Green's function can also be written symbolically as $G = \langle G\rangle + \langle G\rangle T\langle G\rangle + \langle G\rangle T\langle G\rangle T\langle G\rangle + \cdots = \langle G\rangle + \langle G\rangle TG$ (Webman and Klafter, 1982), where the second term represents movement in the effective lattice governed by $W(t)$, then an interaction T with the defective bond, followed by movement under $\langle G\rangle$ again. Higher-order terms in T have more interactions with the defective bond. Taking the average of both sides, over the distribution $g(W)$, implies that $\langle TG\rangle = 0$. The assumption for the effective-medium theory is that $\langle TG\rangle = \langle G\rangle\langle T\rangle = 0$, i.e., $\langle T\rangle = 0$. This condition determines $W(t)$, usually through a numerical evaluation.

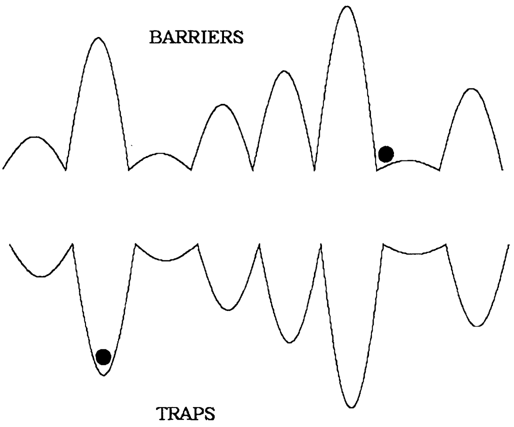

FIG. 11. The top figure represents random barriers, and the bottom one random traps. The dot, in each case, represents a random walker. In the barrier case (top), the walker has unequal probabilities at each site to go to the left or right. In this figure it is easier, from its present position, for the walker to go to the right. The walker tends to get trapped between high barriers. The walker's mean square displacement can grow logarithmically for this Sinai-type random walk. In the random-trap case (bottom), the walker always has equal probabilities to move to the right or left. The walker encounters a distribution of transition rates related to the depth of each trap. For a wide enough distribution of rates a sublinear growth of the mean square displacement with time occurs.

In the effective-medium approximation, one can let the rate to some sites be zero so that these sites are inaccessible. In this case a percolation critical probability p_c enters. If the probability is p that a site is inaccessible, and if $p < p_c$, then a walker is isolated on a finite island of connected sites, and so the diffusion constant would be zero. For a percolation model (Lax and Odagaki, 1982) the effective-medium calculation finds that the real and imaginary parts of the diffusion constant $D(\omega)$ vanish linearly and quadratically with frequency when $p < p_c$ and that $D(0)$ is proportional to $(p - p_c)/(1 - p_c)$ when $p > p_c$. Effective-medium theory was introduced in the 1950s to study scattering of waves in a random medium (Lax, 1952).

The continuous-time random walk discussed in Sec. 6.2 is an effective-medium theory. It was originally applied to electron and hole transport in disordered media (Scher and Lax, 1972). They derived the formula for the frequency-dependent diffusion constant $D(\omega)$ for a random-walk process,

$$\begin{aligned} D(\omega) &= -\frac{\omega^2}{6}\int_0^\infty \exp(-i\omega t)\langle[r(t) - r(0)]^2\rangle dt \\ &= \frac{\overline{r^2}}{6}\,\frac{i\omega\psi^*(i\omega)}{1 - \psi^*(i\omega)}. \end{aligned} \tag{105}$$

The function $\psi(t)$ represents the probability density for a walker (the electron or hole) to remain trapped between movements. The quantity $\psi(t)$ represents an effective medium and it is the same at each lattice site. An infinite first moment $\langle t\rangle$ of $\psi(t)$ was introduced (Montroll and Scher, 1973) to explain scaling behavior in a hole current set up by biased "fractal-time [$\psi(t) \approx t^{-1-\beta}$ for $\beta < 1$]" random walks. For fractal-time random walkers biased in one direction one finds that the first moment and its variance both grow as $\langle r(t)\rangle \approx \sqrt{\langle r^2(t)\rangle} \approx t^{\beta}$, and so the fluctuations (second moment) per distance traveled (first moment) are time independent. An approach to choosing $\psi(t)$ is to focus on the physics of the trapping process. If the hopping time t out of a potential well follows the Arrhenius law, $t^{-1} = \nu \exp(-E/kT)$, and the probability $\rho(E)$ of finding an energy barrier E falls off exponentially as $\exp(-E/E_0)$, then the randomness in energy induces a randomness of hopping times $\psi(t)dt = \rho(E)dE$, which produces the fractal time (see Sec. 8) $\psi(t) \sim t^{-1-\beta}$, where $\beta = kT/E_0$ when $kT < E_0$ and $\beta = 1$ if $kT > E_0$.

Random processes on random geometries is still an active area of research.

GLOSSARY

Brownian Motion: A random walk whose probability distribution is governed by the diffusion equation. The trajectory is fractal with the derivative (velocity) not well defined.

Central Limit Theorem: A theorem showing that a sum of identically distributed random variables with finite second moments converges to a Gaussian distribution as the number of variables becomes infinite.

Chapman–Kolmogorov–Smoluchowski–Bachelier Equation: An equation relating the probability for being at a site at a particular time, in terms of being at a different site at an earlier time and summing over all possible intermediate sites.

Characteristic Function: The Fourier transform of a probability function.

Colored Noise: Noise whose second-order correlation function is broader than a delta function.

First–Passage-Time Density: A probability density to reach a certain criterion (e.g., level, site) for the first time.

Fokker–Planck Equation: A second-order differential equation for a probability distribution based on an expansion relying on the existence of the first two moments of the distribution.

Fractal Brownian Motion: A fractal random process whose next step is built upon correlating its entire previous history. The uncorrelated case is Brownian motion.

Fractal Time: A random process where the mean interval between events is infinite. The set of event times looks like a random fractal set of dimension less than 1.

Gaussian Random Noise: Delta-correlated noise in time with an amplitude following Gaussian statistics.

Kubo Oscillator: An oscillator with a random frequency.

Langevin Equation: An equation of motion with an added noise term.

Lévy Process: A random walk in space with infinite second moment of the jump-size probability, or a random process with the first moment of the waiting-time distribution between events being infinite. A Lévy flight is a Lévy random walk jumping between points and a Lévy walk includes the whole trajectory as well as the end points of each jump.

Markov Process: A random process where the next change depends only on the present state of the random variable, and not on a more detailed prior history.

Master Equation: An equation relating the change with time of a probability for the value of a variable in terms of probabilities for the basic allowed transitions.

One-Over-*f* (1/*f*) noise: A power spectrum whose low-frequency behavior is described by a function that scales with frequency as $1/f$.

Power Spectrum: The Fourier transform of a second-order correlation function. The real part of the transform of a fluctuating current would correspond to the power as a function of frequency.

Random Walk: A sum of random variables. The walk can have correlated or uncorrelated steps.

Self-Avoiding Random Walk: A random walk whose steps may not overlap.

Shot Noise: The noise that arises from the arrival of randomly timed (usually Poisson arrival) distinct pulses each of which has an effect that decays away. Slow scale-invariant decays produce fractal shot noise.

Stochastic Differential Equation: A differential equation for the time evolution of random variables.

Stochastic Process: A random process that involves a time variable.

Subordinated Random Process: A process whose random event times depend on the outcome of a second random process.

Weierstrass Random Walk: A random walk whose generating function is the scaling Weierstrass function, and whose trajectory is a fractal set of hierarchical clusters.

White Noise: A noise whose second-order correlation function is a delta function, i.e., noise that is not correlated in space or time.

Wiener–Khintchine Theorem: A theorem that relates the second-order correlation function of a random process and its power spectrum as Fourier cosine transform pairs.

INTRODUCTION

In 1904, the Nobel prize in Chemistry was awarded to Sir William Ramsay and the prize in Physics was awarded to Lord Rayleigh, in part for their work in the discovery of rare gases as a new family of elements, a whole new column in the periodic table. This family was unknown when they began precise work on the density of nitrogen in 1892, although there was earlier evidence for two of its members: Henry Cavendish isolated a small bubble of what is now known to be argon while studying the composition of air in 1785, and P. J. C. Janssen and J. N. Lockyer had observed a brilliant new yellow line in the solar spectrum in 1868, a line that later turned out to be that of helium.

The presence of argon occupying 1% of the Earth's atmosphere produced the discrepancy in the densities of "nitrogen" obtained from air and from chemical reactions. This provided the critical clue leading to the discovery of argon, the first of the family to be isolated. Forming successively smaller proportions of the Earth's atmosphere and crust are helium, neon, krypton, xenon, and radon. It has been estimated that helium forms one-quarter of the mass of the universe, although on Earth, gravity is too weak to retain helium from escape from the atmosphere, to which it and, for example, radon are released from the Earth's crust by natural processes.

The rare gases have important places both in the development of many branches of science and in numerous technological applications. Neon provided the first clear examples of stable nuclear isotopes when J. J. Thomson, studying liquid-air residues, discovered ^{22}Ne and ^{20}Ne in 1913. The nucleus of ^{4}He (the alpha particle of radioactivity) is the most stable known, whereas all radon isotopes are radioactive. In metrology, from 1960 to 1983 the SI standard of length was defined by an orange line in the ^{86}Kr spectrum; one meter is exactly 1 650 763.73 wavelengths of this line. In thermal science, the properties of helium and neon are used in establishing the temperature scale. General properties of rare gases are given in Table 1. Selected technical applications appear in Sec. 4.

Lennard-Jones (LJ) models for the denser phases of rare-gas atoms have considerable historical significance. Such a model represents the interatomic potential as a polynomial of only two terms in the interatomic separation, one each for the repulsive and the attractive parts, respectively. The computational simplicity of the LJ interaction provided the first qualitative confirmations of the usefulness of molecular dynamics and of Monte Carlo computational methods in representing the properties of fluids, typically the properties of fluid argon. Further, a multitude of scientific articles have been written about the static and dynamical properties of fcc solid models using an LJ 12-6 potential and the mass of a rare-gas atom, again typi-

Table 1. General properties of the rare gases. (The subscripts tp, bp, and c refer to triple-, boiling-, and critical-point coordinates, respectively. For the heliums, which have complicated phase diagrams, only the bcc–fcc–liquid triple point is given.)

cally argon. Among these theoretical investigations of lattice dynamics and of the statistical mechanics of the condensed state are the introduction of many interesting concepts and ingenious computational methods. Because the models can be well defined, with common dependence upon a stated pair interaction with only two parameters, comparisons between models are thus facilitated. For most properties of actual rare-gas solids, however, such models frequently have only qualitative validity. As precision in the knowledge of the pair potential between rare-gas atoms has increased and computational power is enhanced, dependence upon such a poor approximation to the pair potential is no longer necessary, although it continues to have limited usefulness in some qualitative considerations.

1. GASEOUS STATE

1.1 Interatomic Interactions

1.1.1 General Considerations A rare-gas atom consists of a positively charged nucleus surrounded by a negatively charged spherically symmetric electron cloud and hence possesses no permanent dipole. When the atoms are separated by a finite distance, they interact, and the energy resulting from the interaction is the interatomic potential energy $U(r)$, which depends only on the separation between them. Qualitatively, for small separations, the electron clouds overlap. A repulsive force then arises between the atoms, as a consequence of the Pauli exclusion principle, from the increase of energy of the electrons. For large separations, these nonpolar atoms attract one another by means of the London dispersion energy. The electrons of each atom are moving, and at any instant, one atom may possess an instantaneous dipole, which induces an instantaneous dipole in the second atom. The dipoles interact to produce an attractive "dispersion" energy.

An *ab initio* determination of the forces from quantum mechanics has proved to be very difficult except in recent years in the case of helium, the simplest rare gas. An empirical approach has been consistently more successful. In this approach, a flexible potential form is assumed that is realistic at short and at long range and that lends itself to the inclusion of theoretical values in these regions if available. In order to ascertain the potential in the intermediate range, a multiproperty fit to a judiciously chosen set of properties is performed. The set is carefully chosen so that each property probes and constrains the potential in specific regions. The various dilute-gas properties that have been used are

1. macroscopic properties such as second virial coefficients and transport properties, and
2. microscopic properties such as spectroscopic data on the dimer and beam data (differential scattering cross sections and total, or integral, cross sections in the glory region, that relative velocity region where undulations in the cross sections occur as a consequence of the presence of repulsion and attraction in the interatomic interaction).

1.1.2 Like Pairs Researchers at IBM, Oxford University, and California Institute of Technology as well as others determined fairly accurate potentials in the early 1970s. A summary of the situation to 1982 was given by Aziz (1984), who described the fine tuning of potentials for the pure gases. As more accurate data became available and more sophisticated models were developed, state-of-the-art potentials, notably the multidamped Hartree–Fock dispersion (HFD) and exchange Coulomb (XC), have been subsequently constructed. The problem of determining an accurate potential for helium from *ab initio* and semiempirical points of view has been especially difficult, and only recently has agreement been reached between the two approaches.

A particularly realistic but simple potential is the overall damped HFD in which the interaction energy is partitioned into uncorrelated (Hartree–Fock) and correlated parts and a suitable damping function to account for charge-overlap effects. The form is

$$U(r) = \epsilon U^*(x), \qquad (1)$$

where

$$U^*(x) = A^* \exp(-\alpha^* x + \beta^* x^2) - F^*(x)[c_6/x^6 + c_8/x^8 + c_{10}/x^{10}] \qquad (2)$$

with

$$F^*(x) = \begin{cases} \exp[-(D/x - 1)^2], & x < D, \\ 1, & x \geq D, \end{cases} \tag{3}$$

where $x = r/r_m$ and $c_n = C_n/\epsilon r_m^n$.

Parameters for the pure rare gases appear in Table 2. Figures 1 and 2 show a comparison between HFD and LJ potentials for argon.

Properties for which nonadditive many-body interaction energies are significant in pure rare gases are third virial coefficients, binding energies and structure of solids, pressure–volume relations, etc. The relative importance of many-body interactions is greater in the condensed phases.

1.1.3 Unlike Pairs Interactions for unlike pairs are not as well known as they are for the pure gases, largely because few spectroscopic data are available for these systems. Interatomic potentials determined from gas-phase properties for ten mixed systems are reviewed and critically assessed by Aziz (1984). Again, refinements to the knowledge of the interaction of these systems have subsequently been made as more accurate differential-scattering and diffusion data have become available.

1.2 Compounds

1.2.1 Chemical Compounds The term "chemical compound" is understood to mean a substance that is chemically stable at room temperature and pressure, held together by a chemical bond. This excludes hydrates and other clathrates as well as van der Waals complexes, in which the rare-gas atom is not held by a true chemical bond. Other substances that are excluded but that have been studied extensively include the short-lived rare-gas–cation complexes, some of which are important as lasing media.

The chemical reactivity of the rare gases increases with atomic number, as the outer electron shells get increasingly screened by the inner electrons. Nevertheless, the reactivity is always small compared with those of the other elements, because the outermost shell is filled. One would expect radon to be the most reactive rare gas, and this may indeed be the case. However, its rarity and radioactivity make it difficult to study, and its

Table 2. Parameters for HFD-B potentials (Sec. 1.1.2); σ is the value of r at which $U(r) = 0$. (Enough decimal places are displayed to avoid round-off errors.)

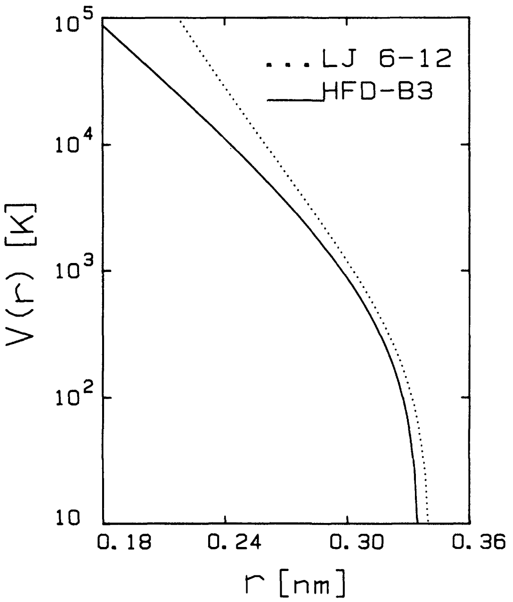

FIG. 2. The repulsive region of the argon pair potential. The same potentials as in Fig. 1.

only known compound is RnF_x, with x unknown.

Xenon is the most reactive of the nonradioactive rare gases. Xenon compounds were predicted by Linus Pauling as early as 1933, although the first one, $XePtF_6$, was not produced until 1962. Subsequently various binary compounds of xenon have been produced. The fluorides XeF_n, with $n = 2$, 4, and 6, are all stable, colorless crystals at room temperature. Evidence of XeF_8 has been reported. Xenon oxides have also been produced. XeO_3 is a white crystal and is dangerously explosive. XeO_4 has been detected but not produced in quantity and is the most volatile xenon compound known. The only other known binary compound of xenon is $XeCl_2$.

There is now a large catalog of more complex xenon compounds (Claassen, 1966). Besides the original $XePtF_6$, a yellow solid, they include $XeOF_4$, a clear, colorless liquid; metallic perxenates such as Na_4XeO_6 that, like the oxides, are very volatile; and mixed fluorides such as XeF_2SbF_5.

Krypton, with atomic number 36, is less reactive than xenon. Its only known binary compound with any stability is KrF_2, which decomposes slowly at room temperature. Some metallic krypton salts such as $KrFAuF_6$ have been made.

The three lighter gases argon, neon, and helium do not form any known stable compounds. However, calculations (Frenking *et al.*, 1990) suggest that all three may form stable compounds with beryllium and oxygen. Spectroscopic evidence for ArBeO has been reported (Thompson and Andrews, 1994), but the compound has not yet been produced in quantity.

1.2.2 Clathrates The weak van der Waals force that acts between two rare-gas atoms can also act between a rare-gas atom and an atom or molecule of another kind, resulting in a weak bond. The attachment of a rare-gas atom to other molecules is further enhanced if the molecules form a cage around the atom. Such a complex is called a clathrate. A familiar example of a clathrate is the hydrate.

Hydrates of argon, krypton, and xenon were prepared as early as 1896. All have a decomposition temperature below 0 °C, although for xenon hydrate it is just −3.4 °C. Many other rare-gas clathrates are now known including RG-hydroquinones (RG =

rare gas), RG-phenols, and the recent RG-fullerenes in which the rare-gas atom is trapped inside a C_{60} "buckyball" (Saunders *et al.*, 1993).

1.2.3 Van der Waals Complexes A physically bound two-atom or molecule-atom system, e.g., Ar_2, ArNe, H_2–Ar (X_2–Y), etc., may form under certain conditions. These dimers can arise when the temperature of the gas is reduced. Such dimers can also be formed in a pulsed supersonic jet. The concentration of dimers is small; for example, only about 0.5% of argon atoms are bound in the vapor phase near NPT (normal pressure and temperature) and are dissociated quickly by colliding atoms. A debate over whether diatomic helium could exist has persisted for many years. Dozens of potentials, *ab initio* and empirical, proposed since the 1939 Lennard-Jones (12-6) potential, produced contradictory conclusions about the existence of He_2. Generally, for potentials with reasonable long-range behavior, those with deeper wells predict the dimer while the shallower ones do not. To make an unequivocal prediction, one requires an accurate potential with, among other things, two key features: an accurate long range and an accurate well depth. The latter was determined from a knowledge of accurate low-temperature second virials provided by the standards laboratories for the ITS-90 temperature scale. Aziz *et al.* (1987) presented such a potential [HFD-B (HE); $\epsilon/k_B = 10.948$ K] from such data, which could predict a large number of other properties. This potential predicted the existence of a weakly bound dimer with a binding energy of 1.6 mK. While earlier *ab initio* potentials had shallower wells that would not predict the virials, recent *ab initio* methods have been refined to the point that *ab initio* and semiempirical potentials are in close agreement (Aziz and Slaman, 1991; Aziz *et al.*, 1995).

There have been a number of groups actively engaged in the pursuit of observing the very weakly bound He_2 dimer that would, by theoretical estimates, have the enormously long bond length of about 5.4 nm. The dimer was first detected in a supercooled beam at the University of Minnesota (Luo *et al.*, 1993) but perhaps the most convincing experimental confirmation lies in the diffraction experiments carried out in Göttingen (Schöllkopf and Toennies, 1994).

1.3 Adsorption

A great deal of experimental and theoretical work has been done on the adsorption of rare-gas atoms on surfaces of various kinds. Much of this work could be categorized as pure rather than applied, dealing, for example, with the general behavior of two-dimensional systems, but there are important applications as well.

Fundamental studies have focused upon using physisorbed layers on structured substrates such as graphite. The pattern of adsorbed rare gas depends upon its atomic size relative to the surface lattice parameter of the substrate, and the resulting layers are commensurate or not depending upon this as well as upon how many layers there are. The resulting systems are excellent prototypes for the investigation of the thermodynamic properties of two-dimensional systems (Nagler *et al.*, 1985). Both the static structures and the dynamics of motion of the adsorbed gas atoms have been studied, the latter using scattering probes such as slow neutrons and electrons.

Rare gases can be separated from gaseous mixtures by adsorption onto certain materials. For example, krypton and xenon can be adsorbed out of impure oxygen onto a certain kind of zeolite, a microporous material sometimes called a "molecular sieve." Conversely oxygen can be adsorbed out of impure argon by another type of zeolite. Neon has also been removed from helium–neon mixtures by adsorption onto activated carbon and silica gel.

1.4 Thermodynamics

1.4.1 Equations of State It has proved difficult to express the behavior of the rare gases over the whole range of pressure *P*, volume *V*, and temperature *T* in a single equation. The first success was the van der Waals equation

$$(P + a/V^2)(V - b) = RT, \qquad (4)$$

which mimics, when used with the Maxwell equal-area construction, all the qualitative features of real equilibrium fluids. The quantity a/V^2 accounts for the attraction between atoms and b accounts for the finite atomic size. The parameters a and b differ from species to species. Many empirical relations have been proposed. Song and Mason (1989) found a compact, analytical equation of state that is simple, general, and accurate (see Sec. 2.3).

A useful equation of state from both a practical and a theoretical point of view is the so-called *virial equation.* In this form, the product PV of n moles of gas is expressed as a power series in $1/v$ where $v = V/n$:

$$Pv = RT[1 + B/v + C/v^2 + D/v^3 + \cdots]. \quad (5)$$

Here B, C, D, etc. are the second, third, and fourth virial coefficients, which depend only on T and the species of gas. The coefficients $B, C, D, \ldots$ represent deviations from ideal behavior when collisions involving two, three, four, ... atoms, respectively, become significant in the gas. Hence B can be related to and provide information on the pair potential, C on the three-body potential, etc.

1.4.2 Heat Capacity and Vapor Pressure The heat capacities of the monatomic rare gases are nearly constant over a wide temperature range. The heat capacity at constant volume is nearly equal to the ideal-gas value of $\frac{3}{2}R$ while the heat capacity at constant pressure is very nearly equal to $\frac{5}{2}R$.

Very accurate values of the saturated vapor pressures P_σ for argon (Gilgen *et al.*, 1994) and other gases along the entire coexistence curve are available in the form

$$\ln(P_\sigma/P_c) = (T_c/T)(A_1\tau + A_2\tau^{1.5} + A_3\tau^{2.5} + A_4\tau^5), \quad (6)$$

where $\tau = (1 - T/T_c)$ where T_c and P_c are the critical temperature and pressure.

Accurate values of the condensed-phase enthalpy, entropy, and internal energy have been determined from accurate vapor-pressure data (Schwalbe *et al.*, 1977; Chen *et al.* 1975, 1978). In addition, accurate values of the cohesive energy at 0 K have been derived from triple-point solid enthalpies and integration of experimental heat capacity of the solid at saturated vapor pressure, C_{sat}, from T_{tp} to 0 K. Cohesive-energy data have been useful in studying many-body forces in solids.

1.4.3 The Universal Gas Constant A new value of the universal gas constant ($R = 8.314\,471 \pm 0.000\,014$ J mol^{-1} K^{-1}) was determined from measurements of the speed of sound in argon as a function of pressure at the temperature of the triple point of water in a spherical acoustic resonator at the National Institute of Standards and Technology (NIST) (Moldover *et al.*, 1988). The error assigned to the measurement is some five times smaller than that assigned to the previous measurements. This reduces the uncertainty of values derived from R, such as the Boltzmann constant k_B and the Stefan–Boltzmann constant.

1.5 Transport Properties

1.5.1 Kinetic Theory Kinetic theory was developed mainly by Maxwell and Boltzmann in the last century. From the laws of mechanics and the theory of probability, it determines the macroscopic properties of gases in terms of the motion of molecules, their collisions with one another, and the forces of interaction. Central to kinetic theory is the time-dependent distribution function. If no gradients of velocity, temperature, or concentration exist, the distribution function reduces to the time-independent Maxwellian distribution. When nonequilibrium conditions prevail, then the distribution function satisfies the Boltzmann integrodifferential equation. When a dilute rare-gas system is not too far from equilibrium, a perturbation method due to Chapman and Enskog is used to solve the equation and derive expressions for the transport properties in terms of the properties of the atoms themselves and their interactions.

Transport phenomena in gases include viscosity, thermal conductivity, and ordinary and thermal diffusion. In terms of kinetic theory, the first three processes are equivalent to the transport through the gas of momentum, kinetic energy, and mass, respectively, when gradients in the gas are present. The viscosity of a gas results from a transport of momentum along a velocity gradient. Thermal conduction is the transport of kinetic energy along a temperature gradient and (ordinary) diffusion is the transport of mass along a concentration gradient. Thermal diffusion is a secondary effect in which an initially uniform gas mixture subjected to a temperature gradient results in a tiny separation of the components.

1.5.2 Measurement of Viscosity and Thermal Conductivity The viscosities of the rare gases and their mixtures are measured (Wakeham *et al.*, 1991) mainly in one of two techniques: capillary flow and oscillating-body viscometry. With the capillary-flow technique, the estimated error of the measurement ranges from ±1% to ±2% while accuracies up to ±0.1% have been claimed with the oscillating-disc method.

Data on the viscosity were measured using the oscillating-disc method at Rostock and Brown Universities (298 to 973 K) and using the capillary method at Oxford (114 to 1600 K) and at Los Alamos National Laboratory (1110 to 2200 K).

The thermal conductivity of the gases can be measured by either a steady-state or a transient method. In the former, the thermal gradient is measured when a heat flux is passed through gas between concentric cylinders or between parallel plates. In the latter, a wire is mounted along the axis of a vertical cylindrical cell and a constant heat flux is electrically generated in it. The thermal conductivity can be determined from temperature rise in the wire as a function of time. The transient hot-wire method seems to be the current method of choice. For very high temperatures, the shock-tube method is used, in which the thermal conductivity is deduced from the measurement of heat transfer rates from the shock-heated gas to the end wall of the shock tube.

1.5.3 Measurement of Ordinary and Thermal Diffusion The most common method of measurement of the diffusion coefficient is with the use of a two-bulb apparatus (Wakeham *et al.*, 1991). In this technique, gases of unequal composition residing in each bulb are allowed to mix through a connecting capillary. The diffusion coefficient is related to the geometry of the two-bulb system and the time required for the gas to approach uniform composition.

There are two basic means of determining the associated transport coefficient, viz., the thermal-diffusion factor. These are a two-bulb technique in which each bulb is maintained at a different temperature, and a thermal-diffusion column. In order to amplify the separation in the case of the former method, the so-called Trennschaukel (swing separator) was devised, in which many two-bulb systems are connected in series. In the column method, a temperature gradient is maintained between a concentric wire and the walls of a vertical tube. The natural convection of the gas in the column amplifies the separation by sweeping the lighter component adjacent to the hot wire up and the heavier component at the cold wall down the column. The column is the prototype apparatus employed for the separation of isotopes. It was the early method for separating uranium isotopes.

Diffusion data on mixtures of the rare gases have been measured at low temperatures at Leiden. More precise and extensive measurements have been performed at Adelaide University including some measurements on thermal diffusion. Self-diffusion and extensive thermal-diffusion measurements were also carried at the Mound Facility of the U.S. Department of Energy in Ohio.

1.6 Law of Corresponding States (LCS)

When expressed in reduced form, a property will have nearly the same value for all gases in a set. This law is based on the hypothesis that all gases in a set have the same reduced intermolecular potential. The reduced potential is defined as $U^* = U(r^*,\beta_i)/\epsilon$, where $r^* = r/\sigma$. The scaling factors ϵ (the energy parameter) and σ (the length parameter) differ from species to species in a set, and β_i are potential-shape parameters, which are identical for all members of the set.

An extended law of corresponding states for the dilute rare gases (helium excepted) and their binary mixtures was developed at Brown University (Kestin *et al.*, 1972). This LCS provided thermodynamically consistent correlations for second virial coefficients and transport properties. On the basis of limited experimental measurements on some of the species, the formulation provided universal functionals for these quantities that, with a set of scaling factors for each species and its binary mixtures, allow one to predict the properties of all the species in a set over an unusually large temperature range.

Realizing the deviation from congruence of reduced potentials for the various species at small separations, the group at Brown (Najafi *et al.*, 1983) improved their LCS principle by allowing some of the shape parameters β_i to be different for different rare-gas pairs. In addition, they appealed to quantum mechanics to determine the asymptotic behavior of the properties. As a result, they were then able to extend the temperature range of the correlation to high and low temperatures and to include helium and its mixtures. The formulation effectively synthesized the equilibrium and transport properties of the five rare gases and the 26 mixtures that can be formed with them.

A further improvement was achieved by the Rostock group (Bich *et al.*, 1987), who published accurate correlations for viscosity and thermal conductivity for the pure gases. It must be noted, however, that data based on accurate interatomic potentials that are more physically based cannot only correlate the data but can extend the range of temperature inaccessible to experiment.

1.7 Optical and Dielectric Properties

1.7.1 Refractivity and Dielectric Virial Coefficients If a rare-gas atom is placed in a uniform electric field, it acquires a dipole moment and is said to be polarized. If the moment **m** is proportional to the field **E** then $\mathbf{m} = \alpha_0 \mathbf{E}$ where α_0 is the polarizability of the isolated atom. In the presence of other atoms, e.g., in a gas, the polarizability α of an atom can be defined in terms of the index of refraction n and the density ρ by the Lorenz–Lorentz equation

$$(n^2 - 1)/(n^2 + 2)\rho^{-1} = A_R + B_R\rho + C_R\rho^2 + D_R\rho^3 \cdots. \tag{7}$$

α will differ from α_0 because of the effects of atomic interactions. If ρ is in moles per unit volume, the left-hand side of Eq. (7) is the molar refraction R_m. As shown, it can be expanded as a power series in the density ρ, where A_R, B_R, C_R, D_R, . . ., respectively, are the first, second, third, fourth, . . . refractivity virial coefficients. A_R is the limiting value of R_m for a very dilute gas. That is, in the limit $\rho \to 0$, $A_R = N\alpha_0/3\epsilon_0$.

Determinations of A_R hence yield values for atomic polarizabilities α_0 for the isolated atom, while B_R, C_R, . . . are related to the excess contribution to R_m as a result of interacting pairs, triplets, . . . of atoms, respectively. Accurate values of A_R, B_R, C_R, . . . have been determined by a differential interferometric technique, and some of these are presented in Table 3 (Achtermann *et al.*, 1993).

The Clausius–Mosotti function for the dielectric constant ϵ may also be expanded as follows:

$$(\epsilon - 1)/(\epsilon + 2)\rho^{-1} = A_\epsilon + B_\epsilon r + C_\epsilon r^2 + D_\epsilon r^3 \cdots. \tag{8}$$

The left-hand side is the molar polarization P_m and A_ϵ, B_ϵ, C_ϵ, D_ϵ, . . . are respectively the first, second, third, fourth, . . . dielectric virial coefficients. Again, these coefficients are related to the contributions from individual atoms, pairs, triplets, quadruplets, . . ., respectively. The limiting value of P_m at low density is $A_\epsilon = N\alpha_0/3\epsilon_0$. For the rare gases, accurate values of the dielectric virial coefficients have been determined by a differen-

tial-capacitance technique (Huot and Bose, 1991; Gugan, 1984).

1.7.2 Spectroscopy of the Dimers Through the use of clever experimental techniques, absorption and emission bands in the vacuum ultraviolet have been observed that have provided information on the vibrational spacings (Ewing, 1975) for Ne_2, Ar_2, Kr_2, and Xe_2 dimers in the ground state and subsequently, with a spectrograph of higher resolution, on the rotational fine structure of Ar_2 and Kr_2 (Colbourn and Douglas, 1976; LaRocque *et al.*, 1986; Herman *et al.*, 1988). Such information has been invaluable for the accurate determination of ground-state constants and interatomic potentials. Results based on the potentials of Table 2 are given in Table 4. Energy levels for the argon dimer are shown in Fig. 3. Observation of vibrationally and isotopically resolved fluorescence excitation spectra has led additionally to information on some of the excited states involved in excimer lasing transitions. Infrared, microwave, radiofrequency, and Raman spectroscopy have been used to reveal the structure and properties of some of the dimers (Xu *et al.*, 1994).

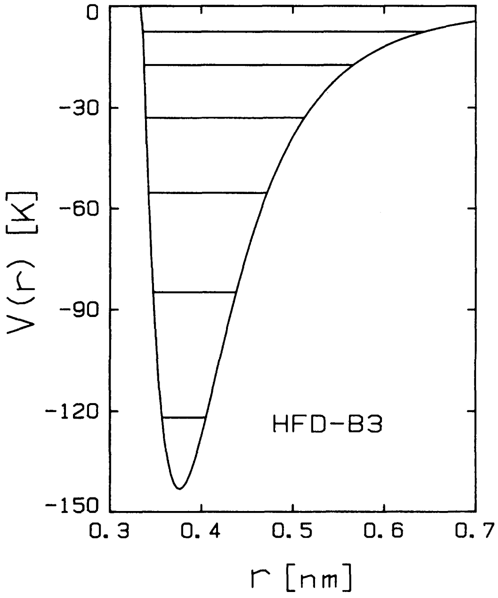

FIG. 3. Energy levels of the argon pair potential. HFD–B3: the Hartree–Fock–dispersion potential of Table 1. The energy levels are those of Table 4.

2. LIQUID STATE AND DENSE GASES

2.1 Interatomic Interactions in the Condensed State

Above the critical temperature, gases and liquids form one continuous state of matter. Coordinates of the critical points for the rare gases are given in Table 1. Experiments on rare-gas fluids can be carried out over very wide ranges of the state variables: pressure *P*, temperature *T*, and density (or molar volume *V*). Because the interatomic pair potentials are well understood, the rare gases form a prototype family of fluids upon which critical experiments can be compared with modern computations of the properties concerned. Such studies form a useful foundation upon which the complications of molecular fluids may be considered, including orientations of the constituents as well as their positions.

It cannot be said that many-body interactions in condensed rare gases are well understood. Quite often, for pressures that are not

too large, a model of an accurate pair potential together with the Axilrod–Teller triple-dipole dispersion energy (DDD) is sufficient to explain properties of the fluids and binding energies of the solid phases. For crystals, the reason for this is that it has been assumed that contributions of the many-body dipole-interaction terms of fourth and higher order $(MBD)_{4\to\infty}$ cancel those of higher multipole third-order terms $(DDQ)_3$, $(QQD)_3$, $(DDO)_3$, and $(QQQ)_3$. D, Q, and O refer to dipole, quadrupole, and octupole, respectively, and subscripts 3 and $4 \to \infty$ refer to third and fourth to higher orders of quantum perturbation theory. In spite of the apparent success of the approach, however, it is worthwhile to point out that there are other nonadditive energies (e.g., nonadditive exchange energies) that could be of the same magnitude as (DDD) and that corrections must be incorporated when the simple approaches fail to yield results that agree with experiment, especially at high density (Barker, 1989; McLean *et al.*, 1988; Meath and Koulis, 1991).

Shock-wave experiments have been carried to high densities in dense-fluid rare gases, with compressions a factor of 3 or more (Yakub, 1994).

2.2 The Structure of Liquids

The structure of matter changes continually with time because its constituents are in motion. In the crystalline state, their displacements are small, and (except in solid helium) they are localized near their lattice sites. In the gas phase, the constituents move over such large distances that the term "structure" is rarely used. Since densities in liquids are similar to those of solids, the packings of the two states are somewhat similar. In fact, liquids possess considerable order or "structure." The static structure of a monatomic liquid may be expressed by a pair-distribution function $g(r)$, which is an equilibrium distribution of interatomic separations averaged over time and direction. Precise measurements of $g(r)$ in rare-gas liquids have been made by x-ray or neutron scattering where the intensity of scattering is obtained as a function of angle (Fig. 4). The measured distribution is then compared with one calculated using assumed potentials. Such calculations have advanced the development of theoretical methods and the understanding of the liquid state.

2.3 Thermodynamic Properties

The function $g(r)$ also plays a central role in determining the thermodynamic properties of the system. For example, the internal energy and the pressure can be expressed in terms of the pair-distribution function $g(r)$ and the potential $U(r)$ together with an ideal-gas term, if the interactions are assumed to be additive. For greater accuracy, a three-body distribution function and three-body

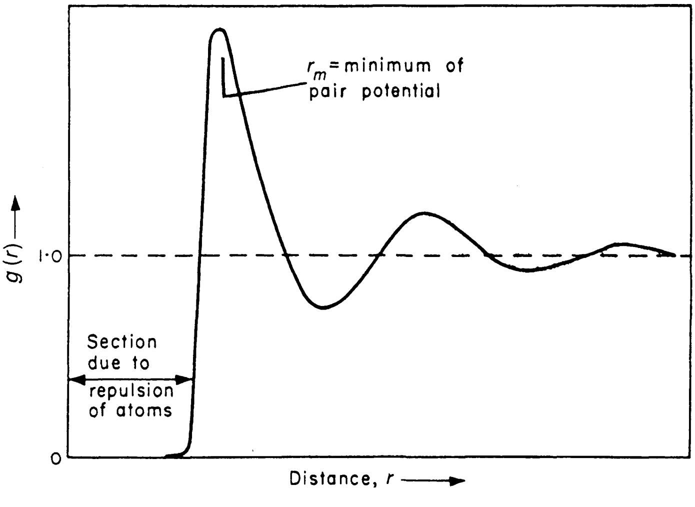

FIG. 4. A sketch of the typical form of the pair-distribution function $g(r)$ for a dense rare-gas liquid. The principal peak of $g(r)$ occurs at a position close to the minimum position r_m of the pair potential. For very low densities these two positions are coincident, and as the density is increased the maximum in $g(r)$ moves to slightly lower values of r than r_m (After Egelstaff, 1992).

potential must be introduced to reflect nonadditive contributions.

Computer-simulation methods can provide, in principle, exact values for most properties on the basis of a given potential model. There are two methods: the Monte Carlo (MC) and the molecular dynamics (MD). The MC method uses ensemble averages as in statistical mechanics and is used to calculate equilibrium properties. The MD method solves the Newtonian equations of motion of the particles and uses time averages. It is used to calculate both equilibrium and transport properties. MC can be applied to both quantum-mechanical and classical systems while MD is applicable only to classical systems. In each method, a small number of particles (less than a few hundred) are used with periodic boundary conditions to simulate the behavior of a large system. Usually an accuracy of 1% or better is attainable for many properties depending on computational speed. Such methods are useful in determining or testing interatomic potentials by comparing the results on the basis of an assumed potential with experiment. The simulated results can also provide a standard by which the results based on approximate methods may be compared.

There are a number of approximate methods to calculate thermodynamic properties that have been or are currently being employed. One of these is the so-called integral equation method. In this procedure, one introduces approximations into $g(r)$ in order to simplify the problem mathematically. One then determines whether such approximations are valid by comparing the results with experiment or computer simulation. Another approximate method meeting with success is the perturbation method (Barker and Henderson, 1976; Weeks *et al.*, 1971). In this approach, the pair potential is written as $U(r) = u_0(r) + \lambda u_i(r)$, where λ is a parameter that, when set equal to zero, gives a reference potential $u_0(r)$ (on the basis of which the properties of the reference system are well known from, say, computer-simulation studies) and, when set equal to unity, gives $U(r)$. The potential is introduced into the partition function and the thermodynamic properties are evaluated. Since the properties of the reference system are known, the properties of the real system can be determined.

Song and Mason (1989) developed a simple analytical equation of state based on perturbation theory for a hard-sphere fluid. By three separate integrations, they determine from a knowledge of the interatomic potential the second virial coefficient, an effective hard-sphere diameter, and a scaling factor as functions of temperature. Since the latter two are nearly universal functions when expressed in suitably chosen reduced units, it results that a knowledge of the second virial coefficient enables one to determine the entire equation of state for the rare gases (except helium; Song and Mason, 1993) up to 3 times the critical density. It allows one to predict such properties as the compressibility of the liquid, the vapor-pressure curve, and the critical constants.

2.3.1 Quantum Corresponding States

The classical restriction of the law of corresponding states for translational states can be removed by introduction of a reduced Planck constant, a measure of quantum effects in the condensed state. For a Lennard-Jones interaction, the de Boer parameter $\Lambda^* = h/(m\epsilon\sigma^2)^{1/2}$ may be regarded as the reduced de Broglie wavelength of a particle of mass m. A property W in reduced form is then expressed by a relation including Λ^* as $W^* = f(P^*,T^*,\Lambda^*)$, where P^* is the reduced pressure. If Λ^* is less than about 0.2, then classical theories of the condensed state are often adequate.

2.3.2 Sound Velocity

Measurements of sound velocity yield the most precise values for adiabatic compressibilities of rare-gas liquids. With knowledge that the heat-capacity ratio is a universal function of the reduced PVT coordinates, it is possible to summarize the sound velocity at saturated vapor v_σ for the heavier rare-gas liquids from their triple points to close to their critical points by a universal relation for the reduced velocity versus reduced temperature, $v_\sigma^* = f(T^*,\Lambda^*) \approx f(T^*)$. The reduction parameters for both velocity and T depend only on the energy parameter ϵ/k_B of some "effective" pair potential. By forcing corresponding states, accurate ratios of the energy parameters of krypton and xenon in terms of that of argon can be obtained (Aziz *et al.*, 1967). In fact, it is interesting to note that velocity appears to be almost perfectly linear with density.

2.4 Transport Properties

2.4.1 Transport Properties, Theory At low densities, transport properties can be accurately calculated at any temperature using exact kinetic-theory expressions. At high densities, however, there is at present no formal theory that provides an exact evaluation of transport properties in terms of a realistic characterization of the atomic interaction.

The MC method has provided significant progress toward a successful molecular theory of transport properties in dense fluids. It requires extensive numerical computation in order to determine the dependence of the transport coefficients on the experimental variables.

Enskog developed a kinetic theory of dense gases consisting of rigid spherical molecules of finite diameter. By considering only two-body collisions and the finite size of the molecule, Enskog modified the kinetic theory of the dilute gas. In this model there is an instantaneous transport of energy and momentum on collision from the center of one molecule to the center of the other; and because of the finite diameter, the frequency of collisions is altered. The density dependence of self-diffusion is given directly by the Enskog theory while viscosity and thermal conductivity require a knowledge of experimental data in order to bring theory and experiment into agreement. There is only one adjustable parameter, the molecular core size, which is determined from the data fit. In this modification as applied to the rare gases (smooth hard-sphere theory), the exact smooth hard-sphere transport coefficients P_{shs} are given by the product of the values from the Enskog theory P_{E} and computed corrections to it: $P_{\mathrm{shs}} = P_{\mathrm{E}}(P/P_{\mathrm{E}})_{\mathrm{MD}}$.

MD methods have been used to characterize the detailed time response in a model Lennard-Jones fluid (de Schepper *et al.*, 1988).

2.4.2 Neutral and Charge Transport, Experiment At the U.S. National Institute of Standards and Technology, extensive measurements have been obtained of the equation of state and the viscosity of liquid argon as a function of density, the latter using a torsional oscillating crystal. Thermal conductivity data for argon are also available. Since acceptable equations of state for krypton and xenon are unavailable, LCS can be used (Hanley *et al.*, 1974) to determine values of viscosity and thermal conductivity as follows. A reduced viscosity is defined as

$$\eta^* = \eta[r_{\mathrm{m}}^2(N/M)^{1/2}(k_{\mathrm{B}})^{-1/2}(\epsilon/k_{\mathrm{B}})^{-1/2}] \qquad (9)$$

and a reduced thermal conductivity is defined as

$$\lambda^* = \lambda[r_{\mathrm{m}}^2(M/N)^{1/2}(k_{\mathrm{B}})^{-3/2}(\epsilon/k_{\mathrm{B}})^{-1/2}] \qquad (10)$$

where ϵ/k_{B} and r_{m} are potential parameters for an "effective" pair potential. A reduced pressure is given by

$$P^* = Pr_{\mathrm{m}}^3[(\epsilon/k_{\mathrm{B}})k_{\mathrm{B}}]^{-1} \qquad (11)$$

and a reduced temperature is given by

$$T^* = T/(\epsilon/k_{\mathrm{B}}). \qquad (12)$$

To obtain η and λ of krypton or xenon at a given temperature and pressure, a corresponding temperature and pressure are first found for argon using Eqs. (11) and (12). The equation of state for argon is used to find the density, and then the transport coefficients can be determined from Eqs. (9) and (10) and the appropriate potential parameters.

Charge-transport studies in rare-gas liquids show that injected electrons are in a quasifree state of high mobility. Carrier transport has typically been determined by time-of-flight methods using electrical shutters (Shikin, 1977). More unusual have been studies of the annihilation of positrons injected into rare-gas liquids (Stewart *et al.*, 1990). A localized bubble state is formed in liquid krypton, argon, neon, and helium (and in solid helium). The bubble radius is determined by a balance between shrinking forces of bubble surface tension and external pressure and the zero-point pressure exerted by the confined positronium. The lifetime for decay of each positronium mode is a measure of the electron charge density at the positron-annihilation site.

2.5 Microscopic Dynamics from Neutron-Scattering Evidence

Slow-neutron scattering has provided a powerful tool for extending studies to include the dynamics of liquid structure. That is, it can be used to measure various correlation functions appearing in dynamical models for liquids—for example, the self-correlation (the average motion of an atom among others) and the density–density correlation (the relative motion of atoms). In practice, argon provides a rare example of a liquid system in which both the coherent scattering (from a ^{36}Ar sample) and also the incoherent scattering (from a suitable mixed ^{36}Ar–^{40}Ar sample) can be determined (Skold *et al.*, 1972). For argon, analysis of the experimental results in view of molecular-dynamics simulations shows good agreement with a picture in which the atoms exhibit free-particle behavior at very short times with a smooth transition to simple diffusion already at times about 2 ps.

At very small scattering vectors Q, i.e., long wavelengths, observed fluid modes correspond to fluctuations in the density, at frequencies $\omega = cQ$, where c is the velocity of sound, and to fluctuations in the entropy, centered at zero frequency. These three peaks broaden and merge at larger Q, about 1 nm^{-1} for the rare gases. At very large Q the modes correspond to single-particle motion. At intermediate values of Q, interpretation of the response of rare-gas fluids is somewhat controversial, although results on argon and neon show interesting differences. Helium seems to be a special case (Montfrooij *et al.*, 1992).

2.6 Special Properties of Liquid Heliums and Their Isotopic Mixtures

Superfluidity in liquid-helium systems has been treated in many thousands of research papers (see SUPERFLUIDITY: LIQUID HELIUM SYSTEMS). The behavior of liquid ^{4}He (a boson) is qualitatively different from that of liquid ^{3}He (a fermion), although both exhibit superfluid phases at low temperatures. The only atom that forms an *anisotropic* liquid is ^{3}He.

Landau gave a phenomenological theory of normal Fermi liquids in 1956, only a few years after sufficient quantities of ^{3}He became available for its thermodynamic properties to be measured. The Landau theory uses the concept of elementary excitations to clarify the properties of strongly interacting quantum systems at low temperatures. It provides a useful way to correlate measured properties directly, such as the transport coefficients, with a limited number of parameters, without the need for a microscopic theory. Subsequent microscopic derivations of the Landau theories have been produced. In ^{3}He these excitations are quasiparticles, a concept that has proven useful in other forms of condensed matter.

Thermodynamic and physical properties of isotopic helium mixtures have an extraordinary range. For example, varying the ^{4}He content in ^{3}He produces an adjustment of the Fermi temperature with little change in number density of the liquid. Measurements of thermal conduction, viscosity, diffusion, etc. have been used to check theories of Fermi liquids over a very wide range of parameters. Work on nuclear matter and on nuclei is parallel, but only a much more limited range of parameters can be studied.

We note that the properties of these extraordinary liquids can be linked to those of the heavier rare gases when the heliums are brought to high density, at which internuclear distances are nearer the characteristic length of the pair potential, and at which the statistics obeyed by the atoms is insignificant (Boninsegni *et al.*, 1994).

3. CRYSTALLINE STATE

3.1 Melting, Corresponding States

The rare-gas solids form an interesting family. Among all interatomic interactions, van der Waals cohesion is the weakest in forming condensed systems, and the pure rare gases have low condensation temperatures (Table 1) and energies (Table 5). One kind of corresponding-states analysis simply uses the triple points as scaling parameters. The search for a critical point at the end of the solid–fluid line in a P-T diagram has been carried furthest in helium, for which one can access experimentally the largest range of V of any substance. No such point has been found.

In the rare-gas family, effects of different kinds occur in a smooth progression as one goes from one row of the periodic table to another. For example, Table 5 shows that with increasing mass comes a decrease in the importance of macroscopic quantum effects (compare the ratios E_z/E_s). The solid

Table 5. Binding energies $E(0)$ of rare-gas solids at 0 K based on the potentials of Table 2. [$E(0) = E_S + E_Z$ where E_S is the static energy of face-centered-cubic lattice and E_Z is the zero-point energy including anharmonic effects. Units of J mol^{-1}. "Complete" energies include $(DDD)_3$, $(DDQ)_3$, $(QQD)_3$, $(DDO)_3$, $(QQQ)_3$, and $(MBD)_{4\to\infty}$. (See Sec. 3 for definitions of these multibody interactions.)]

[a] McConville (1974).
[b] Schwalbe *et al.* (1977).

heliums are a special case, because they require external pressure for solidification; for them, the ratio E_z/E_s is about unity. On the other hand, with increasing mass comes an increase in the relative importance of many-body interactions.

3.2 Thermoelastic Properties

For the heavier rare-gas solids under saturated vapor pressure, the heat capacity and thermal expansivity have been measured with high precision over the entire crystalline ranges above about 1 K. Heat capacity has been well determined by adiabatic calorimetry (Korpiun and Lüscher, 1977). Thermal expansion has been precisely measured by capacitance dilatometry at low temperatures and by x-ray diffraction at temperatures up to melting. X-ray measurements of lattice parameters of single crystals have approached the best accuracy available for usual solids (Losee and Simmons, 1968). On account of very large thermal expansion, the heat capacity at constant pressure for argon, krypton, and xenon rises to about 35 J mol^{-1} deg^{-1}, which is 40% above the Dulong–Petit value $3R$. This fact, together with the relatively large vibrational energies of these solids, has attracted the attention of theorists interested in the dynamics of crystals that are highly anharmonic. For example, because the isobaric coefficient of thermal expansion corresponds to a third derivative of the free energy, this is a most demanding test of a statistical-mechanical model.

Precise values have been obtained of the thermal properties of the solid neon isotopes ^{20}Ne and ^{22}Ne over the entire temperature range. Direct measurements of kinetic energy of crystalline neon, using eV neutron scattering, show that the vibrational energy is about 35% of the cohesive energy. The vibrational energy differs for the two isotopic masses. The isotopes therefore have different internal pressures and exhibit different equilibrium lattice parameters, vapor pressures, specific heats, etc. These can be correlated by a single-particle model in which the dominant agent is the vibrational energy (Batchelder *et al.*, 1968).

Elastic constants of the rare-gas solids are not as well determined. For these solids the equilibrium vapor pressures and thermal expansions are large and the melting temperatures low, which defeats ultrasonic pulse-echo techniques as usually applied to oriented and prepared single crystals. The solid heliums are an exception; for these, ultrasonic transducers can be kept in contact with the crystals confined at constant volume. For other crystals near melting, where single crystals could be kept in good optical contact with transparent cell walls, values have been obtained by Brillouin scattering, which is inelastic scattering of a photon by an acoustic phonon.

Anisotropy in the deduced elastic constants has been attributed to two effects: for the lighter rare gases, large zero-point energies, and for the heavier ones, many-body interactions. These attributions are qualitatively correct, but detailed interpretations remain somewhat inconclusive as long as the temperature dependence of the elastic constants is not well known over the entire temperature range.

Rare-gas solids are extraordinarily compressible compared with other solids. Unlike other materials, for them it is practical to study many properties under essentially isochoric conditions or over large changes in density. Brillouin scattering has been used to measure the velocity of sound (and hence the density) in argon compressed up to 30 GPa (Polian *et al.*, 1986). Isochoric studies of heat capacity have been carried out for the heliums, for neon, and for argon. For heliums, these have been correlated with precise measurements of pressure, using the relation $(\partial S/\partial V)_T = (\partial P/\partial T)_V$. For some phonon branches, dispersion has been studied in isochoric neon and argon samples using slow-neutron scattering.

Measurement of pressure–volume–temperature (*PVT*) relations by piston-displacement techniques have given the density dependence of the bulk modulus B of the heavier rare gases (Swenson, 1977). It has been found that a Birch type of relation often represents the results well at low temperature: $B = B_0 + bP$, where P is the pressure and b is a parameter having a value 5 to 6. It is remarkable that all members of this family that have a solid–liquid–vapor triple point fall on a common curve ($\pm 15\%$). At higher temperatures for the heavier rare-gas solids, the temperature dependence of the solid equation of state is approximately given by $(dP/dT)_V$ = constant, with the constant having a value about 2.7 to 2.9 MPa K^{-1}.

3.3 Microscopic Properties

3.3.1. Phonons, Experiment and Theory Measurements of phonon energies and dispersion, by coherent inelastic scattering of neutrons, provide information about the dynamics of interatomic interactions in rare-gas solids. All rare-gas solids except radon and ^{3}He have been studied in this way, radon because it is radioactive and ^{3}He because of its enormous neutron absorption.

It is conventional to parametrize results by fitting a Born–von Kármán model. This is an atomistic formulation of lattice dynamics that sets up the interaction forces in general fashion. Calculations of properties using the parameters of the model can then be compared with corresponding properties calculated from lattice-dynamical theories. Properties of interest within the harmonic approximation include the one-phonon density of states and its frequency moments, and the lattice specific heat. By examining the energy versus wave-vector relations at very small Q, the "zero-sound" elastic constants are obtained, i.e., those at frequencies large compared with a typical phonon–phonon collision frequency. Once again, the large compressibility of rare-gas solids has permitted measurement of dispersion in some phonon branches in isochoric helium, neon, and argon crystals, which exhibit considerable anharmonicity. This has the great advantage of displaying the intrinsic temperature dependence of anharmonic effects, which are often masked by changes in phonon frequencies due to changes in crystal density from thermal expansion.

Results for the fcc phases have provided a continual object of theoretical attention, as both experiment and theory were refined. For the heavier solids such as argon, very satisfactory agreement has been reached using computer simulations. Theories that use modern interatomic potentials are now able to account for many details of the phonon-excitation line shape as well as for the dispersion structure and hence the bulk thermodynamic properties. In favorable cases, observed agreement between theory and experiment tests the theory, the potential, and the experimental technique. On the other hand, results for solid ^{4}He are interesting, showing multiple-phonon interactions, but they are incomplete for higher phonon energies.

Thermal resistivity in perfect insulators arises from umklapp processes, those phonon-scattering processes for which the rule for conservation of wave vector is $\mathbf{Q}_1 + \mathbf{Q}_2 = \mathbf{Q}_3 + \boldsymbol{\tau}$, where $\boldsymbol{\tau}$ is a vector in the reciprocal lattice. Again, the large compressibility of rare-gas solids makes it possible to investigate thermal conduction in samples at constant volume, which removes the effects of thermal expansion from the analysis. Similarly, studies of the thermal conduction at different densities are possible; such studies are extremely rare in usual solids. At the highest temperatures, accessible for argon, krypton, and xenon, thermal conductivity at constant volume goes as T^{-1}, as given by a phonon-gas model, and it follows a law of corresponding states (Batchelder, 1977). At lowest temperatures, defects and boundary scattering limit thermal conduction. In highly pure and perfect helium crystals, an enhancement of thermal conduction has been observed, which can be attributed to a regime in which Poiseuille flow of the phonons is significant. Helium-isotope crystals have provided important information on mass-defect scattering processes, because the mass ratio is very large.

3.3.2 Momentum Distribution, Kinetic Energy The momentum distribution of individual atoms can be measured by analyzing the neutron recoil-scattering process in terms of neutron energy transfer at a given momentum transfer (Simmons, 1993). Neutrons of energy about 1 eV are required. From the momentum distribution, the kinetic energy can be deduced and compared with the results of simulations in order to test both the simulations and the experiments in a very direct fashion. For the heavier rare-gas solids the results have been according to expectation; for example, the equipartition law holds for translational states regardless of density of the system.

On the other hand, measurements on helium have shown that the actual kinetic energy is significantly larger than what would be expected from the Born–von Kármán (harmonic) analysis of neutron-measured phonon dispersion. Actually, for solid helium, the high-energy excitations corresponding to single phonons are generally so broad and weak that a Born–von Kármán analysis including these states is unjustified. For helium, path-integral Monte Carlo methods have proven most satisfactory (Ceperley, 1995). An illustration is provided by considering kinetic-energy results for samples of ^{4}He at fixed number density but in different phases, bcc or hcp or liquid (depending upon P and T); such a study is only possible with helium. The result is that the kinetic energies of these three phases are essentially the same, that is, helium is a quantum system dominated by the density, not by details of the local order (Blasdell *et al.*, 1993).

3.4 Dielectric and Electronic Properties

Experimental results on many dielectric and electronic properties of the rare-gas solids can be fruitfully interpreted using atomic characteristics. These solids have very large forbidden-energy gaps for electrons (Rössler, 1977). The gaps at low pressures range from about 9.3 eV in xenon to about 30 eV in helium. For these prototype insulators, optical properties at energies below the valence-band transitions can be succinctly expressed by the Lorentz–Lorenz function that relates the dielectric constant or index of refraction to the atomic polarizability [Eq. (7)]. Quantitative (phenomenological) descriptions of the dielectric properties can be constructed on the assumption that principal contributions arise from excitons (bound electron–hole pairs, the hole being a positive charge carrier) originating from the atomic doublet $^1S_0$-$^{3,1}P_1$.

Measurements of UV and XUV (extreme ultraviolet) reflectivity and absorption data on the heavier rare-gas solids have been correlated and extended by Kramers–Kronig analysis to give the complex optical constants (Sonntag, 1977). These have been further compared with electron energy-loss spectra. Again, information on atomic properties, and theoretical calculations of electron structure, are useful for interpretation of spectral features, although explanation of the observed intensities continues to provide a challenge to theorists. Data near the x-ray absorption edges are of special interest and have been collected for all rare gases xenon through helium (Schell *et al.*, 1995). Exciton effects are prominent, and the type of excitons observed depends upon the particular rare gas (Schwentner *et al.*, 1985; Varding *et al.*, 1993).

Drastic modification of the electron structure is possible at high pressures. For example, usual xenon (fcc structure at 34.7 cm^3 mol^{-1}) has a gap between the 5p valence band and the (empty) 6s conduction band. When compressed in diamond-anvil pressure cells solid xenon is found to transform at 17 GPa to a complex hcp structure, then at about 75 GPa to hcp, then finally to a metallic state, presumably through approach of the 5p and 5d electron bands. The observed pressure of transformation is 130–150 GPa, at a density of about 11 $\mathrm{cm}^3\ \mathrm{mole}^{-1}$. In xenon, the metallization has no accompanying structural transition; x-ray diffraction shows a hcp structure from 75 to 175 GPa (Jephcoat *et al.*, 1987). For lighter rare-gas solids, expected pressures of transformation are higher, for example above 600 GPa in solid argon. The results of attempts to reach such pressures in shock-wave experiments are difficult to interpret because the accompanying large temperature rise also causes electronic excitations, apparently beginning at about 40 GPa in argon. Some insight into these processes has been gained through observations at high pressures on ionic compounds having an ion with the rare-gas–like electron configuration $(ns)^2(np)^6$ and on structural transformations in metals that involve promotion of electrons to the d band (Ross and Radousky, 1989).

Finite–sample-size effects were first seen in observations of the cutoff of excitonic series in thin films. More recently, as cluster physics and chemistry develop, measurements have been made of the soft x-ray spectra of rare-gas clusters of sizes from about 10^2 to about 10^4 atoms, produced in jets. Finally, electron energy-loss spectra have been collected both from thin films and from clusters. In films, evidence of plasma excitations has been seen.

Charge transport has been investigated using excess carriers injected by pulsed-electron excitation of the heavy rare-gas solids (Spear and le Comber, 1977) and by ionizing decay products of radioisotopes embedded in solid heliums. Charged-particle excitation has proven more convenient than photon excitation, because condensed rare gases exhibit photoemission more readily than photoconduction. For the solids formed from neon, argon, krypton, and xenon, low-field electron mobilities typically display a $T^{-3/2}$ temperature dependence, which is characteristic of quasifree-electron transport limited by phonon scattering. On the other hand, the drift mobility of excess holes (positive charge carriers) in these solids is typically several powers of ten smaller in magnitude than for electrons. In this case, it is more appropriate to describe the process as the formation and transport of localized entities, such as a polaron, a charge carrier trapped in its own polarization field. In this case the temperature dependence of the process is dominated by a term $\exp(-E_b/2k_BT)$, where E_b is a characteristic binding energy for the polaron. At high electric fields, electron velocity depends on essentially the square root of the applied field, an indication that the electron distribution becomes "hot." It saturates at a velocity near that of sound.

Altogether, rare-gas solids are providing rich sources of information about how electronic properties of condensed matter in various degrees of aggregation can be quantitatively related to the properties of the constituent atoms.

3.5 Crystal Defects

3.5.1 Point Defects The formation of equilibrium atomic vacancies has been measured in all rare-gas solids. The concentrations (n/N) are determined directly and absolutely by precise comparisons of changes in x-ray lattice parameter $(\Delta a/a)$ and of macroscopic expansion $(\Delta L/L)$ at a succession of temperatures. The applicable formula is

$$(n/N) = 3(\Delta L/L) - 3(\Delta a/a). \tag{13}$$

From the concentration the free energy of formation of the vacancies, f, follows from the relation

$$(n/N) = \exp(-f/k_BT). \tag{14}$$

The free energy has two parts: an energy e, and a nonconfigurational entropy s. From the magnitude of the entropy some idea of the local structure of the vacancy can be obtained. Table 6 displays some directly measured values for thermal-vacancy energies.

Other physical properties are affected by the presence of equilibrium defects—for example, the heat capacity and the compressibility. Inferences of vacancy content using these other properties depend, however, upon the assumption that one knows the behavior of a hypothetical perfect crystal, so that the vacancy contribution can be obtained by difference. Such assumptions have frequently proven unreliable, and so a direct method is preferred.

Rare-gas solids are composed of neutral atoms, so that comparison of their cohesive

Table 6. Some thermal-defect properties of rare-gas solids (Sec. 3.5.1). (The formation energies e correspond to the values shown for the entropies, s/k_B. The last column is a test for the influence of many-body interactions, present if the ratio is less than unity. For Ar an average value for e is used.)

Rare gas	$f/k_B T_M$	s/k_B	e (meV)	$e/(E_P - E_Z)$
Neon[a]	9.7	1.6	21	1.0
Argon[b]	8.5	0–4	62–93	0.9
Krypton[c]	7.8	2.8	86	0.8
Xenon[d]	7.0	~2	~100	0.6

[a] Schoknecht and Simmons, R.O. (1972).
[b] Schwalbe (1976).
[c] Losee and Simmons (1968).
[d] Granfors *et al.* (1981).

energies per atom with the energy of vacancy formation gives direct information about the presence of many-body forces and of local lattice relaxation around the vacancy site. Such a comparison is given in the last column of Table 6 for entropies near $2k_B$. The table shows that many-body effects become more important as one goes from solids composed of the less polarizable (neon) to the more polarizable atoms.

Self-diffusion in all rare-gas solids except ^{4}He has been measured by NMR methods or by exchange with radioisotopes in the vapor, because the usual sectioning of samples containing radiotracers is not practicable, on account of the low melting points and high vapor pressures of these solids. A consistent picture has emerged (Chadwick and Glyde, 1977). The dominant mechanism of self-diffusion in all solids except the heliums is the motion of single vacancies. In solid heliums, diffusion may occur both through direct interchange of atoms and through vacancy migration.

In principle, point defects analogous to some of the "color centers" in ionic crystals can be created in rare-gas solids by ionizing radiation. A likely example is a dimer–ion analogous to the V_K center found in alkali halides.

Extrinsic point defects such as foreign atoms, molecules, or radicals can be studied over a vast range of photon energies, microwave through x ray, because of the closed-shell character and large band gap of the rare-gas host. Low temperatures slow reaction kinetics so that ephemeral processes can be studied. Neutron scattering is also a useful tool to examine molecular excitations when the nearly (neutron) transparent ^{40}Ar is used as host (Langel, 1992).

3.5.2 Line and Surface Defects, Thin Films, Clusters Dislocations and surface defects in rare-gas solids have been studied extensively by transmission electron microscopy (Venables and Smith, 1977). Contrast methods for stacking faults (a planar defect in the crystal resulting from misstacking of successive planes of atoms) are applicable as in other thin films. Arrays of dislocations (a one-dimensional defect) are seen, and twinning as in other fcc crystals. Because of high equilibrium vapor pressures, grain boundaries that intersect a bulk surface can be thermally etched. In thin films of neon, both fcc and hcp structures are observed. The classic rare-gas structural question was "Why are most bulk structures fcc and not hcp" (as would be expected in a static lattice containing only pair interactions)? The answer is that experiments show that the energy differences are very small, and that relatively small amounts of zero-point motion, of many-body interactions, etc. are required to produce the observed fcc structures.

Clusters of rare-gas atoms can be formed in supersonic jets. Cluster size can be varied by varying the conditions of the jet. For argon, clusters of fewer than about 800 atoms exhibit a quasicrystalline (isocahedral) structure as analyzed by electron diffraction, whereas larger clusters exhibit the fcc structure of bulk argon (Kovalenko *et al.*, 1994; Schöllkopf and Toennies, 1994). Simulations suggest that in small neutral clusters there may be a dynamical coexistence between crystal and fluid structure that permits the investigation of melting mechanisms (Matsuoka *et al.*, 1992). For argon clusters, excitation by x rays or electron bombardment can produce effects such as x-ray fluorescence and fragmentation of the clusters. The phenomena can be consistently linked to atomic and bulk properties (Wörmer *et al.*, 1991). For helium clusters, however, considerable inconsistencies in such an interpretation remain (Joppien *et al.*, 1993). As usual, heliums are a special case in this rare-gas family.

3.6 Solid Heliums, Unique Properties

The two helium isotopes, ^{4}He and ^{3}He, are the only substances that do not solidify at atmospheric pressure even when their temperatures approach 0 K. External pressure is required, larger for ^{3}He (about 3.1 MPa) than for ^{4}He (about 2.5 MPa). The quantum zero-point motion of the lighter isotope is larger, producing a larger internal pressure to be overcome in order to bring the substance to a density at which the interatomic spacing is close to the distance at which the interatomic potential energy is a minimum. Table 1 indicates the remarkable differences in the properties of the helium solids from the other members of the family. These properties present a special challenge to lattice-dynamical theory. Max Born first addressed the possibility of a self-consistent phonon theory, and such theories, numerically computed, have been the most successful so far for phonons in solid heliums.

The isotope ^{3}He has a pronounced minimum in its melting curve; that is, the thermodynamic derivative along the solid–fluid coexistence line, $(\partial P/\partial T)_V$, is negative over a significant range of temperature. Qualitatively, the reason for this may be seen from the Maxwell relation, which can be used to equate the slope of the melting curve to the change in entropy with change in volume across the phase boundary: $(\partial S/\partial V)_T = (\partial P/\partial T)_V$. The liquid is less dense than the solid phase. However, in the temperature range concerned, the liquid phase is a Fermi liquid having a high degree of order in the spin system (although it has the usual positional disorder of a liquid) whereas the solid phase has much magnetic disorder (it is well above its magnetic transition temperature below 10 mK and hence has entropy about $R \ln 2$). This has led to very unusual studies such as the production of spin-polarized *solid* ^{3}He by sudden compression of the liquid, by cooling through sudden pressurization at temperatures below the minimum, and so on.

The magnetic structure of solid ^{3}He depends upon its density and upon the temperature. Magnetism in ordinary materials is accounted for by quantum-mechanical "exchange" of electron spins, which may appear to be a theoretical construct. In ^{3}He, which has only paired electrons, the spin concerned is nuclear, which, although linked to a very weak magnetic moment, becomes a dominant interaction at low enough temperatures and high enough densities. Because of the extraordinary mobility of the atoms, even in the solid state, there can be literal atomic exchanges (actually, in rings of three or of four atoms) to produce several observed magnetic phases (Roger *et al.*, 1983).

The properties of isotopic mixtures have been systematized by Edwards and Balibar (1989).

3.7 Defects and Excitations in Solid Heliums

By x-ray lattice-parameter measurements, thermal-vacancy concentrations have been directly measured in both hcp and bcc phases of both ^{3}He and ^{4}He (Simmons, 1994). The deduced activation energies have the expected variation with volume; that is, they are larger at smaller molar volumes. Nevertheless, the results are puzzling, because the concentrations are larger than those inferred indirectly from measurements (in isochoric samples) of pressure change and of specific heat. Because of the extremely high diffusivities measured by NMR in ^{3}He, explanations have been sought in vacancy excitations that are nonlocalized as a result of rapid tunneling processes. It has even been proposed, but not yet observed, that the ground states of these crystals contain vacancies. This would be one of the more bizarre consequences of the well-known nonlocalization of the atoms in solid heliums.

Negative-ion transport in the solid heliums can be attributed to motion of a hollow bubble surrounding a trapped electron (Dahm, 1986; Golov and Mezhov-Deglin, 1994). Such "bubble" states have been seen in both liquid neon and liquid helium, and in the latter have been used to probe excitations in superfluid helium samples. Bubble radii, determined by minimization of the total energy (electron confinement versus surface energy of the bubble), are thought to be about 0.7 nm in neon and from 1 to 2 nm in helium, depending upon the applied pressure.

The isotope ^{4}He also has a minimum in its melting curve, near 0.7 K, and the fact that at this temperature the adjacent liquid phase is superfluid has remarkable consequences. From the relation $(\partial S/\partial V)_T = (\partial P/\partial T)_V$ one sees that at and near this temperature the latent heat of freezing (melting) is zero or small. At the same time, the adjacent superfluid has extremely large thermal conduction, so that heat can be carried away from (or toward) the interface very rapidly. There is an interfacial energy, that is, a surface tension to be associated with the interface, so that "melting-freezing waves" can exist at this interface (Parshin, 1982; Chevalier *et al.*, 1994). Indeed, the observed frequencies of oscillation can be used to deduce information about the interfacial energy and structure. Observed velocities of propagation for these waves show the fastest freezing exhibited by any macroscopic condensed matter.

Fundamental optical studies of crystal growth have been made on ^{4}He and ^{3}He crystals growing in superfluid (the latter at 1 mK; Wagner *et al.*, 1994). Roughening transitions are seen, that is, temperatures at which the crystal–fluid surface changes from atomically smooth to rough.

4. SCIENTIFIC AND TECHNOLOGICAL APPLICATIONS

Scientific and technological applications for rare gases cover an extremely broad range. Many depend upon the inert property of the rare gases. The descriptions that follow are indicative, not comprehensive.

4.1 Arc Welding and Cutting

In volume of material, the largest use for argon and helium lies with gas-shielded welding and cutting of metals in an electric arc. They are used to exclude surrounding air from the molten weld metal. In this way, welds can be made in metals such as aluminum, magnesium, molybdenum, nickel, titanium, zirconium, and some stainless-steel alloys that are otherwise difficult to join. For some applications, one or more chemically active gases, such as hydrogen, may be added to control arc characteristics.

4.2 Passive Atmospheres and Inert Condensed Environments

The second-largest use for argon and helium, in terms of total quantity of gas, is as a passive atmosphere when processing or sparging reactive metals or other materials such as semiconductors. They are also used to regulate the rate of chemical reactions that depend on the concentration of the active gas. The excellent thermal conductivity of helium provides an efficient heat-transfer medium during the annealing of metals.

Condensed rare gases have often been used as inert matrices for spectroscopic studies of molecules and radicals that cannot otherwise be stabilized for extended study. Their transparency to electromagnetic radiation is extraordinary, and the low temperatures serve to retard kinetic processes. Spectroscopic properties of the guest molecules and radicals can therefore be studied from the microwave region through the far ultraviolet. This trapping can be carried to extreme selectivity: for examples, studies of the electron spin resonance of cesium atoms in solid helium and the influence on polarized light by rubidium implanted in solid xenon.

4.3 Illumination

A minor use of rare gases in terms of quantity, but all-pervasive in devices, is in sources of illumination. Electrical light sources fall into two groups: incandescent and gaseous discharge. In the case of incandescent lamps, a metal filament is heated to incandescence to produce light, usually in an atmosphere of argon gas together with a small amount of nitrogen. High-intensity incandescent bulbs are filled with krypton. Gaseous-discharge tubes produce light when an electric current is passed through an ionized gas between two electrodes. The color of the light produced depends on the specific gas present in the tube. Neon-discharge tubes, for example, emit light mainly in the red or orange region of the spectrum, while helium or argon or mixtures of these gases are used to produce other colors. Fluorescent lamps contain some argon, neon, or krypton to facilitate initiation of the discharge in the mercury vapor. Similarly, argon helps to start the electric discharge in mercury-vapor or sodium-vapor lamps. Xenon-filled flashlamps provide the photographer with economic, reproducible, brilliant, and brief illumination with a spectral distribution similar to that of daylight. A continuous source of extremely bright illumination for use in sports stadiums and in motion picture production is produced by an arc in high-pressure xenon placed in a quartz envelope.

4.4 Lasers

When highly collimated and monochromatic light is desired, rare-gas laser sources may be used. In the familiar helium–neon laser, laser emission results from excited levels of neutral neon atoms that have been populated by collision with excited helium atoms. Commercial versions are normally of a sealed-tube configuration. They typically have an output power of 1 mW and a lifetime about 10 000 h. Lasers based upon Ne–He mixtures are among the most widely used, including such technical applications as precise land-based surveying. Argon- and krypton-ion lasers provide high cw laser output power in the visible and near-ultraviolet regions of the spectrum but only at the expenditure of a considerable amount of electrical power. Other lasers involving rare gases are the He–Cd and pulsed rare-gas halide lasers. The latter class of "excimer" lasers produce stimulated emission as a result of transitions from a strongly bound excited state to a weakly bound ground state. For example, the laser transition occurs when $Kr^+ + F^-$ in a bound $^2\Sigma$ state undergoes a transition to the thermally unstable $X^2\Sigma$ state, which then dissociates into neutral ground-state atoms.

4.5 Thermometry

The International Temperature Scale of 1990 (ITS-90), adopted by the International Committee of Weights and Measures, is defined, in part, in terms of the properties of rare gases for its realization below 25 K. This scale (Preston-Thomas, 1990) supersedes previous scales, which have serious differences with the thermodynamic temperature. In the range from 0.65 to 5.0 K, ITS-90 is defined in terms of the *vapor pressure* of ^{3}He and ^{4}He. In the range from 3.0 K to the triple point of neon (24.5561 K), ITS-90 is defined in terms of a ^{3}He or ^{4}He gas thermometer of the constant-volume type calibrated at three experimentally realizable temperatures (the triple point of neon, the triple point of equilibrium hydrogen, and a temperature between 3.0 and 5.0 K determined in a prescribed way using a ^{3}He or ^{4}He vapor-pressure thermometer). The nonideality of the gas must be accounted for explicitly using the appropriate and accurate virial coefficient. To this end, many standards laboratories proceeded to measure these coefficients with the highest possible degree of accuracy.

4.6 Cryogenics and Refrigeration

The liquid heliums serve as cryogenic fluid baths at temperatures that can be precisely controlled through control of the vapor pressure. With readily available pumping the limiting temperatures are about 1.2 and 0.3 K for ^{4}He and ^{3}He, respectively. The isotopic mixture of ^{4}He and ^{3}He can be used to produce a continuously operating refrigerator at temperatures down to about 3 mK. ^{3}He displays about 6% solubility in the liquid mixture, even at the lowest temperatures. Concentrated ^{3}He floats on a mixture at higher temperatures, providing a source of ^{3}He, which dissolves into the dilute ^{3}He phase. This is analogous to ordinary evaporation, with accompanying absorption of heat. On the other hand, ^{3}He has a higher vapor pressure, which permits it to be distilled out of the resulting mixture and recirculated continuously.

Large-scale use of liquid ^{4}He occurs in the cooling of superconducting magnetic structures in accelerators and detectors used by high-energy physicists. This use will be important until high-T_c superconductors can be used in these structures, which experience extremely large magnetic forces and must operate with changing currents.

4.7 Other Uses

Rare gases have found an extremely wide variety of other applications. Among these for helium are as buoyant filling for nonrigid airships and balloons, and as a gas for wind tunnels at extremely high Mach numbers. A "wind" tunnel for unusual hydrodynamic regimes could use liquid helium. Perhaps most familiar to scientists are uses for highly sensitive vacuum leak detection with mass spectrometers and as a carrier gas in chromatography. Rare gases have been a common filling for gas detectors of radiation. High-energy particle physicists continue to develop the use of liquid Xe, Kr, and Ar as vacuum-ultraviolet scintillation materials that have high quantum efficiency, uniformity, and resistance to radiation damage.

An important application of rare-gas adsorption is the measurement of the total surface area of a microporous material. The area can be determined if the pores are large enough to allow the gas to enter and if its adsorption behavior on the material is well known. Conversely the nonadsorption of helium makes it useful in volume measurements of microporous materials. Helium penetrates the finest pores of a substance without being adsorbed appreciably. The volume of displaced helium then provides an accurate measurement of the volume of the substance.

All the rare gases have been investigated for biological effects and possible medical use. Helium is useful in breathing atmospheres in deep diving or in sealed environments, and it and xenon have been investigated for use as nonexplosive anesthetics. The radioactive isotopes ^{85}Kr and ^{87}Kr have found some use, for example as tracers in studies of circulation and in radiotherapy.

It is remotely possible that xenon oxides and perxenates could find application as specialized explosives or oxidizing agents (Asimov, 1966). Another possible application of solid or liquid rare-gas compounds would be as a storage method for the gas. Such compounds, if sufficiently stable, might eliminate the need for the high-pressure and cryogenic facilities currently used to store the fluids.

GLOSSARY

Chemical Compound: A substance that is chemically stable at room temperature and pressure, held together by a chemical bond.

Clathrate: A **van der Waals force** can act between a rare-gas atom and an atom or molecule of another kind, resulting in a weak bond. This attachment is further enhanced if the molecules form a cage around the rare-gas atom. Such a complex is called a clathrate.

Correlation Function: In dynamical models for liquids, for example the self-correlation (the average motion of an atom among others) and the density–density correlation (the relative motion of atoms).

Equation of State: For a gas, a relation over a range of pressure P, volume V, and temperature T in an equation, such as $PV = RT[1 + B/V + C/V^2 + D/V^3 + \cdots]$. Here B, C, D, etc. are the second, third, and fourth **virial coefficients,** which depend only on T and the species of gas. For condensed systems, the relation $P(V,T)$ generally has no such simple analytical form.

Extrinsic Point Defects: Examples are foreign atoms, molecules, or radicals.

HFD Potential: In the overall damped HFD potential the interaction energy is partitioned into uncorrelated (Hartree–Fock) and correlated parts and a suitable damping function to account for charge-overlap effects.

Kinetic Theory: From the laws of mechanics and the theory of probability, it determines the macroscopic properties of gases in terms of the motion of molecules, their collisions with one another, and the forces of interaction.

Landau Theory: A phenomenological theory of normal Fermi liquids, which are formed of spin-$\frac{1}{2}$ particles. It uses the concept of elementary excitations to clarify the properties of strongly interacting quantum systems at low temperatures. It provides a useful way to correlate measured properties directly, such as the transport coefficients, with a limited number of parameters, without the need for a microscopic theory. Subsequent microscopic derivations of the Landau theories have been produced. In ^{3}He these excitations are quasiparticles, a concept that has proven useful in other forms of condensed matter.

Law of Corresponding States: A physical relation based on the hypothesis that all gases in a set have the same reduced intermolecular potential. The reduced potential is defined as $U^* = U(r^*,b_i)/e$, where $r^* = r/s$, where e and s are scaling parameters for the energy and length, respectively. One kind of corresponding-states analysis simply uses the triple points as scaling parameters.

Many-Body Interactions: Many-body multipole interaction terms of third order are $(DDQ)_3$, $(QQD)_3$, $(DDO)_3$, and $(QQQ)_3$ and those of fourth and higher order $(MBD)_{4\to\infty}$. D, Q, and O refer to dipole, quadrupole, and octupole, respectively, and subscripts 3 and 4→∞ refer to third and to fourth to higher orders of quantum perturbation theory. Short-range many-body interactions may result from charge overlap.

Monte Carlo (MC) and Molecular Dynamics (MD) Methods: The MC method uses ensemble averages as in statistical mechanics and is used to calculate equilibrium properties. The MD method solves the Newtonian equations of motion of the particles and uses time averages. It is used to calculate both equilibrium and transport properties.

Pair-Distribution Function $g(r)$: An equilibrium distribution of interatomic pair separations averaged over time and direction, used to describe the static structure of a liquid or amorphous material.

Path-Integral Monte Carlo (PIMC) Method: A simulation technique employing Feynmann's path-integral approach to extend the applicability of the **Monte Carlo** method to quantum systems.

Phonon: In the vibrations of crystal lattices, a collective mode with well-defined energy and wave vector. Generally, there is phonon dispersion: The energy depends upon the wave vector.

Polaron: A charge carrier trapped in its own polarization field.

Quantum Corresponding States: The classical restriction of the law of corresponding states for translational states can be removed by introduction of a reduced Planck constant, a measure of quantum effects in the condensed state. For a Lennard-Jones interaction, the de Boer parameter $L^* = h/(m\epsilon s^2)^{1/2}$ may be regarded as the reduced de Broglie wavelength of a particle of mass m.

Umklapp Processes: Those **phonon**-scattering processes for which the rule for conservation of wave vector is $\mathbf{Q}_1 + \mathbf{Q}_2 = \mathbf{Q}_3 + \boldsymbol{\tau}$, where $\boldsymbol{\tau}$ is a vector in the reciprocal lattice.

Vacancy: A vacant atomic site in a crystal.

Van der Waals–London Interaction: An attraction that varies as the inverse sixth power of the separation of two electric dipole oscillators.

Van der Waals Complex: A two-atom system physically bound by the van der Waals force, e.g., Ar_2, ArNe, H_2–Ar(X_2–Y), etc.

Virial Coefficients, Refractivity and Dielectric: Those pertaining to optical refraction and to dielectric properties.

INTRODUCTION

Rarefied-gas dynamics rests upon the theoretical disciplines of statistical mechanics and the molecular theory of gases and derives essential parameters from several areas of the physical sciences. In this subject we are concerned with those dynamic processes in which the discrete particle nature of gases plays a critical role in the modes of analysis and the prediction of behavior. The gas is said to be "rarefied" wherever the ratio of the mean distance between molecular collisions (mfp) to a characteristic length of the flow exceeds a very small value, usually of the order of 0.01. This ratio, the Knudsen number, *Kn*, expresses the departure of the flow from a near-continuum regime at low values of *Kn* to one at large values of *Kn* in which intermolecular collisions occur infrequently.

At one time it was thought that rarefied gases were found principally in laboratory vacuum systems or at extreme altitude. Rarefied gases were identified as being of "low density" as compared with the "normal density" of our familiar atmosphere. One sees, however, that the phenomena of rarefaction are a matter of scale, independent of the absolute number density of molecules or the physical size of the field, so long as binary molecular collisions predominate. Flows about microscopic filaments, through small orifices, or in particle beds may be subject to the effects of rarefaction, just as are flows about orbiting bodies. Regimes of rarefied flow are customarily defined in terms of the Knudsen number, as follows:

Near-continuum flow, $0.01 < Kn < 0.1$; (1a)

Transition flow, $0.1 < Kn < 10$; (1b)

Nearly free-molecule flow, $10 < Kn < 100$. (1c)

Discussions of the analysis and applications of rarefied flows in these regimes and in the regime of free-molecule flow in which no intermolecular collisions occur comprise the material of this article.

The physical phenomena associated with the rarefied-gas–dynamic regimes are so singularly numerous and so varied that it is not possible to categorize them in compact form. This is true in part because of the wide range of energy transfers that lie within these regimes, and in part because of the extreme variation in scale of the phenomena that lie within its domain. It is not surprising that scientists from so many areas of the physical sciences and engineering have contributed. A possible unifying factor may be found in the attractions that lie beyond the limits of continuum fluid mechanics. In addition there is always the promise of exploration, to learn, as we have learned in the past few years, of our Earth and its relation to the universe. Each period in the history of rarefied-gas dynamics has been filled with a sense of exploration, but each has had its particular nature. It is useful to distinguish among these as we approach this subject.

The formative years, which began with the rise of classical physics, were marked by the great works of Maxwell and Boltzmann during which the mathematical consolidation of the molecular hypothesis was achieved. Pioneering studies continued during this period until its close in about 1939. There next came a period of expansion and discovery in which, aided by rapidly developing research technology and by man's incursion into space, our knowledge grew with unprecedented speed. In the third and present period there exists a new departure in inquiry; we are enabled to look more deeply into gas-dynamic processes and we now have computational tools allowing the exploration of problems that once seemed unsolvable. This article examines these perceptions and skills as they relate to present applications.

1. HISTORICAL SUMMARY

1.1 Fundamental Beginnings, to 1939

Natural scientists had agreed over many years on the atomic nature of matter, but it was not until the first of the twentieth century, following Dunoyer's (1911) demonstration using a molecular beam of sodium, that the discrete particle structure of dilute gases became fully accepted. Still, the model of the particulate gas had been used by kinetic theorists for at least ninety years prior to that experiment. Maxwell had formulated the law for the distribution of molecular velocities in such a gas in 1859, and by 1866 had made substantial progress in establishing the basis for modern theories of nonuniform gases, that is, gases in which gradients of temperature, velocity, and density are present. Boltzmann (1872) published the celebrated equation that would guide the acquisition of much of our present knowledge of gas transport properties and that provided the link between continuum fluid motion and that of dilute gases. At the same time, he also presented his H theorem, which demonstrated the inevitable relaxation of nonuniform gases toward the Maxwellian distribution of velocities. Efforts to determine general expressions for the distributions of velocity in nonuniform gases met with little success until Chapman in 1916 and Enskog in 1917 published work leading to equivalent terms in expressions for the general velocity distribution function f and, thus, provided the background for the modern theory of transport coefficients. This phase in the development of rarefied-gas–dynamic theory was essentially completed in 1935 by Burnett, who introduced Sonine polynomials as terms in the expansion for f, and extended the order of expansion to the second. A readable, more detailed account of this period may be found in the well-known treatise by Chapman and Cowling (1939).

1.2 Second Phase, the Expansion Period, to 1978

The close of World War II marked the beginning of a period of an extraordinary increase in interest in the field of rarefied-gas dynamics. Attention was now given to simplification of the Boltzmann equation, as in the work of Bhatnagar *et al.* (1954), and to alternative modes of solution for the full equation, as is seen in the work of Grad (1949). Experimental laboratories were set up in departments of physics, chemistry, engineering, and aeronautics throughout the world and also in the research arms of defense departments and aeronautics agencies such as NACA, the National Advisory Committee for Aeronautics, precursor to NASA. Hirschfelder *et al.* (1954) published a monumental resource incorporating theoretical background and experimental results over a broad range of topics relating to collision processes and transport properties, covering much of importance to that year. Sputnik electrified the world in 1957 and many nations turned more directly to the application of rarefied-gas dynamics in space. An important series of symposia was begun in 1958 by Devienne at Nice, France. These meetings, the International Symposia on Rarefied Gas Dynamics, have brought together a significant number of the world's specialists every two years. The Proceedings of the symposia serve to define the field and to provide a compact entrée to it. A list of volume titles appears elsewhere in this article.

New experimental techniques were developed or adapted to a new environment. These included optical methods involving the excitation of fluorescence radiation, making possible noninvasive determinations of temperatures and velocities in monatomic gases and rotational temperatures in diatomic gases. Cryogenic pumping was introduced to enhance the extreme low-density capability of rarefied-gas wind tunnels. Several sources of flow were developed, notably the free-jet expansion. Plasma torch and arc-jet stagnation heaters were introduced to elevate the stagnation enthalpy. Space does not permit enumeration of the large number of investigators, but the record may be found in the proceedings of the RGD symposia. Rapid growth was also seen in the number and sophistication of studies on the interaction of gas molecules and surfaces. These were undertaken in numerous laboratories throughout the world by several thermal and dynamic methods. A few of these are discussed here in Sec. 3. It is particularly worth noting that the experimental study and parametrization of free-jet expansions by Ashkenas and Sherman (1966), which led to the frequent application of these flows in work with rarefied-gas wind tunnels, also led to the revolutionary method of aerodynamic intensification for molecular beams proposed by Kantrowitz and Gray (1951), now very widely used.

This second phase was one of great experimental activity, resulting in enormous extensions of our understanding of molecular collision parameters and of the aerodynamics and thermodynamics of bodies in high-speed rarefied-gas flows, and in our knowledge concerning the processes of momentum and energy exchange in gas–surface interactions. It was also a period of important theoretical activity, much of which was directed to the further exploration of the Boltzmann equation and its derivatives. Other interesting work was undertaken on "first-collision" departures from the free-molecule regime.

By the end of the 1970s there began a general reduction in activity, due, as one immediate cause, to changes in funding patterns, and we may mark the close of the second period as corresponding with this time.

1.3 Contemporary Phase; the Growing Sophistication of Tractable Problems

Beginning in the middle years of the 1980s the content of rarefied-gas dynamics broadened substantially in many aspects but most particularly in connection with the interest in more realistic treatments of molecular collisions, inelastic processes, and chemical reactions. The method of direct simulation using Monte Carlo techniques had been introduced by Bird in the late 1960s. During subsequent years the development of this method had been continued by Bird and by others, but it was not until several years had passed that the method of DSMC reached the current level of acceptance in the scientific community. This important topic is discussed more carefully here in Sec. 2.4. The contemporary period has just begun, but an important feature is visible; it is marked by a significant growth, both experimental and theoretical, in attention to inelastic and reactive collision processes, a growth coincident with and dependent upon the growing capability of DSMC.

2. THEORETICAL DESCRIPTIONS

2.1 Preliminary Discussion

Modern descriptions of rarefied gases rest upon concepts that are well verified by physical observation; gases are composed of discrete molecular particles that are small by comparison with their mutual separation and with the mean distance between collisions. Molecules are constantly in motion; their trajectories are interrupted by collisions with other molecules or with surfaces; the collisional potentials of interaction are relatively short ranged; in general analytical representations it is assumed that only binary collisions occur. The distribution of molecular velocities for such a gas in thermal equilibrium translating at velocity U with respect to a certain coordinate system is known as the translating or drifting Maxwellian and is written as follows:

$$f(\xi) = (n/2\pi RT)^{3/2} \exp[-(\boldsymbol{\xi} - \mathbf{U})^2/2RT]. \qquad (2)$$

In equation (2), n is the number density, T is the thermodynamic temperature, R is the species gas constant, $\boldsymbol{\xi}$ is the molecular velocity, and $\mathbf{U}$ is the velocity of translation. The difference between $\boldsymbol{\xi}$, the total velocity, and $\mathbf{U}$ gives the local velocity of thermal motion, the *peculiar* velocity. With the help of equation (2) and standard concepts of the kinetic theory and thermodynamics relations, we can find most of the expressions applied in free-molecule aerodynamic calculations. This matter will be taken up in subsequent paragraphs.

2.2 The Boltzmann Equation

It should be noted that the macroscopic velocity $\mathbf{U}$ is determined by averaging the total velocities of all molecules in a certain region, whether or not the gas is rarefied. Values of other quantities such as the flux of momentum across a control surface are determined by taking the average of appropriate velocity components over the velocity distribution function. However, where values of field properties such as density alter significantly within lengths of the order of the mean distance between collisions, the gas may be slightly or perhaps greatly out of equilibrium, in which event the Maxwellian distribution cannot be used in performing the weighted average. When the departures from equilibrium are small we are enabled to find velocities, temperatures, densities, and so on, through application of the Boltzmann equation. The Boltzmann equation is a conservation equation expressed in terms of the complete molecular velocity distribution, f. The equation equates the time rate of change in the number of particles of a certain velocity class within a certain small volume due to the physical movement of those particles to the change in the number within that same velocity class in that same volume due to molecular collisions. Solutions of the Boltzmann equation are found in terms of the distribution function f.

The Boltzmann equation is an integro-differential equation of considerable complexity. The several approaches to solutions are discussed in Schaaf and Chambré (1958) and in the monograph for the *Encyclopedia of Physics* (Schaaf, 1963) in which Schaaf has provided an extensive entrée to the literature to 1960. In their monumental work, Chapman and Cowling (1939) set forth a detailed and authoritative coverage. Excellent accounts are also found in Hirschfelder *et al.* (1954) and in Vincenti and Kruger (1965).

Solutions for f are often sought as a series expansion in powers of a small number, essentially the Knudsen number. If f_0 is the Maxwellian then f may be written

$$f = f_0[1 + \phi_1(\lambda/L) + \phi_2(\lambda/L)^2 + \cdots]. \qquad (3)$$

In Eq. (3) λ is the mean distance between collisions and L is a characteristic length of the flow. Clearly λ/L must be small. At normal densities, gradients of velocity and temperature are usually sufficiently small to permit the assumption that the system is in local equilibrium within each elementary region. In this event $f = f_0$. From the zeroth order of the expansion, Eq. (3), we are led directly to the Euler equations. The Navier-Stokes equations result from the retention of the first-order term in λ/L while the Burnett equations (1935) result from the retention of the second-order term. It is sometimes useful to think of small departures from this condition in terms of the ratio of Mach number M to Reynolds number. Since the kinematic viscosity ν is proportional to $a\lambda$, where a is the sound speed, and the Reynolds number is given by $Re = VL/\nu$, in which V is a velocity and L is a characteristic length, we find that $\lambda/L \approx M/Re$. Thus M/Re is a measure of rarefaction equivalent to the Knudsen number for small departures from continuum flow.

Tests of the validity of the Navier-Stokes equations and of the Burnett equations have been made under conditions that minimize the influence of wall–gas collisions. Sherman (1955) and Talbot and Sherman (1959) examined shock-wave profiles in weak shock waves of helium and air, and later in argon. It was found that the Navier-Stokes computations produced shock-wave profiles in fair agreement with experiment, but except for the very low–Mach-number calculations, the Burnett terms did not yield stable solutions. This matter is discussed again in subsequent paragraphs.

In applications of the Navier-Stokes equations in the presence of boundaries within regimes of near-continuum flow, it is necessary to apply slip-flow and temperature-jump boundary conditions. These boundary conditions express an important effect of rarefaction. Within a distance λ from the surface, the gas cannot be considered exactly at rest with respect to the surface, nor, where a gradient of temperature exists, can the gas be exactly at the surface temperature. Thus, there will be a "slip" of velocity and a "jump" in temperature at the wall, although these will be of small magnitude where the Navier-Stokes equations remain valid.

2.3 Momentum and Energy Transfers in Free-Molecule Flow

2.3.1 Background During the years when the foundations of the kinetic theory were taking shape, little thought was given to the idea that man's own satellites would orbit the Earth. However, collisionless flows were of practical and theoretical interest to physicists and chemists, so that by the early 1900s an increasing number of persons were measuring momentum and thermal transfers and attempting to understand the relation between these effects and the nature of the bounding surface. The Maxwellian distribution of molecular velocities was experimentally verified by Stern (1920), wall–gas interaction studies were conducted by Millikan (1923), and heat transfers in rarefied gases were examined by Knudsen (1911). By the end of the first quarter of the twentieth century, a great deal had become known about processes that were of low thermal order and that involved modest molecular velocities. The context broadened greatly with the flight of Sputnik, but much of the mathematical background for the description of flows about satellites had already been well established. There still remained the problem of describing the aerodynamic and thermal effects of wall–gas collisions.

Free-molecule flows are considered to occur for values of the Knudsen number greater than about 100. The flow is collisionless only in the sense that intermolecular collisions do not alter the distribution of velocities incident upon a body; however, the Maxwellian distribution assumed for the incident flow would normally have arisen from intermolecular collisions at remote distances or from diffusely scattering surroundings. Densities and molecular velocities in the vicinity of the body, on the other hand, become greatly modified by wall collisions. This point is elaborated in paragraphs to follow.

A body in free-molecule flow is assumed to be subject to the collisions of large numbers of independently moving molecules. Our knowledge of molecular energy, momentum, and number flux incident upon an element of surface or across any arbitrary elementary plane, and our knowledge of energy density and other densities, must be reported in terms of averaged values. These averages are found by integrating appropriate quantities, usually products of velocities, over the molecular velocity distribution function. Coordinates for an element of surface are illustrated in Fig. 1. As is customary in aerodynamic calculation, the attack angle θ is defined to be taken between the surface tangent and the macroscopic velocity vector **U**, and the axes are oriented to place **U** in the (x_1,x_2) plane. The number flux to an elementary surface dA is

$$dN_i = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{0}^{\infty} f\xi_1 d\xi_1 d\xi_2 d\xi_3, \qquad (4)$$

in which f is the Maxwellian distribution from Eq. (2). It is useful to define a molecular speed ratio S as the ratio of the macroscopic speed of flow, U, to the most probable molecular speed, $(2RT)^{1/2}$. Integration of equation (4) leads to

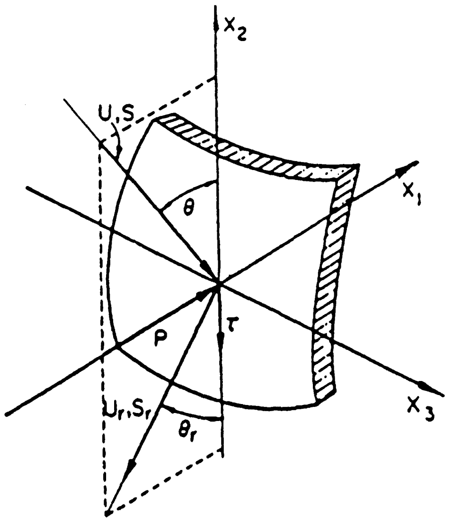

FIG. 1. Schematic diagram of coordinates for molecular flow at the surface.

$$dN_i = n\sqrt{RT/2\pi}\{\exp[-(S\sin\theta)^2] + \sqrt{\pi}(S\sin\theta)[1 + \mathrm{erf}(S\sin\theta)]\}dA. \quad (5)$$

Conservation in number density at the surface is assumed so that dN_r, the reemitted number flux, is equal to that incident, $dN_r = dN_i$. Expressions for the flux of momentum incident to the surface in the normal direction, the flux of momentum in the tangential direction, and the flux of energy are found in a similar fashion. Let p_i be the flux of normal momentum to the surface as given by the integration of $m\xi_1^2 f d\xi_1 d\xi_2 d\xi_3$, and let τ_i be the flux of tangential momentum given by the integration of $-m\xi_1\xi_2 f d\xi_1 d\xi_2 d\xi_3$. Let $S\theta = S\sin\theta$. We may then write

$$p_i = \frac{\rho U^2}{2\sqrt{\pi}S}[(S\theta)e^{-(S\theta)^2} + \sqrt{\pi}[0.5 + (S\theta)^2][1 + \mathrm{erf}(S\theta)]\}, \quad (6)$$

$$\tau_i = \frac{\rho U^2\cos\theta}{2\sqrt{\pi}S}\{e^{-(S\theta)^2} + \sqrt{\pi}(S\theta)[1 + \mathrm{erf}(S\theta)]\}. \quad (7)$$

The flux of incident energy, which may be found in an analogous manner, must include that due to the translational energy, $\frac{1}{2}m\xi^2$, and that of the internal energy, $\frac{j}{2}RT$, in which j is the number of internal degrees of freedom:

$$E_i = E_{i,\mathrm{tran}} + E_{i,\mathrm{int}}. \quad (8)$$

We find

$$E_{i,\mathrm{tran}} = \rho RT\sqrt{\frac{RT}{2\pi}}[(S^2 + 2)e^{-(S\theta)^2} + \sqrt{\pi}(S^2 + \tfrac{5}{2})(S\theta)[1 + \mathrm{erf}(S\theta)]], \quad (9a)$$

$$E_{i,\mathrm{int}} = \frac{\rho(5 - 3\gamma)}{\sqrt{\pi}(\gamma - 1)}\left(\frac{RT}{2}\right)^{3/2} \times \{e^{-(S\theta)^2} + [1 + \mathrm{erf}(S\theta)]\}. \quad (9b)$$

2.3.2 Momentum- and Energy-Transfer Coefficients Our next task is to develop expressions for the fluxes of momentum and energy that leave the surface through molecular scattering. At this point we encounter one of the least understood and most speculative areas of rarefied-gas dynamics, since our knowledge of these exit fluxes is extremely limited. Few molecular exit-velocity distributions have been obtained from laboratory experiment and none at all from observations aboard orbiting satellites. Much more is known about angular distributions of number flux, particularly in connection with laboratory studies of scattering from clean, regular surfaces at energies of thermal order. While speculations based upon reasonable conjectures can be made in light of present knowledge, there are insufficient experimental data to permit accurate performance predictions for extended shapes. A short account of our present knowledge of wall–gas interactions is given in Sec. 2.5.

The standard kinetic theory does, however, include useful formulas for drag, lift, and heat transfer for bodies in free-molecule flow, which treat the effects of gas collisions at the wall in terms of momentum- and energy-transfer coefficients. These coefficients, in essence, are measures of the degree to which the net reflected momentum or energy approaches that which would be emitted in Maxwellian equilibrium at the wall temperature. These coefficients can be connected with Maxwell's nonphysical conjecture dividing reflection into two kinds, specular and diffuse, but that is not their meaning, although some confusion persists. In the current and standard usage, thermal energy transfer is discussed in terms of α, the thermal accommodation coefficient, following von Smoluchowski (1911) and Knudsen

(1911), where

$$\alpha = (E_i - E_r)/(E_i - E_w). \tag{10a}$$

The subscript i identifies the energy carried to the surface by incident molecules, the subscript r identifies the energy carried away from the surface, and the subscript w identifies the energy that would be carried away by molecules in diffuse Maxwellian scattering.

In similar fashion we define σ, the transfer coefficient for tangential momentum, as

$$\sigma = (\tau_i - \tau_r)/(\tau_i - \tau_w), \tag{10b}$$

in which τ_w represents the tangential momentum carried from the wall by molecules scattered in Maxwellian reemission from it. However, these molecules are scattered diffusely and hence isotropically, in which event the value of τ_w is 0.

The coefficient of normal momentum transfer, σ', was introduced by Schaaf to complete the triad of surface interaction coefficients. It is seen as an essential feature in the current analysis of aerodynamic forces:

$$\sigma' = (p_i - p_r)/(p_i - p_w). \tag{10c}$$

The energy carried from the wall in Maxwellian reemission is given by

$$E_w = (4 + j)mRT_w \frac{dN_i}{dA} = \frac{\gamma + 1}{2(\gamma - 1)} mRT_w \frac{dN_i}{dA}. \tag{11}$$

We write the scattered normal momentum flux p_w in equation (10c) as

$$p_w = \tfrac{1}{2}m\sqrt{2\pi RT_w}\frac{dN_i}{dA}. \tag{12}$$

The coefficients σ, σ', and α are, in principle, independently determinable by physical measurement in particular physical systems. Through these empirical coefficients one may express the net shear stress τ, or the net pressure p, or the heat flux Q, acting on a surface, since these coefficients link the incoming with the outgoing quantities.

The quantities p_i and p_r are added to form the total normal pressure, giving

$$\begin{aligned} p = \frac{\rho U^2}{2S^2}\Bigg\{&\left(\frac{(2 - \sigma')}{\sqrt{\pi}}(S\theta) + \frac{\sigma'}{2}\sqrt{\frac{T_w}{T}}\right)e^{-(S\theta)^2} \\ &+ \Bigg[(2 - \sigma')[(S\theta)^2 + 0.5] \\ &+ \frac{\sigma'}{2}\sqrt{\frac{\pi T_w}{T}}(S\theta)\Bigg][1 + \operatorname{erf}(S\theta)]\Bigg\} \end{aligned} \tag{13}$$

and in a similar manner, letting $\chi(S\theta) = \exp[-(S\theta)^2] + \sqrt{\pi}S\theta[1 + \operatorname{erf}(S\theta)]$, we find

$$\tau = \frac{\sigma\rho U^2 \cos\theta}{2S\pi}\chi(S\theta) \tag{14}$$

and

$$\begin{aligned} Q = \alpha\rho U^2 RT\sqrt{\frac{RT}{2\pi}}\Bigg\{&\left(S^2 + \frac{\gamma}{\gamma + 1}\right. \\ &\left. - \frac{\gamma + 1}{2(\gamma - 1)}\frac{T_w}{T}\right)\chi(S\theta) - 0.5e^{-(S\theta)^2}\Bigg\}. \end{aligned} \tag{15}$$

Expressions (13), (14), and (15) provide the essential key to free-molecule analysis. It should be noted that each expression depends solely upon a single transfer coefficient, thus permitting a clear separation of effects in experimental studies. Both the pressure and the net heat flux, but not the shear stress, depend upon the wall temperature. No complication arises where T_w is known, but where it is not it may be necessary to solve for T_w with Q set equal to zero. Terms for radiation exchange will be needed.

2.3.3 Forces of Lift and Drag on a Flat Plate, General Expressions Where the transfer coefficients are known, solutions to problems of external free-molecule aerodynamics are accessible in principle but may be difficult to solve in analytic form. In general the transfer coefficients will be dependent on the angle θ, measured between the incoming gas molecules and the surface tangent. This feature may add substantially to the complication of solution. A number of authors have calculated values of aerodynamic coefficients and heat transfer for various conventional shapes, but have treated the coefficients as independent of the incident angle. For cases of high-speed flows over vehicles in orbit, where it is probable that the elementary assumpical are inadequate, it seems advisable to treat complex shapes through numerical integration over elementary areas. To this end the expressions for drag and lift per unit area for a flat plate at angle of attack θ may prove useful. These are listed as follows:

$$\begin{aligned} F_D = \frac{\rho_\infty U_\infty^2}{\sqrt{\pi} S} A \Bigg\{ & [(2 - \sigma') \sin^2\theta \\ & + \sigma \cos^2\theta] e^{-(S \sin\theta)^2} + \frac{\sigma' \pi}{2} \sqrt{\frac{T_W}{T}} \sin^2\theta \\ & + \sqrt{\pi}(S \sin\theta) \operatorname{erf}(S \sin\theta)[(2 - \sigma') \\ & \times (\sin^2\theta + \tfrac{1}{2} S^2) + \sigma \cos^2\theta] \Bigg\}, \end{aligned} \tag{16}$$

$$\begin{aligned} F_L = \frac{\rho_\infty U_\infty^2}{\sqrt{\pi} S} A \Bigg\{ & (2 - \sigma - \sigma') \cos\theta \sin\theta \, e^{-(S \sin\theta)^2} \\ & + \frac{\sigma' \pi}{2} \sqrt{\frac{T_W}{T}} \sin\theta \cos\theta \\ & + \frac{\sqrt{\pi}}{2} S \cos\theta \Bigg[2(2 - \sigma - \sigma') \sin^2\theta \\ & + \frac{(2 - \sigma')}{S^2} \Bigg] \operatorname{erf}(S \sin\theta) \Bigg\}. \end{aligned} \tag{17}$$

2.4 Direct Molecular Flow Simulation using Monte Carlo Methods

During the late 1950s scholars turned to the examination of computational models that exploited directly the dynamics of molecular motion and collisions and that left aside immediate concern with time-varying fluid behavior. Such directions were made possible by the increasing capability of high-speed computers. Alder and Wainwright (1958) used exact dynamical calculation to study the behavior of one hundred hard spheres. These were started into motion with uniform speeds and with randomized directions within a cubical enclosure. Velocities were found to approach the Maxwellian distribution following a few collisions. It was recognized, however, that the approach would quickly impose unrealistically large demands on computer capability as the number of molecules increased. Davis (1960), in what proved to be very promising directions, studied the free-molecule conductance of a tube having a right-angle bend. Randomized direction and position were given to each of a sequence of test particles started from the tube entrance. Trajectories were followed and statistical decisions were made for next directions of flight. These directions were based on diffuse scattering at the wall. The probability of success, as measured by the ratio of the number of molecules emerging to those starting, may be seen as a measure of the conductivity of the system. Haviland (1965) introduced the calculation of intermolecular collisions as an extension of the test-particle method in application to heat conduction at intermediate Knudsen numbers.

It was a natural step to move from these beginnings to the method of direct simulation of molecular dynamic processes using Monte Carlo methods (DSMC), a step that has most profoundly affected the landscape of rarefied-gas dynamics. The conceptual basis for the method and much of its operational detail are due to Professor Graeme Bird (1976). DSMC rests upon two critical assumptions. In the first of these Bird assumed that the calculation of collisional outcomes occurring within a very short period of time in a certain region of the flow may be decoupled from the positional changes of molecules occurring within the same period. It is also assumed that the outcomes of intermolecular collisions and molecule–wall collisions can be determined using statistical methods when appropriate physical parameters are given. A number of enabling assumptions are made. Molecules move within a field divided into a large number of cells, each containing 15 to 20 numbered particles; the motions and collisions of these are followed. Each particle represents a very large number of "real" gas molecules. The cell dimension is small as compared with the molecular mean free path, so that only small changes in gas properties can occur within the cell. The motion of the particle is followed through successive time intervals Δt_m, each of which is followed by calculations of collisional outcomes. The basic time interval is smaller than the mean collision time per molecule. Collision partners are selected from within the cell. Since the change in gas properties is small over cell dimensions, the exact coordinates of collision partners are immaterial, each partner being representative of molecules anywhere within the cell. A cell-by-cell record of densities and velocities is maintained for the later calculation of flow properties. The method of DSMC is developing swiftly. Numerous comparisons have been made between the results of experiment and the predictions of DSMC, leading now to general acceptance of molecular flow simulation as the mode of solution for rarefied-gas problems. Calculations incorporating chemical reactions and electron production are often made. Recent work, notably by Harvey (1989) and later by Boyd (1991) and others, has focused on the examination of phenomenological methods to guide calculation for inelastic collisions. As a result of these several advances, it would appear that some of the problems that had imposed an apparently impenetrable barrier to the advancement of understanding and application have been removed.

It is useful to consider again the determinations of temperature and density distributions within a shock wave. Experiments by Sherman (1955) and by Talbot and Sherman (1959) were conducted in the Berkeley tunnel using a free-molecule temperature probe. Argon was used in this work, in which the flow Mach numbers were low, always below 1.61. Experimental results were compared with Navier-Stokes solutions and also, as permitted, those of the Burnett equations. In addition comparisons were made with solutions to the 13-moment equations of Grad (1949) and with those from the two-temperature equations of Mott-Smith (1954). Experimental profiles of temperature compared well with density profiles from Navier-Stokes and with those from the Burnett equations (1935) at these low Mach numbers but not with those from the 13-moment solutions nor those from the two-temperature model. In subsequent work Schmidt (1969) used electron-beam fluorescence (EBF) to measure density profiles for Mach-8 flows of argon. At a later date remarkable agreement was found between Schmidt's experimental results and those from DSMC (Bird, 1976). Robben and Talbot (1965) using EBF-measured rotational temperature and density profiles for a shock wave of nitrogen at Mach 1.71. Again, results obtained by Bird (1976) using DSMC were found to be in excellent agreement with experiment. Much more recently, Lumpkin and Boyd (1993) examined flow properties for a detatched shock resulting from high–Mach-number air flow over a half-sphere. Comparisons of DSMC simulations with results of a Navier-Stokes–based computation agree well except in prediction of the flow angle at the rim, DSMC showing a much greater deflection of flow toward the central axis than given by Navier-Stokes. The Burnett equations did not yield stable solutions. Clearly, physical experiment is now required.

The foregoing material leads to the following important observations. Rarefied-gas experimentation can provide information concerning dynamic processes in high-speed flows. Where boundary conditions are simple, as, for example, for a plane shock held at the entrance to a shock holder, and the Knudsen number is small enough, Navier-Stokes solutions model the physical process fairly well. On the other hand, Monte Carlo simulations, which are also good in these cases, are not limited to low–Knudsen-number flows and accommodate more readily to complex geometries. With DSMC, as is also the case for Navier-Stokes, we are not always sure of the values of essential parameters or of the validity of physical assumptions. Physical experimentation is needed, to validate codes and to assist in the determination of essential parameters.

2.5 Gas–Surface Interactions

Collisions of gas molecules with walls occur in gas flows of any density, but at normal densities the frequency of collisions in the stream greatly exceeds that for collisions of gas molecules with solid surfaces. Under conditions of low Knudsen number, where knowledge of velocity slip and temperature jump is required, the determination of these quantities has been formulated in terms of a coefficient σ for velocity slip and α for temperature jump. In the context of the conventional formulation, σ is defined as the number of molecules diffusely reflected per unit time and surface area, $1 - \sigma$ is the number specularly reflected, while α is the standard thermal accommodation coefficient. Both α and σ are assumed equal to 1 in the absence of well-documented information.

At larger Knudsen numbers, wall–gas collisions become relatively more numerous until, in the limit of free-molecule flow, only wall–gas collisions remain. Throughout the rarefied regimes it is critically important to incorporate wall–gas collision data into computations. Where free-molecule assumptions can be made, a knowledge of the transfer coefficients, Eqs. (1a)–(1c), will permit the calculation of forces and heat transfer. In all other regimes it is essential to know the exit distributions of velocity, that is, to know the statistical description of postcollision velocities, in order to proceed in computation with DSMC.

In current conventional computions, exit distributions follow directly from the assumption that the scattering is diffuse or that it is specular. This nonphysical approximation is used in simulations of high-speed flows simply because there has been no generally accepted alternative in the aerospace context. Accordingly, it is useful to examine the understanding that has come to us from physical experiment and to look, too, at models for exit distributions that are currently being studied.

The first studies of thermal accommodation in wall–gas collisions were made using the loss of heat from a central wire through molecular transport to a cylindrical enclosure. The system could be freed of adsorbed gas molecules by baking under high vacuum. Much was learned from these experiments regarding the formation of adsorbed gas films, and values of thermal accommodation coefficients were obtained for gases of many sorts on various surfaces, both clean and with gas layers. The method was brought to its present level of development through the work over many years of Thomas (1981) and associates. Almost all gas–surface combinations exhibited incomplete thermal accommodation, i.e., $\alpha < 1$, for clean surfaces, the lowest values being found for helium in contact with clean tungsten. Values of α close to unity were found for complex molecules interacting with gas-covered surfaces. Values of α ranged from 0.0164 for helium on tungsten to 0.89–0.97 for air on etched aluminum. It seems safe to conclude that for many gas–surface combinations, some degree of incomplete thermal accommodation will be found.

Somewhat similar results were obtained in experimental studies of the tangential momentum-transfer coefficient. These studies were usually conducted in rotating-cylinder devices or by the measurement of flow through tubes. Values of σ were found to lie near to but often less than 1.0, although very infrequently, values have been found to exceed 1.0. There is no anomaly here; the result can be produced by backscattering due to roughness. Representative values for σ and for α are shown in Tables 1 and 2.

Table 1. Representative values of the tangential momentum-transfer coefficient σ, obtained from rotating-cylinder experiments.

Measurements using heat-conductivity cells or rotating cylinders, as in the foregoing, do not yield velocity or flux distributions of scattered molecules. On the other hand, from the earliest experiments using molecular-beam methods, it had been observed that distributions of scattered molecular flux were often of strikingly lobal form, although for many systems the flux patterns followed the cosine distribution to close approximation. In cosine scattering the flux of molecules scattered from the point of impingement of a collimated beam into a small element of solid angle above the surface is proportional to the cosine of θ, where θ is the angle from the surface normal to the center of the element of solid angle. Once the Kantrowitz–

Gray sources came into common use, it was soon found that fast beams of heavier molecules could be produced by the expansion of a mixture of light and heavy species. The heavier species in beams skimmed from such mixture expansions might reach kinetic energies of one or more electron volts. The production of such "seeded" beams became standard in the art and is now used by molecular physicists and physical chemists in many research applications.

Molecular-beam methods have been used in a number of studies of the scattering of common gases from many kinds of surface including regular crystals, machined surfaces, and foils. The observations of Hinchin and Sheppard (1967) on the angular density distributions of argon scattered from platinum foil surfaces are represented in part in Fig. 2. One may see in these results certain patterns that are commonly observed and that merit discussion. It is first apparent that all distributions in this instance exhibit a strong lobality and show a remarkable regularity in the location of the lobe maxima. These positions are related to the beam reservoir temperature so that the most energetic beams scatter in patterns nearest to the surface tangent. Scattering patterns such as these, and in fact other scattering patterns that show a departure from the pure diffuse or cosine pattern, imply that the energy- and momentum-transfer coefficients also must depart from the value 1. The scattering from rough surfaces or those heavily laden with adsorbed gas layers is most often diffuse. One may summarize the results of much observation by noting that patterns of molecular scattering depend upon the nature of gas and surface, upon the surface smoothness, upon the cleanliness of the surface, and upon the energy of the gas molecule relative to the surface. Other factors may also be important if molecule internal energies are transferred or reactive events occur. Lobality, when present, tends to increase with surface cleanliness, with surface regularity, with incident velocity, and with a reduction in the angle of attack. Scattering patterns from suitably degassed and adequately crystalline surfaces are, with few exceptions, of distorted elliptical form having maxima near the exit specular angle.

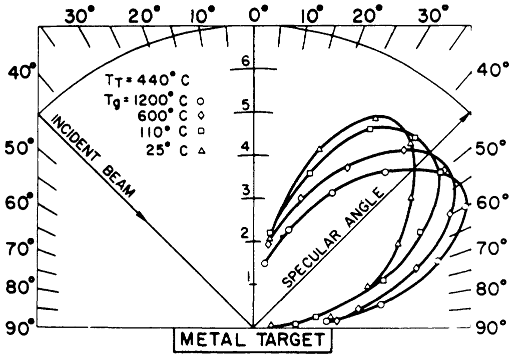

FIG. 2. Scattering of argon from degassed platinum surface (Hinchen and Shepherd, 1967).

Technologic change again intervened to make possible the measurement of distributions of velocity for the scattered molecular flux. Results from two of the relatively few studies completed are shown in Fig. 3. Both studies, Subbarao and Miller (1973) and Jih and Hurlbut (1977), employed argon beams of energy up to 1.3 eV on (111) surfaces of silver. Jih and Hurlbut observed exit velocities increasing from directions near to the surface normal to those near the surface tangent except for a pronounced dip in the region of the density peak. Subbarao and Miller, measuring only in the vicinity of the peak, observed a less pronounced dip. At higher energies, Tenner *et al.* (1986) found calculated energy distributions for 35-eV potassium ions scattered from the tungsten (110) surface to reproduce remarkably the observed experimental distributions in density and energy of exit particles. The reader is referred to surveys by Hurlbut (1986, 1989), for more detailed reviews of these and related observations.

We are also instructed by measurements of the transfer of momentum to common surfaces from high-speed beams of neutral molecules or of ions. Studies by Doughty and Schaetzle (1969) using neutral argon or nitrogen molecules of 25-eV energy on surfaces of aluminum or fresh varnish gave values for the normal momentum-transfer coefficient that decreased from values of 0.9 or smaller at normal incidence to values of 0.5 or smaller at incidence angles of 60° from the normal. Knechtel and Pitts (1969), using nitrogen ion beams incident on aluminum surfaces at 5 to 15 eV, observed coefficients for normal momentum transfer over the same range of incident angles that differed

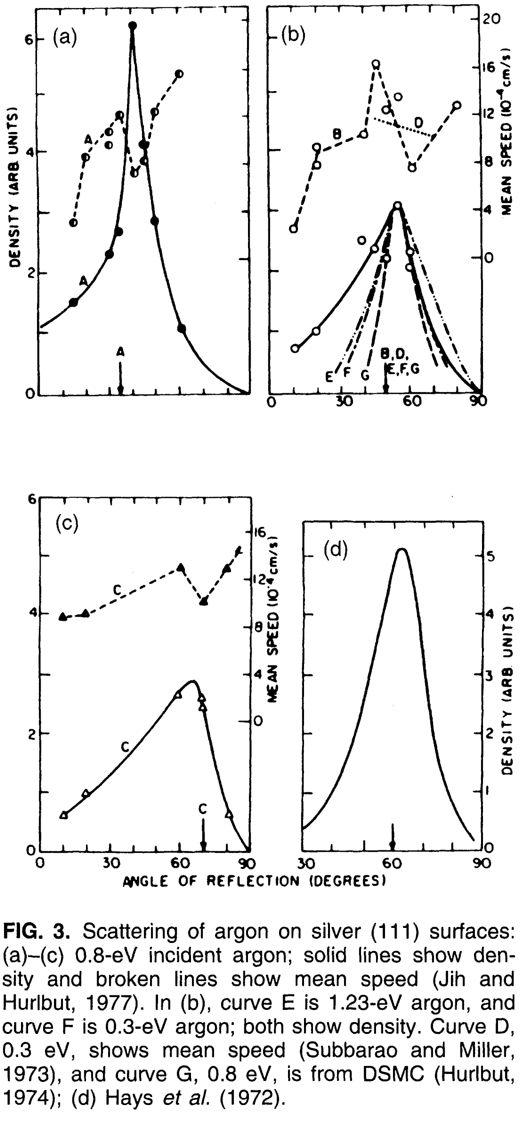

FIG. 3. Scattering of argon on silver (111) surfaces: (a)–(c) 0.8-eV incident argon; solid lines show density and broken lines show mean speed (Jih and Hurlbut, 1977). In (b), curve E is 1.23-eV argon, and curve F is 0.3-eV argon; both show density. Curve D, 0.3 eV, shows mean speed (Subbarao and Miller, 1973), and curve G, 0.8 eV, is from DSMC (Hurlbut, 1974); (d) Hays *et al.* (1972).

slightly in numerical value, as one might expect, but were qualitatively very similar to the observations of Doughty and Schaetzle. These slender fragments of data suggest very strongly that much more experimental observation is needed, some of it in the orbital environment, before one can predict with confidence in rarefied regimes.

Data from detailed measurements of velocity distributions for scattered particles must be parametrized or modeled in order to make them accessible for use in DSMC. Two general models are identified here as having merit, since each is based on its own substantive technical premise. The first derives from a conjecture due to Nocilla (1961) that lobal exit distributions could be modeled by use of suitable drifting Maxwellians consisting of a macroscopic velocity upon which a random thermal velocity is superimposed. The macroscopic velocity vector makes an angle θ_r with respect to the surface normal. Subsequently, molecular-beam experiments have shown the best representation of reflected distributions of velocity along observed directions to be the drifting Maxwellian. Hurlbut and Sherman (1968) used Nocilla's conjecture to develop a model in which parameters for the exit Maxwellian distribution are connected with those for the incident molecular flow. For a given system, experimental values of the thermal accommodation coefficient are required and a functional relation between the angle θ_i and the magnitude of the exit molecular speed ratio S_r is also required. The model is easily applied in DSMC calculations and has been used by a number of authors.

The second of these general models is based on the conjecture that the principle of reciprocity must apply between incident and exit velocity distributions in scattering processes if thermal equilibrium is to be preserved. It is further asserted that the same exit distributions found for a given set of incident conditions should correctly apply to the nonequilibrium flow. Detailed formulation and application to surface scattering appears in Cercignani and Lampis (1971). Formulas for flux distributions and for aerodynamic forces have been given in subsequent work. Both models have created substantial interest, but to the time of the present writing, neither is fully explored.

3. EXPERIMENTAL METHODS

3.1 Ground-Based Experimental Systems

Experimental systems used in the study of rarefied-gas aerodynamics and of related molecular processes are of four major types: wind tunnels, shock tunnels, molecular- and ion-beam systems, and ballistic ranges. There are also specialized systems developed for the study of momentum and energy transfers.

3.1.1 Wind Tunnels and Shock Tunnels Rarefied-gas wind tunnels are designed to produce low-density, high-speed flows of gas through a diagnostic region in which models may be placed for test. Low-density flows are frequently produced by oil-vapor booster pumps backed by lobe-type blowers that are exhausted to the atmosphere by rotary vacuum pumps. A few tunnels have been cryogenically pumped, some have been pumped by mechanical systems alone, and some have been pumped by steam-jet ejectors. All are characterized by offering an extended period of continuous testing. They are usually of large size and serve as the test bed for a wide variety of experiments. From the beginnings of orbital flight, however, it was acknowledged that limitations imposed on the magnitude of the stagnation enthalpy would make full flight simulation impossible. This notwithstanding, rarefied-gas wind tunnels are valuable research tools.

Experiments may be conducted over a wide range of flow conditions, permitting the comparison of flows in highly rarefied regimes with those in regimes of smaller Knudsen number. Long-duration flows are of particular advantage in studies involving the detection of low-level electrical or optical signals.

Many features of tunnel construction, modes of operation, instrumentation, force balance design, etc., may be found in Maslach and Schaaf (1959). Accounts of more recent design and practice may be found in the RGD Symposium Volumes 9 (1974) through 12 (1980).

Shock tunnels are, in essence, wind tunnels that derive reservoir supply gas at high temperatures from a shock tube and yield flows of substantially larger stagnation enthalpy than can be obtained in steady-state devices. While stagnation temperatures can reach several thousand kelvins, the flow duration is short, typically a few milliseconds.

3.1.2 Flow Production In continuous-flow wind tunnels and in shock tunnels, gas flows from the reservoir through a converging region and then emerges through a throat into a nozzle. Following expansion in the nozzle the flow passes into the test section. Alternatively, gas emerges from the throat directly into a test section of size sufficient to permit free-jet expansion. Such expansions contain a region of supersonic flow that is terminated by a plane shock and is bounded at its circumference by a shock barrel, as we see in the schematic, Fig. 4. Whereas the analysis of flow in nozzles is taken up in standard texts, the most satisfactory guide to free-jet expansions remains the original paper by Ashkenas and Sherman (1966).

It is useful to consider certain characteristic features of free-jet expansions. The gas, which is at sonic speed as it leaves the throat, rapidly expands to supersonic velocities along straight flow lines. These diverge from a single point of origin, as shown. Properties of the flow at any value of the nondimensional distance x/D may be fully characterized in terms of γ, the ratio of specific heats, the stagnation temperature T_0, and the ratio of the stagnation pressure p_0 to the downstream tunnel pressure p. As the Mach number increases with larger values of x/D, the local density and temperature of the flow decrease and the Knudsen number, based on the size of a diagnostic probe, can become large. Rarefied conditions are easily achieved, the flow properties can be calculated for any molecular species, and every region of the flow field is physically and optically accessible. For some purposes, these advantages are offset by the divergence of the flow.

3.1.3 Molecular and Ion Beams Molecular-beam systems are powerful tools for the study of molecular collision processes and for the study of gas collisions at the surface. A collimated stream of molecules traverses a region of high vacuum in which it can intersect a second beam or impinge on a solid test surface. Measurements of densities,

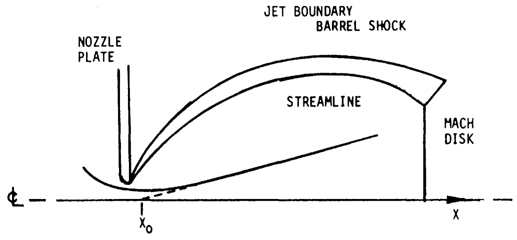

FIG. 4. Schematic diagram for free-jet expansion. (See Ashkenas and Sherman, 1966).

of composition, and of distributions of velocity and of electronic state may be obtained. In most current systems beams are formed by "skimming" from the rarefied region of a free-jet expansion, a method introduced by Kantrowitz and Gray (1951). The skimmer is simply a hollow conical shell with a small sharp-edged hole at the tip. Flow external to the skimmer is diverted to a large pump, while the skimmed beam passes into and through a high-vacuum region and thence to the target. Beam flux is higher than that from effusive sources, and because of the mechanics of expansion, the mean speed of the beam is higher and the thermal spread of velocities is much smaller. These features offer critical opportunities.

To reach beam energies above a very few electron volts it is necessary to accelerate ionized molecules. These may be used directly, or as neutral molecules following neutralization by charge exchange. Space charge limits the beam current to very low values at beam energies of the order of 10 eV. Unfortunately, energies of approximately this value are of particular interest to the experimenter interested in the effects of gases at the velocities encountered by satellites.

Beam systems are designed for operation under conditions of very high vacuum through careful attention to materials, welds, seals, and pumping equipment. A typical experiment might require scattered particles to be velocity selected, then ionized and accelerated into an electron multiplier detector. The reader is referred to the RGD Symposium proceedings for accounts of developments and applications of beams in rarefied-gas research.

3.2 Instruments and Diagnostic Methods

Wind tunnels and other experimental systems for the study of rarefied gases are, in essence, vacuum systems that must be equipped with the standard instrumentation for vacuum measurement. Balance systems are required that are suitable for the measurement of aerodynamic forces of perhaps a few hundredths of a newton. Advantage is often taken of the relatively large mean free path to position noninvasive physical probes in the field of flow. This point is illustrated by the pioneering measurement of shock-wave profiles by Sherman (1955) using a free-molecule thermocouple probe, and at an earlier time by Stalder *et al.* (1950), who measured the recovery temperature of a thermocouple probe in free-molecule flow.

Most of today's noninvasive measurement systems are based in some way upon the production and detection of light. The familiar methods of interferometry and of Schlieren flow visualization are not suitable in rarefied regimes because of insufficient optical depth. However, certain methods that employ the emission or absorption of light through the alteration of molecular electronic states have proved to be very useful. The most prominent of these methods has used an energetic electron beam to excite fluorescence radiation from well-defined regions of a flowing gas. A slender electron beam of 10- to 30-keV energy and a few milliamperes of current excites fluorescence radiation specific to the species and its state. Collection optics, focused on a portion of the electron beam, connect through a fiber optic to analyzing equipment. Detection is usually accomplished by photomultiplier and pulse counter or electrometer. Spectroscopic data from molecular gases, frequently N_2, lead to density measurement and to determinations of rotational temperatures and vibrational states. Atomic fluorescence radiation is used in density determinations, and, with the help of very high-resolution instruments such as the Fabry–Pérot interferometer, translational velocities and translational temperatures can be determined through the measurement of Doppler shifts. The method of electron-beam–induced fluorescence (EBF) in its various aspects is largely to be credited to its pioneering development by Muntz (1966) and to his continuing productive research.

During the past decade the quality and availability of tunable lasers have facilitated more general use of these systems in diagnostic applications. A valuable survey due to Lewis (1989) compares the utility of EBF, laser-induced fluorescence (LIF), Rayleigh scattering, and Raman scattering (RRS and VRS), and rates the relative difficulty of measurement over a wide range of gas densities. A bar graph from the Lewis paper is reproduced in Fig. 5. In the production of fluorescence, changes in electronic state are precisely determined by the controlled laser wavelength. Experience has shown that the laser beam is more easily focused into the

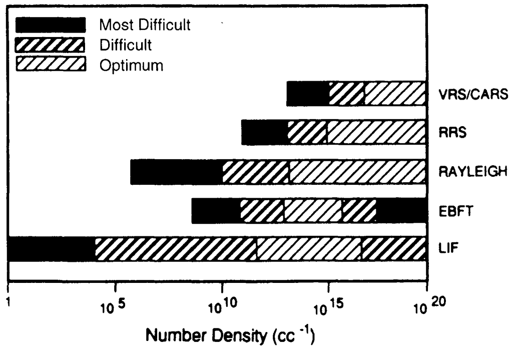

FIG. 5. Optical diagnostic comparisons (Lewis, 1989).

flow and is more stable in operation than the electron beam. Moreover, laser excitation avoids side effects due to secondary electrons, which compromise the effectiveness of EBF under some circumstances. One sees that the range of usable densities for LIF is much greater than for EBF. These advantages must be weighed against the potential for economical exploratory investigation using the electron beam as a broad-spectrum exciter.

3.3 Rocket and Satellite Experimental Systems

Once rockets were sufficiently developed to carry instruments to extreme altitudes, explorations of the thermosphere were conducted to measure atmospheric density and composition, charged-particle concentration, solar energy flux, and so on. These studies by sounding rocket have been of the greatest importance to the development of atmospheric models and to the understanding of atmospheric processes. Orbiting satellites, the next level of development, soon served as valuable experimental platforms. These vehicles may be instrumented for mass spectrometry, optical spectrometry, the detection of charged particles of various kinds, or the detection of electromagnetic fields, and with high-resolution systems for Earth viewing. Issues of astrophysical interest have largely displaced studies of the Earth's atmosphere or the gas dynamics of vehicle interactions with the flow, in part because of the altitude required for long-lived orbits. It should be noted, however, that the understanding of rarefied-gas dynamics always is important in the design of the satellite and its instrumentation.

In the late 1980s the tethered satellite became increasingly discussed as a potential research tool for atmospheric and aerodynamic studies. A research satellite, tethered to a parent satellite by a small-diameter line, may be deployed perhaps 100 km Earthward from the parent vehicle, where it will find an appropriate environment for the study of thermal and aerodynamic effects on the vehicle. The potential for aerodynamic testing using an orbiting "wind tunnel" is very attractive. By the date of this writing, two tethered satellites have been launched, the second demonstrating fully the feasibility. Dynamic and aerodynamic analysis are in progress. For further information relating to applications in space sciences and to related materials, the reader is referred to the *Journal of Geophysical Research* (see, e.g., Jacchia *et al.*, 1977, on atmospheric modeling) and to recent volumes of the *Journal of Spacecraft and Rockets.*

4. APPLICATIONS

The world's technologic life has been extraordinarily transformed through the effects of our knowledge of the behavior of rarefied gases. The influences are pervasive, touching our lives at every moment. Consider, for example, this short list of industrial processes that derive help from vacuum science and engineering: vacuum film deposition, chip manufacture, ion implantation, the production of vacuum electronic devices from x-ray sources to klystrons, diagnostic industrial control. One must also consider the essential aids to laboratory research, including electron microscopes, spectrometers, mass spectrographs, particle accelerators, and lasers.

Probably the greatest change of our times has come from the growth in our facilities for communication. This change, with its uncountable societal consequences, must be attributed to the rise of Sputnik and to the subsequent development of a vast communication umbrella based upon satellites in low Earth orbit. Every part of the technical and operational background for this enterprise rests upon aspects of rarefied-gas dynamics, just as will our continuing exploration of the Earth and its solar planetary environment.

At present much of the focus of aerospace work is on thermodynamic and thermochemical processes in very high-speed flows. This work is motivated by a need for more efficient space transportation. Specific emphasis is placed in two areas, the development of the aerospace plane and of the lifting aeropass and aerobraking shapes for reentry or orbit changes. The aerospace plane will depend upon airbreathing propulsion for much or all of its ascent and requires much new research before this concept of propulsion wherein the vehicle is an integral part of the propulsion system can be implemented. The aerobraking, lifting configurations also require much new research in order to resolve the many questions of chemistry, heat transfer, and wake flow that surround these new shapes at very high speeds and in unfamiliar atmospheres.

Both of the foregoing examples involve vehicles that will experience the full range of flow conditions from continuum to free molecule. There are in these efforts fascinating technical challenges; meeting these will result in new discoveries, and create new knowledge the impact of which cannot be predicted.

GLOSSARY

Cosine Law: Refers to molecular scattering in which the number flux of molecules scattered from a small element of surface into a small solid angle at θ with respect to the surface normal is proportional to the cosine of that angle.

Degassing: In vacuum systems, the process of removing adsorbed gas films on surfaces by heating to elevated temperatures.

Dilute Gases: A model of discrete particle gases in which only binary collisions occur.

Direct Simulation Monte Carlo Method (DSMC): A method for the simulation of the flow of rarefied gases in which the collisions and trajectories of representative particles are treated using statistical techniques.

Free-Jet Expansion: The expansion to supersonic speed of a gas issuing from an orifice into a suitably large region maintained at low pressure.

Free-Molecule Flow: Flow of very dilute gases in which the number of intermolecular collisions within or near to the system is negligibly small.

Knudsen Number: The ratio of the mean distance between molecular collisions to a characteristic length of the system. In external flows the characteristic length may be a diameter, but the choice is particular to the system.

Noninvasive Diagnostic Methods: Methods, usually optical, for determining the properties of flowing gases without altering the flow field.

Normal Momentum-Transfer Coefficient: Defined in Eq. (10c). Characterizes the effectiveness of the wall in absorbing the normal component of momentum carried to it by the incident molecular flux.

Phenomenological Methods: In the present context, statistical methods for selecting the transformation of excited states in molecular collisions from a range of alternatives.

Rarefied Gases: Dilute gases in which the ratio of the mean distance between molecular collisions to a characteristic length of the system lies between 0.01 and 100, approximately.

Specular and Diffuse Molecular Scattering: By specular scattering of molecules at surfaces it is implied that the full normal component of momentum is reversed and that the full component of tangential momentum is preserved. Diffuse scattering of molecules implies scattering according to the **Cosine Law.**

Tangential Momentum-Transfer Coefficient: Defined in Eq. (10b). Characterizes the effectiveness of the wall in absorbing the tangential component of momentum carried to it by the incident molecular flux.

Thermal Accommodation Coefficient: Defined in Eq. (10a). Characterizes the effectiveness of the wall in absorbing the thermal energy carried to it by the incident molecular flux.

Vehicle: Used in the aerospace context to refer to the entire rocket or satellite or other space system designed for flight in the upper atmosphere or beyond.

20.1
Introduction

The interaction of light with matter is of fundamental importance. Indeed, all of the energy we derive from fossil fuels was deposited over vast periods of time by photochemical processes, which converted energy from the sun into chemical energy. The study of chemical reactions induced by light (RIL) is usually termed *photochemistry*, whereas laser photochemistry (LP) refers to the study of reactions promoted with laser light. Photochemistry is concerned specifically with the ways that light can bring about changes in materials and has become very important in the investigation of chemical kinetics or chemical dynamics since photoinitiation is a much more selective and, in the case of the use of laser pulses, a much faster process than thermal initiation of reactions, providing greater control over the reactions. Moreover, lasers have proved invaluable not only to initiate reactions but also to analyze their products. Reaction intermediates, normally prepared thermally via precursors or collisions, can be formed directly by a selective photoprocess, permitting a vast array of reactive intermediates of known composition and energy to be available for new syntheses or experimental studies.

20.2
Fundamental Principles of Photophysics and Photochemistry

Changes in chemical structure caused by light are the subject of *photochemistry*, whereas light-induced changes in the ways electrons are distributed within a chemical entity while the atomic nuclei remain intact are the realm of *photophysics*. The initial event in any photochemical or photophysical process is the absorption of a photon by an atom, molecule, or complex ion, resulting in an electronically excited state. What happens after this event determines whether or not a photochemical reaction will occur, or whether some other photophysical process occurs such as fluorescence, phosphorescence, or the simple conversion of the light energy to heat. The following discussion describes the fundamental principles governing these processes.

20.2.1
Light and Energy

To understand the process of photolysis, that is, how light causes changes in

ISBN: 978-3-527-40773-6

the structure and reactivity of chemical systems, it is necessary to describe some of the properties of light. On the one hand, it is convenient to think of light as an electromagnetic wave, summarized by the expression

$$\lambda = \frac{c}{\nu} \tag{20.1}$$

relating the wavelength, λ, to the frequency, ν, through the speed of propagation, c. On the other hand, light consists of quanta, or photons, each of which has energy given by

$$E = h\nu \tag{20.2}$$

where h, known as Planck's constant, can be interpreted as the proportionality constant between the energy and frequency of the wave associated with the photon.

Laser light has certain advantages over conventional, thermal light sources for use in photochemistry, such as high-power flux density, low angular spread, narrow frequency (or wavelength) distribution, and extremely short pulsewidths in pulsed lasers.

When chemical systems absorb light, individual molecules or atoms absorb only those photons with the right amount of energy to effect an excitation of the molecule from a lower to a higher energy level, if such a transition is allowed. Because light is an oscillating electric field, a transition is allowed for a normal absorption process only if the excited state has a different dipole moment than the ground state. Energy is distributed in molecules in the various levels of molecular motions, that is, translation, rotation, vibration, electronic, and so on, and the kind of electromagnetic radiation absorbed will depend on the kind of motion that is affected (see Chapter 11 by Lipson).

20.2.2
Light-Absorption Principles

The first law of photochemistry from Grotthus (1817) and Draper (1843) states that only the light that is absorbed by a molecule can produce photochemical change within the molecule. The amount of light absorbed in a homogeneous medium is defined by the Beer–Lambert law:

$$I = I_0 10^{-\varepsilon c l} \tag{20.3}$$

where I_0 and I are the light intensities at the front of the absorber and at distance l within the absorbing medium, respectively, and ε is the extinction coefficient in units consistent with the pathlength l (usually in centimeter) and the concentration c (usually in mole per liter). If one is to do quantitative continuous photolysis studies, it is important that an accurate value of the light absorbed by a photoactive sample can be measured since this determines the rate of the reaction. From Eq. (20.3) one can show that the absorbed light intensity, or radiant flux J, is given as

$$J = I_0(1 - 10^{-\varepsilon c l}) \tag{20.4}$$

Photochemists generally measure the incident light intensity, I_0, falling on a sample, and then use this equation to calculate J. The accurate measurement of light intensities, or actinometry, is very important in determining the photokinetics of the system. One convenient method for doing this is the photolysis of a chemical actinometer, which has been calibrated for the wavelength of the photoreaction under study. Almost any photoreaction system that has a well-defined quantum yield at the irradiating wavelength can be used as an actinometer, but for continuous photolysis work in the wavelength range 250–550 nm, the potassium trioxalatoferrate(III) system, developed by Hatchard and Parker (1956), is the most widely used and reliable actinometer available. For longer wavelengths to 750 nm, the photoaquation of aqueous Reinecke's salt, $KCr(NH_3)_2(NCS)_4$, works quite well (Wegner and Adamson, 1966). The common unit for J and I_0 in the aforementioned equations is einstein per second, where an einstein is 1 mol or 6.02×10^{23} photons. Occasionally it is expressed per unit volume of reactant, such as einstein per second per liter, analogous to the method for expressing rates of reactions.

20.2.3
Quantum Yields

The quantum yield or quantum efficiency of a photochemical reaction is normally defined as the fraction of photoactivated molecules that undergo some change. If there are a number of parallel pathways resulting in different products, then each pathway will have its own quantum yield, ϕ. Sometimes the primary step in a photoreaction is the initiator of subsequent thermal reactions resulting in quantum yields, which may exceed unity. The second law of photochemistry states that the absorption of light by a molecule is a one-quantum process, so that the sum of the primary process quantum yields, ϕ, must be unity, that is, $\Sigma\phi_i = 1$, where ϕ_i is the quantum yield of each of the primary processes, which may include, but are not limited to, dissociation, isomerization, charge-separation, luminescence, or radiationless deactivation.

For a reaction,

$$A \xrightarrow{h\nu} B + C + \cdots \tag{20.5}$$

the rate can be expressed as

$$\frac{-d[A]}{dt} = \phi_A J_A \tag{20.6}$$

where $[A]$ is the concentration of photoactive species. One thus determines quantum yields by measuring the ratio of the reaction rate to the absorbed light intensity, J_A.

20.2.4
Quantum-Mechanical Principles of Absorption

If A and A^* represent the ground and excited states, respectively, the process can be written as the reaction

$$A \xrightarrow{h\nu} A^* \tag{20.7}$$

For the absorption to occur, two criteria must be met by the absorbing species:

1. the difference between the energy of the excited state, E_2, and the energy of the ground state, E_1, must be exactly equal to the energy of the photon, that is,

$$h\nu = E_1 - E_2 \tag{20.8}$$

and

2. there must be a finite probability for the transition, as defined by the electronic structure of the molecule.

The Einstein transition probability for absorption, B_{12}, is given by the following expression:

$$B_{12} = \frac{8\pi^3}{3h^2c} g_2(\mu_{12})^2 \tag{20.9}$$

where g_2 is the degeneracy of the excited state, and μ_{12} is the transition moment given by the integral,

$$\mu_{12} = \int \Psi_1 \left(e \sum_i r_i\right) \Psi_2 \, dq \qquad (20.10)$$

In this equation, Ψ_1 and Ψ_2 are the wave functions of the ground and excited states, respectively; the sum is over all of the lengths of the dipole-moment vectors, r_i, of the electrons; e is the charge on the electron; and the integral is taken over the three-dimensional coordinates, q, of the molecule.

While the exact solution of Eq. (20.10) is impossible for anything but the hydrogen atom, approximate wave functions can be used to derive for various transitions qualitative selection rules that reveal when the transition moment, μ_{12}, is nonzero and thus results in an allowed transition, as opposed to one that is forbidden. Two selection rules are particularly important and relate directly to photochemical processes: the spin conservation rule and the Laporte rule. For systems containing atoms with relatively few electrons (i.e., light atoms), a reliable approximation allows for the separation of the spin wavefunctions, S_1 and S_2, from the total wavefunctions Ψ_1 and Ψ_2, such that the transition moment can be written as the product of two integrals:

$$\mu_{12} = \int \phi_1 \left(e \sum_i r_i\right) \phi_2 dq \times \int S_1 S_2 \, dq \qquad (20.11)$$

where ϕ_1 and ϕ_2 are the orbital wavefunctions of ground and excited states, respectively. The spin part of the transition moment vanishes when $\Delta S \neq 0$, that is, when the total spin quantum numbers, or spin multiplicities, of the excited and ground states are not the same, and the transition is said to be "*spin-forbidden*." The Laporte rule applies to species with a center of symmetry, such as octahedral complexes, and requires that transitions between orbitals must be either $u \rightarrow g$ or $g \rightarrow u$ (g, gerade or even and u, ungerade or uneven, that is, symmetric and antisymmetric, respectively, for inversion of the orbital about the center of symmetry), but not $g \rightarrow g$ or $u \rightarrow u$, such transitions being "parity-forbidden." The methods of group theory are often necessary in applying the Laporte rule.

In practice, not only allowed transitions but also sometimes forbidden transitions may be observed because of subtle perturbations in the system, such as spin–orbit coupling, not taken into account in the approximation procedures used to derive the selection rules. The allowed transitions, of course, are much stronger, as indicated by the bandwidth and extinction coefficient of the absorption band. The classical oscillator strength f of the band is related to the Einstein absorption probability by the following expression:

$$f = \left(\frac{m_e c^2 \omega_{12}}{\pi e^2}\right) B_{12} \qquad (20.12)$$

where m_e is the mass of the electron and ω_{12} is the frequency of the transition in cm^{-1}. Experimentally, the oscillator strength can be determined from the integral of the absorption band, that is,

$$f = 4.32 \times 10^{-9} F \int_{\omega 1}^{\omega 2} \varepsilon \, d\omega \qquad (20.13)$$

where the integration is over all frequencies from the onset to the disappearance of the band in question, and the value of F is related to the index of refraction, n, through $F = 9n/(n^2 + 2)^2$. As a very crude approximation, the oscillator strength can be estimated from

$$f \cong 4.32 \times 10^{-9} F\varepsilon_{\max}\Delta\omega_{1/2}, \quad (20.14)$$

where $\Delta\omega_{1/2}$ is the width of the band at $\varepsilon = 1/2\omega_{\max}$ (half-bandwidth).

Since the oscillator strength for a single electron in a fully allowed transition should be unity, the highest value of $\varepsilon_{\max}$ one should observe is about 5×10^4 M^{-1} cm^{-1}, for a half-bandwidth of 5000 cm^{-1}. Parity- and spin-forbidden transitions have much smaller oscillator strengths, resulting in values of ε on the order of 10^2 or less, but they are easily measured with the crudest of spectrometers. Thus, measurement of the oscillator strengths of various bands observed in a spectrum can be of help in making the correct assignments to the transitions.

The foregoing discussion has been based on the assumption that nuclear motions in ordinary molecular vibrations are so slow that they do not affect the electronic energy levels of the molecule, an approximation known as the *Born–Oppenheimer principle*. This means that the total wavefunction for the molecule can be separated into the product of an electronic part and a nuclear part:

$$\psi_{\text{total}} = \psi_{\text{elec}} \times \psi_{\text{nucl}} \quad (20.15)$$

and each part is treated independently. This permits the construction of the familiar energy diagrams of diatomic molecules, which show the electronic potential energy as a function of internuclear distance, a general example of which is shown in Figure 20.1. From a purely classical viewpoint, one would expect the molecule to reside at the exact bottom of either well, but, in fact, this is not the case because it would imply that the atoms would be stationary, that is, not vibrating.

The quantum-mechanical treatment of the simple harmonic oscillator (which approximates a diatomic molecule to the extent that the bottom parts of the potential wells are approximated by a parabola) requires that the lowest energy of the vibrating molecule must be $1/2h\nu_0$ above the minimum (a result of the uncertainty principle, which does not allow both the position and momentum to be completely defined as would be the case if the zero-point energy were 0), where ν_0 is the fundamental frequency of vibration in this ground state. Several vibrational levels for each electronic state are represented in the wells by horizontal lines that show not only the value of vibrational energy but also the turning points, that is, limits of compression and extension of the atoms during the vibrations.

Figure 20.1 shows what happens during an electronic excitation by absorption of light. Because nuclear motions are vastly slower than electronic transitions, the latter occur vertically, that is, the excited molecule has the same internuclear separation as the ground-state molecule, a rule known as the *Franck–Condon principle*. At temperatures in the vicinity of 25 °C most molecules in a thermally equilibrated system are in the ground vibrational state as a result of the Boltzmann distribution law; therefore, nearly all of the electronic transitions will arise out of this ground vibrational state, as shown in the diagram. However, because the excited electronic potential well is wider and slightly displaced to the right as a consequence of having a weaker

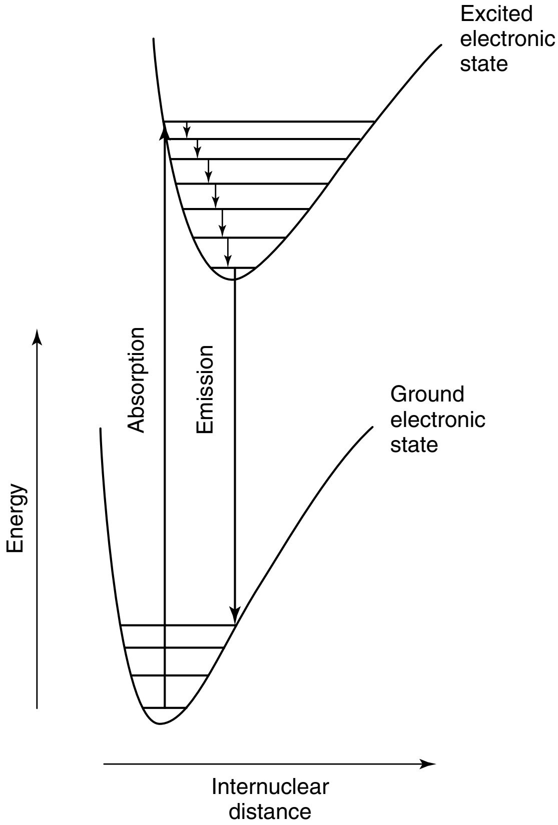

Fig. 20.1 Typical ground- and excited-state potential-energy wells for a molecule, showing vibrational relaxation and emission.

bond than in the ground electronic state, the vertical transitions end in excited vibrational levels in the upper well. Because of the necessity for optimum mixing of the initial and final vibrational wavefunctions in the transitions, those with highest probability occur between vibrational levels in which the molecule is near a turning point in its vibration (except for ground-state vibrations where this highest probability occurs at the center, or equilibrium internuclear distance). This results in a series of transitions to excited vibrational levels in the upper well, giving rise to a set of closely spaced lines in the absorption spectrum of a gas at low pressure or to a broad absorption band in a condensed medium in which the lines are broadened and overlap.

In polyatomic systems, there are numerous vibrational modes and internuclear distances, requiring a multidimensional analog of Figure 20.1 to describe the energy states. Nevertheless, one can still imagine minimum electronic potential-energy wells with superimposed vibrational levels in the hyperspace of n dimensions, where *n* is the number of atoms in the system. Thus, the simple principles of the energetics of diatomic molecules are routinely conceptually applied to more complex systems.

20.2.5
Energy Partitioning and Dissipation Pathways

What happens to the photoactive species after initial electronic excitation by absorption determines the eventual outcome of the photophysical or photochemical process. Since the excited system has a large number of its molecules in excited vibrational levels, it usually undergoes a very rapid thermal equilibration with its surroundings resulting in a Boltzmann population distribution, which means that most molecules drop back to the lowest vibrational level of the excited electronic state, a process called *vibrational relaxation* and shown by the short, downward arrows in Figure 20.1.

Certain bonds between atoms give rise to characteristic frequencies in the infrared (IR), corresponding to bond stretches and bends. Thermal sources of radiation are ineffective in breaking specific bonds, since energy cannot be supplied fast enough to stretch a bond to breaking, in competition with intramolecular and intermolecular energy relaxation.

In recent years, the topic of mode-specific photochemistry has revived in the context of a better understanding of the energy redistribution that may occur inside molecules.

20.2.5.1 Photophysical Pathways: Luminescence and Nonradiative Decay

After the vibrational relaxation of the excited electronic state, the system may return to the ground-state potential well by spontaneously emitting a photon, also shown in Figure 20.1. Note, however, that in this case, since the excited-state potential well is shifted slightly to the right, the most likely electronic transitions are from the lowest vibrational level in the excited electronic state to vibrationally excited states in the ground potential well. This gives rise to an emission band, said to be *Stokes-shifted*, which is at lower energies than, and almost an exact mirror image of, the absorption band. This form of luminescence is often referred to as *fluorescence*, a term which is generally applied to emissions of very short lifetimes between singlet energy levels. From quantum mechanics, the Einstein probability for spontaneous emission, A_{21}, is related to the oscillator strength of the absorption band, through

$$A_{21} = \left(\frac{8\pi^2 {\omega_{21}}^2}{m_e c}\right)\left(\frac{g_1}{g_2}\right) f \qquad (20.16)$$

where g_1 and g_2 are the degeneracies of the ground and excited electronic states, respectively, and the other variables have been previously defined. If emission is the only mode of decay, then

$$\tau_0 = \frac{1}{A_{21}} \qquad (20.17)$$

where τ_0 is the mean radiative lifetime for the emission, a quantity which is thus inversely proportional to the oscillator strength of the absorption.

Nonradiative decay from excited electronic states may occur if there is sufficient overlap between the excited vibrational levels of the lower electronic level and the lowest vibrational states of the excited electronic state. If this occurs between electronic levels of the

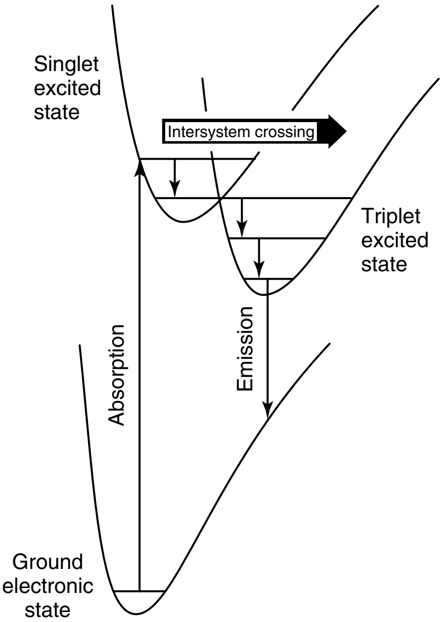

Fig. 20.2 Potential-energy diagram showing excited singlet and triplet states.

same multiplicity, it is called *internal conversion*; if electronic levels of different multiplicities are involved, it is termed *intersystem crossing*. Figure 20.2 illustrates the situation in which there are two excited electronic states of differing multiplicities, for example, singlet and triplet, which have considerable overlap in their vibrational manifolds with each other.

Intersystem crossing from the uppermost potential well to the one that crosses it should be relatively easy from the viewpoint of vibrational relaxation, but forbidden because of the spin conservation rule. However, such processes occur readily because of spin–orbit coupling. Decay of either of the two excited electronic states to the ground state is less likely from the viewpoint of vibrational relaxation because of the poor mixing of vibrational levels, but it can occur through collisional deactivation in which other molecules absorb the energy difference and behave as quenchers of the excited states without actually undergoing chemical change. Since this process is controlled by the collision rate in the system, it is easy to see why this kind of deactivation increases in liquid media at higher temperatures, causing competing luminescence processes to be decreased.

Decay from the excited state of different multiplicity back to the ground state may also occur by emission or nonradiative processes. In both cases, however, the transition has a low probability because of the different spin multiplicities of the two states and the wide separation between the two electronic levels; thus, the excited state has a rather long lifetime. Emission from such a state is often called *phosphorescence* and is characterized by lifetimes as long as seconds, minutes, or even hours after the absorption of light.

Tab. 20.1 Photophysical processes, typical rate constants, and lifetimes in liquid media.

Process	**Rate constants (s^{-1})**	**Lifetimes**
Absorption of photon	$\sim 10^{15}$	1 fs
Vibrational relaxation	$10^{11}-10^{12}$	1–10 ps
Fluorescence	$10^{8}-10^{9}$	1–10 ns
Intersystem crossing between excited states	$0-10^{10}$	>0.1 ns
Phosphorescence	$0-10^{3}$	>1 ms
Radiationless deactivation		
Internal conversion	$0-10^{9}$	>1 ns
Intersystem crossing	$0-10^{3}$	>1 ms

Table 20.1 summarizes the various photophysical processes that may occur in liquid media and the typical ranges in rate constants and lifetimes for each process. Not all emission processes fall neatly into the definitions for fluorescence and phosphorescence and therefore all types of emission can be generally referred to as *luminescence.*

In the condensed phase, vibrational relaxation typically occurs on the order of tens of femtoseconds to hundreds of picoseconds, as shown in laser pump–probe experiments (Elsaesser and Kaiser, 1991). However, it is interesting to note that in some simple liquids, such as liquid nitrogen or inert gases, vibrational relaxation times on the order of minutes have been found (Brueck and Osgood, 1976).

20.2.5.2 **Photochemical Pathways**

The extent to which photochemical products are formed will depend on how well the photochemical pathways compete with the various photophysical decay processes described above. This, in turn, will depend on the reactivity of the excited states, which are usually chemically very different from the ground states. Figure 20.3 is another way of outlining the many choices of pathways through which the excited system can dissipate the energy it gained in absorbing a photon. Nearly all types of reactions can be classified as either unimolecular or bimolecular. The excited states that are reactive may be those which were originally excited in the absorption of light, or they may be other states, labeled *reactive intermediates* in Figure 20.3, accessible by radiationless decay.

There are two special types of reactive intermediates that are formed by bimolecular processes: *excimers* that are formed by dimerization of an excited state, and *exciplexes* that are formed by a complexation reaction of an excited state with ligands. In any case, the potential-energy well of the excited reactive intermediate relative to the ground and excited states of the photoreactant can also be represented by the diagram in Figure 20.2. Photophysical processes are those which result in a return of the system to the ground state while photochemical processes result in different products.

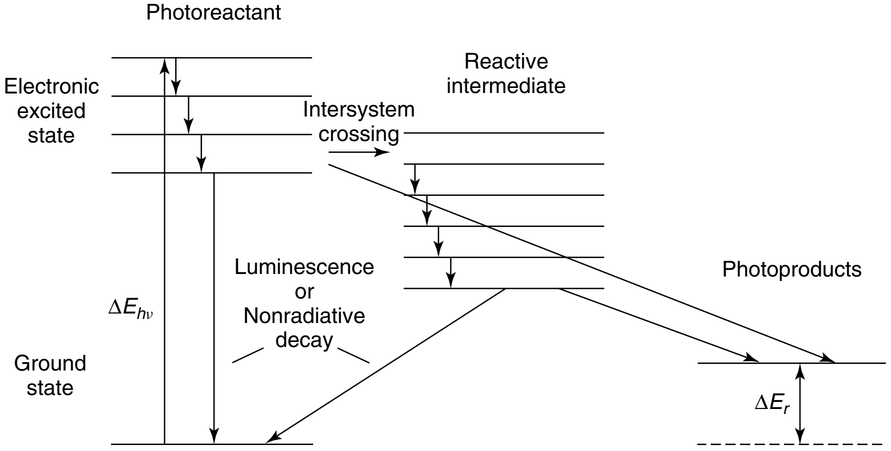

Fig. 20.3 Energy diagram (so-called Jablonski diagram) summarizing the various pathways available to an excited molecule or complex.

Many of these processes occur simultaneously and compete with each other such that one usually observes a mixture of outcomes, each with its own quantum yield. Each of the various decay pathways leading away from the excited photoreactant has its own rate, and the quantum yield for a specific pathway, ϕ_j, is the ratio of an individual rate of decay for that pathway to the sum of the rates of all of the decay pathways, such that (assuming first-order reactions);

$$\phi_j = \frac{k_j}{\sum_i k_i} \tag{20.18}$$

where k_j is the rate constant for the pathway of interest and k_i represents the rate constant for each of the other pathways.

An often-cited quantity is the lifetime, τ, of an excited state or reactive intermediate. This is defined as the time required for a sample to decay to $1/e$ of its original concentration and can be shown to be equal to the reciprocal of the sum of the first-order rate constants for all decay pathways:

$$\tau = \left(\sum_i k_i\right)^{-1} \tag{20.19}$$

It is often the case that excited states may react through bimolecular collisions with other species, thus causing the excited states to be "quenched." Such reactions offer additional pathways for the decay of the excited states, and they must be accounted for in any quantum-yield expression. Since these reactions are second-order processes, their rates will be proportional to the concentrations of both the excited state and the quencher; thus, the quantum-yield expression, Eq. (20.18), will contain a second-order rate constant times quencher concentration for each of these quenching pathways. For example, suppose that the only pathways for decay of an excited photoreactant are luminescence, nonradiative decay, or reaction with a quencher Q, to form a product, as in

$$A \underset{k_L,\, k_{\mathrm{NR}}}{\overset{h\nu}{\rightleftarrows}} A^* \xrightarrow{K_P[Q]} \text{Products} \tag{20.20}$$

where k_L and k_{NR} are the first-order luminescence and nonradiative decay constants, and k_P is the second-order constant for the bimolecular quenching, which forms the product. The quantum yield of product formation, ϕ_P, would then be

$$\phi_P = \frac{k_P[Q]}{k_L + k_{\mathrm{NR}} + k_P[Q]} \tag{20.21}$$

where $[Q]$ is the concentration of the quencher. One can establish that a second-order quenching process occurs by obtaining a linear plot of $1/\phi_P$ versus $1/[Q]$ since the reciprocal of Eq. (20.21) is

$$\frac{1}{\phi_P} = 1 + \frac{k_L + K_{\mathrm{NR}}}{k_P[Q]} \tag{20.22}$$

The slope of such a plot, known as a *Stern–Volmer plot*, can be used to calculate the second-order quenching constant if the lifetime in the absence of quencher is known. An alternative method of obtaining the second-order rate constant directly is from the slope of measured pseudo-first-order decay constants versus $[Q]$.

Many photoreaction schemes are considerably more complex than that shown in Figure 20.3. For an excellent detailed analysis of photochemical kinetics, the reader can consult the book Demas (1983).

20.3
Types of Photochemical and Photophysical Experiments

There are usually two kinds of experiments performed by photochemists: continuous (wave) cw or photolysis, and flash photolysis. Each type is useful for gaining certain kinds of information.

20.3.1
Continuous (cw) Photolysis

In cw photolysis, a continuous source of light, such as a halogen or an arc lamp, is directed or focused onto a sample in a cuvette or photochemical reactor. For the determination of quantum yield, one generally utilizes a well-collimated beam of light impinging on the sample in a cuvette. The beam may first be passed through a monochromator or filter if wavelength information is desired. The rate of reaction may be determined by monitoring at various time intervals properties that are functions of concentration, such as absorbance, pH, conductance, luminescence, or volume of gas emitted or absorbed. The light-absorption rate can be determined from actinometry (see Section 2.2).

Since photochemical processes are sensitive to specific wavelengths of light, careful attention must be paid to the spectral output of the light source selected for experiments.

For quantitative cw experiments, the usual type of lamp used is a high-pressure arc lamp containing mercury, xenon, or a mixture of mercury and xenon. These types of lamps are efficient converters of energy; they have a wide spectral response from the ultraviolet (UV) to the infrared; and because of their short-arc lengths, it is easy to focus

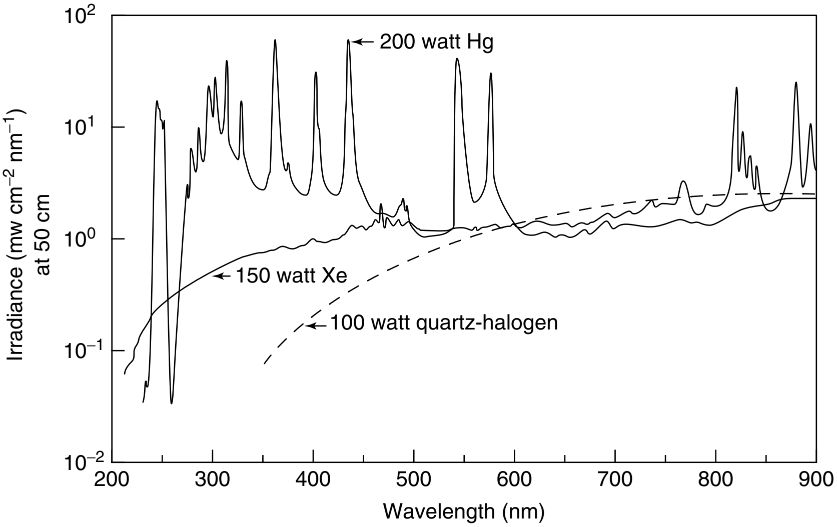

Fig. 20.4 The energy-output spectra for (solid curve) 200-W mercury, (dot-dashed curve) 150-W xenon high-pressure short-arc lamps, and (dashed curve) 100-W tungsten–halogen lamp.

their outputs through monochromators and onto a cuvette. The energy output of a high-pressure mercury arc lamp is concentrated primarily on the series of emission lines of the mercury spectrum, excluding the resonance line at 254 nm, whereas xenon arc lamps tend to give a more continuous output from the UV to the IR (Figure 20.4). The features of both types of lamp can be obtained in an arc lamp envelope filled with a mixture of xenon and mercury. Figure 20.4 also shows the visible portion of the output from a tungsten–halogen lamp, which behaves as a blackbody radiator.

20.3.2
Laser Flash Photolysis

In flash photolysis, a pulsed light source delivers a short burst of light to the sample. This generates short-lived intermediates whose properties, such as absorption or luminescence, can be monitored as a function of time and displayed on an oscilloscope screen. The kinds of information obtained for the intermediates are lifetimes and decay constants, absorption and luminescence spectra, and quantum yields of formation. Such pieces of information lead to an understanding of the intermediate steps and the mechanism of the photochemical reaction. Thus, flash photolysis can “observe” intermediates directly, even those of very fast lifetimes on the nanosecond or picosecond timescale. Both cw and flash photolysis yield important complementary information about photochemical systems.

Modern flash-photolysis experiments rely almost exclusively on pulsed lasers to produce the required high-energy and short pulsewidth flash. Lasers may operate in either the pulsed or cw mode, depending on the type. In all cases, they have extremely narrow bandwidths and virtually nonexistent beam divergences compared to noncoherent light sources. The energy output is centered only at one wavelength and depends on the material in the optical cavity. Availability of a wide selection of wavelengths and the ability to tune lasers over a limited wavelength range have emerged in the past several decades by the use of a variety of cavity materials, dye lasers, frequency modulating crystals, and optical parametric oscillators. Another type of laser, the *free electron laser*, produces coherent light at wavelengths from the far IR to the deep X-ray region, by the relativistic acceleration of a cluster of electrons in a storage ring. Such radiation is called *synchrotron radiation* (see above) and can be a very useful source of tunable laser light at almost any given pulse width, provided one has access to the rather expensive equipment required for its generation. For a complete description of the many laser configurations possible for laser flash photolysis, the reader is referred to Andrews (1992).

A simple laser flash-photolysis setup is diagramed in Figure 20.5. When the sample is excited by absorption of the laser pulse, the oscilloscope is triggered to receive the signal coming from the photomultiplier (PM) attached to the monochromator. The monochromator selects the wavelength of light of interest, and if the transient produced by the flash absorbs at this wavelength, a signal like that shown may appear as the transient decays over a selected time span. This signal can be computer-processed to yield absorbance versus time plots, and the decay constant and lifetime can be calculated. Alternatively, if the monochromator has a photodiode array detector, or if the sample is exposed to series of flashes, each one at a different wavelength, then it is possible to obtain a time-resolved spectrum, that is, an absorption spectrum of the short-lived transient at a given time after the flash. The setup also allows the user to obtain analogous luminescence decay information with the analyzing lamp turned off.

Owing to the limitations of PM rise times and oscilloscope time resolution, a rather different technique has to be used for experiments in the picosecond or femtosecond time regime. In this case, a *pump–probe* configuration is used in which time resolution is controlled by varying the pathlength of the probe pulse. In such experiments, the laser pump and probe pulses are produced in synchrony, but the probe pulse is diverted through an adjustable optical

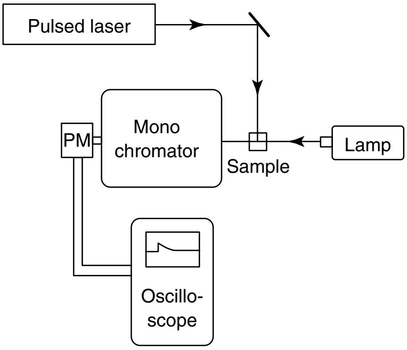

Fig. 20.5 A typical laser flash-photolysis experimental setup.

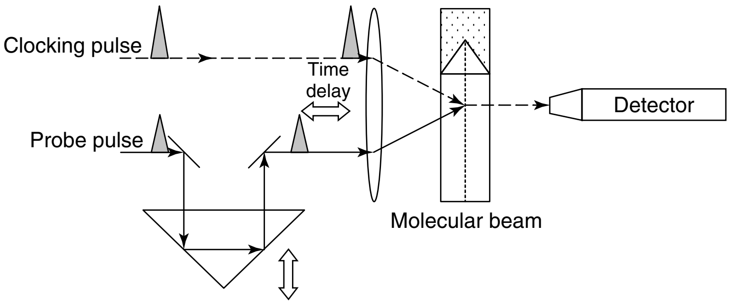

Fig. 20.6 A simplified scheme of the experimental layout for clocking in femtochemistry apparatus.

path length (Figure 20.6). Considering that light travels only about 0.3 mm in 1 picosecond and 0.3 μm in a femtosecond, accurate and precise time delays can be made by very small adjustments in the probe pathlength with respect to the pump pulse.

20.3.3
Laser Spectroscopy

The extremely high spectral purity of a laser beam, coupled with the advances in tunability of lasers, has made them indispensable tools for obtaining high-resolution spectral information of materials. Figure 20.1 shows two electronic energy levels depicted as potential-energy wells, with several vibrational levels superposed on each one. The more closely spaced molecular rotational levels that should be superposed on top of each vibrational level are not shown. In normal spectroscopy, the exciting source for the various transitions between energy levels is some kind of lamp–monochromator combination that has a fairly wide bandwidth and thus limits the degree of resolution of the energies of the transitions. On the other hand, lasers have an extremely narrow bandwidth as an excitation source, so that high-resolution spectra can be obtained. Several important laser spectroscopy techniques are briefly described. For more details on these techniques, the reader is referred to the book by Andrews (1992).

In *electronic photoabsorption spectroscopy*, a sample is excited by a visible or UV laser such that electronic excited states can be probed in the absorption mode. Determining the absorption spectrum of an excited state can yield important information about photochemical intermediates and the various reaction pathways available to a photoexcited species. Alternatively, because the bandwidth of a laser may be considerably smaller than the line width of the electronic transition, which absorbs the laser beam, replacing the conventional monochromater of a spectrometer with a tunable laser can result in highly resolved spectra of the ground state, yielding precise energies and transition probabilities of the excited electronic states. This is especially applicable to gaseous systems at low temperatures, in which the rotational and vibrational features of the spectra become minimized and the electronic transitions become "purer." One common method of significantly lowering the temperature of a gas under study is by supersonic jet-cooling, that is, ejecting the gas from a nozzle at supersonic speeds.

Laser-induced fluorescence (*LIF*) *spectroscopy* is a technique that produces a fluorescence spectrum by exciting the sample with a laser. In conventional fluorescence spectroscopy, one can obtain two types of spectra: an *excitation spectrum* in which the intensity of emission at a fixed wavelength is measured as a function of excitation wavelength and an *emission spectrum* in which intensity of emission is measured as a function of emission wavelength while exciting at a fixed wavelength. Figure 20.1 shows how the fluorescence process occurs and indicates that the excitation spectrum gives the energy changes occurring in the absorption process, whereas the emission spectrum gives the energy released when the excited species returns to the ground state. The use of a tunable laser as the excitation source significantly increases the resolution of an excitation spectrum so that vibrational and rotational fine structure can be observed in samples such as jet-cooled gases, crystals, and molecular beams. Important temporal information can also be obtained by using ultrashort pulsed lasers as the excitation source.

The absorption of laser light can sometimes occur in a multistep process, because of the very high light intensities of a laser beam. For example, a molecule can be excited to an electronic energy level that has a value of E above the ground state by the absorption of two photons of energy, $E/2$, at precisely the same time. This nonlinear effect gives rise to multiphoton absorption spectroscopy. One important advantage of this technique over conventional spectroscopy is that the electronic transitions do not obey the Laporte rule; in two-photon absorption, for example, the transitions must be $g \leftrightarrow g$ or $u \leftrightarrow u$, rather than $g \leftrightarrow u$ or $u \leftrightarrow g$. This increased access to excited states results in a greater understanding of the electronic and vibrational structure of molecules.

20.4
Femtochemistry

In femtochemistry, studies of physical, chemical, or biological changes can be made on the same timescale as that of molecular vibrations, that is, the actual nuclear motions. The femtosecond timescale is unique for the creation of coherent molecular wave packets on the atomic scale of length, a basic problem rooted in the development of quantum mechanics and duality of matter. Molecular wave functions are spatially diffuse and exhibit no motion, but superposition of a number of separate wave functions of appropriately chosen phases can produce the spatially localized and moving coherent wave packet. The powerful concept of coherence lies at the core of femtochemistry and was the key advance in observing the dynamics. Thus, the coupling of ultrafast lasers with molecular beams was essential for the initial developments in this field (Zewail, 2000a,b). The generation, amplification, and characterization of ultrashort pulses are a major part of femtochemistry experiments. Further details can be found in Zewail (1994, 2000a,b).

Such fundamental processes in chemical reactions as energy dissipation, molecular motions, and structural changes occur in the picosecond (10^{-12} seconds) to femtoseconds (10^{-15} seconds) timescale. With the advent of femtosecond lasers, it has become possible to measure events that occur on a timescale shorter than a single vibrational oscillation of a molecule. Thus, ultrafast “snapshots” can be taken of molecules, crystal lattices, unstable intermediates, or other structures in various stages of distortion, yielding valuable information about the structures of molecules and the dynamics of crystal lattices, liquids, individual molecules, and biological systems.

Many systems have recently been examined via femtosecond timescale experiments by Polanyi and Zewail (1995). For example, the dissociation of the ionic compound NaI through a covalent intermediate to the atomic products, Na + I, upon absorption of energy, occurs in less than 10 picoseconds. During this time, the activated intermediate oscillates on the average about eight times, and through an ultrafast series of probe laser pulses the amounts of activated intermediate, ionic $Na^+ I^-$ species, and product sodium atoms can be monitored, with a time resolution down to about 7 femtoseconds. The results have given direct information about the reaction time, the probability of dissociation, and the extent of ionic and covalent character in the NaI bond, and have confirmed many theoretical predictions about reaction dynamics. First, it was shown experimentally that the wave packet was highly localized in space (ca. 10 pm), thus establishing the concept of dynamics at atomic-scale resolution. Second, spreading of the wave packet was minimal up to a few picoseconds, thus establishing the concept of single-molecule trajectory. Third, vibrational (rotational) coherence was observed during the entire course of the reaction, thus establishing the concept of coherent trajectories in reactions, from reactants to products. Finally, the NaI case was the first to demonstrate the resonance behavior, in real time, of a bond converting from being covalent to being ionic along reaction coordinates (Zewail, 2000).

20.5
Reactions of Excited Species

The apparent reactivity of an excited species may be determined by the intrinsic reactivity of its electronic arrangement, by the excitation energy, and by the lifetime of the particular excited state.

The intrinsic reactivity of a species largely depends on the way in which its electrons are distributed in the available orbitals. Electronic excitation alters this arrangement and thus influences the geometry, the dipole moment, the electron-donating or -accepting ability, and the related acid–base properties.

20.5.1
Electronic Energy Transfer

An important overall mechanism of quenching in which the excitation energy is transferred to the quencher in a bimolecular process

$$M^* + Q \longrightarrow M + Q^* \qquad (20.23)$$

is also called *photosensitization*, where Q^* is some excited state of Q usually not directly accessible by optical absorption. The quencher, Q, is said to be sensitized by M, that is, although Q is by itself normally transparent at this wavelength, it is able to become excited by the excited sensitizer, M^*, whose energy should be greater than (or equal to) that of Q^*.

Energy transfer can be either radiative or nonradiative. In the previous case, the emission from M^* is reabsorbed by Q.

(Of course, the absorption spectrum of Q should overlap the emission spectrum of M^*.) Since the S_0-T_1 transition is spin-forbidden, the dominant radiative energy-transfer processes are from a singlet to a singlet or from a triplet to a singlet state.

Nonradiative energy transfers involve the mutual perturbation of the electronic structures of M^* and Q. In long-range coulombic energy transfer (Förster, 1959), the donor and acceptor molecules may be coupled through an electrostatic interaction at large (up to 10 nm) intermolecular separations. The energy-transfer processes favored by the coulombic mechanism are from a singlet to a singlet or from a singlet to a triplet state. In many sensitization reactions, triplet–triplet energy transfer plays the key role.

20.5.2
Photochemistry of Organic Compounds

If excitation affects the nature of the bonding, the shape of the molecule may also be changed. For example, while the ground state of an alkene (e.g., ethene) is planar, in the equilibrium structure of the (π, π^*) excited state the two CH_2 groups lie in perpendicular planes and only a σ bond remains between the carbon atoms.

Excited species are generally both better electron donors and better electron acceptors than the corresponding ground-state species. Therefore, excitation both decreases the ionization energy and increases the electron affinity of the molecule.

Generally, the excited singlet may be more reactive than the triplet. However, since for most organic molecules the ground state is a singlet, the triplet excited state may survive radiative and radiationless quenching so much better than the more reactive singlet. Thus, generally, the triplet is the more important excited species in terms of the overall reactivity in photoinduced organic reactions.

20.5.2.1 Electronic Transitions and Spectra of Organic Molecules

Absorption of a photon by an organic molecule causes a change in its electronic state in a variety of ways that depend on the type of the substrate and the energy of the photon. The highest energy occupied molecular orbitals (HOMOs) of an alkene are the π orbitals in the C–C bond. Absorption of a photon of wavelength around 180 nm promotes an electron from this HOMO to the lowest unoccupied molecular orbital (LUMO) π^*-orbital. The excited state is termed the (π, π^*) *excited state*, and the electronic transition leading to it is a $\pi \rightarrow \pi^*$ transition. While simple alkenes absorb at wavelengths below 200 nm, conjugation of double bonds can shift the absorption maximum into the visible range; for example, $\lambda_{max} = 476$ nm for $CH_3(CH{=}CH)_{10}CH_3$.

The HOMOs of molecules containing heteroatoms (such as N, O, or halogen) are usually nonbonding, and the lowest energy transitions for such molecules are $n \rightarrow \pi^*$ (in the presence of multiple bonds) or n $\rightarrow \sigma^*$ (for saturated molecules). Since $n \rightarrow \pi^*$ transitions, ketones and aldehydes have the lowest energy absorption maxima at 280 and 290 nm, respectively. Acids, anhydrides, and esters have absorption bands at shorter wavelengths (<250 nm), whereas aromatic substitution causes a considerable redshift (e.g.,

$\lambda_{max} \approx 340$ nm for benzophenone). The allowed $\sigma \rightarrow \sigma^*$ transitions of alkanes are less important, giving rise to bands in the vacuum UV.

Most organic molecules are singlets in their ground states; thus, their first excited triplet state is of lower energy than the corresponding singlet state, because of the repulsive nature of interactions between electrons of the same spin.

20.5.2.2 Correlation Rules and Symmetry Conservations

Electron-spin correlation rules are also valid for reactions in which chemical change occurs. Thus, in the permitted adiabatic reactions the total electron spin is conserved, that is, the sum of the spins of the reactants should be the same as that for the products. Conservation of symmetry is especially important to the understanding of pericyclic reactions, or reactions that pass through a cyclic transition state in a concerted manner, that is, with bond-breaking and -forming processes occurring essentially simultaneously. The well-known Woodward–Hoffmann rules (Woodward and Hoffmann, 1970), using the concepts of orbital symmetry, give a good compass for prediction or interpretation of these reactions.

20.5.2.3 Intramolecular Processes

Dissociation Dissociation of a diatomic molecule can give only two atomic fragments with unambiguous chemical identity, whereas that of a polyatomic molecule can sometimes yield many sets of products. For a detailed discussion of the methods used to elucidate primary dissociative mechanisms, the reader can consult the books by Calvert and Pitts (1966) and by Okabe (1978).

Photoisomerization The perpendicular configuration of ethene and its derivatives in the lowest energy (π, π^*) excited state is geometrically equivalent whether it is derived from a cis or trans ground-state molecule. Thus, the probability ratio for the formation of cis and trans isomers depends on the conversion rates of the excited state to the two (isomeric) ground-state forms.

In accordance with the Franck–Condon principle, the significant difference between the geometries of the ground and excited states forbid emission from the latter one. Therefore, in the case where the quantum yields are similar for both cis → trans and trans → cis, prolonged irradiation of either isomer results in the composition of the isomeric mixture at the photostationary state being predominantly determined by the individual absorbances of each isomer at the excitation wavelength. For simple alkenic systems, trans isomers generally possess higher extinction coefficients at longer wavelengths. Thus, irradiation in that range results in the predominance of the cis isomer in the photostationary state. Electrocyclic ring-closure reactions of dienes and trienes are well-known examples of valence and structural isomerizations. These processes leading to the formation of cycloalkenes require the s-cis conformation.

The reactions of polyenes in the excited singlet state often differ from those in the triplet state. Although direct excitation (to S_1) results in internal cyclization, triplet sensitization usually leads to (cyclic) dimerization. Photocyclization of aromatic compounds often results in nonaromatic products. Cyclic conjugated enones and dienones can also undergo structural photoisomerizations with ring rearrangement. These concerted stereospecific reactions proceed via a triplet (π, π^*) state. Another important type of photoisomerization is the di-π-rearrangement, which is formally a 1,2-shift with ring closure. This reaction, however, is probably a nonconcerted process, and promoted via the excited singlet.

Photochemical sigmatropic shift is also a significant type of photoisomerization. In these pericyclic reactions, a σ-bond migrates with respect to a system of π-electrons, resulting in a switching of double and single bonds. A more detailed discussion of these topics is given by Wagner and Hammond (1967).

Hydrogen Abstraction Intramolecular hydrogen atom abstractions, in contrast to photoisomerization processes, involve molecules almost exclusively in the (n, π^*) excited state. This type of reaction is especially significant in the photochemistry of most carbonyl compounds (Wagner, 1971).

20.5.2.4 **Intermolecular Processes**

Hydrogen abstraction can also take place from (n, π^*) excited states (especially of carbonyl compounds, see Scaiano (1973)) in intermolecular processes.

Addition Reactions Both homo- and heteroaddition reactions can be photochemically induced. The latter type of reaction can take place between unsaturated hydrocarbons and water, alcohols, and carboxylic acids or between aromatic compounds and amines. Cycloaddition of benzene and its derivatives can take place across 1,2-, 1,3-, or 1,4-positions. The 1,3-addition predominates with alkenes having only alkyl substituents on the double bonds. 1,2-addition is the main mode of reaction if the electron donor–acceptor properties of the aromatic species and the alkene are significantly different. The 1,4-cycloaddition occurs least frequently and may take place through an exciplex interaction as do the 1,2-additions as well. Cyclobutane derivatives are the main products in the photoaddition of alkenes to the unsaturated bond in α, β-unsaturated ketones. Cyclic enones undergo photocyclic addition more readily than their acyclic analogs because their reduced flexibility inhibits intersystem crossing from the excited triplet state to the ground state. The addition of the carbonyl group itself (in the excited ketones or aldehydes) to suitable alkenes can also occur, producing oxetanes (Arnold, 1968).

Oxygen is one of the most important reactants in photochemical addition reactions of unsaturated compounds. Very efficient photosensitized oxidations are observed with alkenes, dienes, dienoid heterocycles, and polycyclic aromatic compounds. The first products of these reactions are often peroxides or hydroperoxides, which may undergo subsequent oxidation steps. In most of these photosensitized oxidations, the very reactive excited singlet state of oxygen, O_2 ($^1\Delta_g$), is favored via energy transfer from the triplet state of the sensitizers (Foote, 1968). Hence, carotenoids (e.g., β-carotene) are very important photobiological reagents, because as efficient quenchers of singlet oxygen they can protect photosynthetic organisms against photooxidation sensitized by their own chlorophyll.

20.5.3
Photochemistry of Inorganic and Coordination Compounds

To illustrate the kinds of electronic transitions that occur in inorganic photochemical reactions, Figure 20.7 shows a generic molecular-orbital diagram for an octahedral transition–metal coordination complex and the various kinds of electronic transitions that may occur between the orbitals. These are categorized as follows:

1. intraligand (IL) bands, which are transitions between energy levels of the ligands (as discussed earlier about organic photochemistry) and are relatively unaffected by the metal centers;
2. ligand-field (LF) bands, which are the low-intensity transitions, usually in the visible region, caused by the splitting of the metal d orbitals (hence the other often-used term, d–d bands) by the field generated by the coordination of ligands to the metal;
3. ligand-to-metal-charge-transfer (LMCT) bands, which are transitions in which electronic charge is essentially transferred from the ligands toward the coordinating metal;
4. metal-to-ligand-charge-transfer (MLCT) bands, in which electronic charge is transferred from the coordinating metal to the ligands; and
5. charge-transfer-to-solvent (CTTS) transitions, in which electronic charge moves to the solvent. Charge-transfer bands are characterized by their tendency to produce charge separations, which may result in oxidation–reduction reactions.

Charge-transfer bands are characterized by their tendency to produce charge separations, which may result in oxidation–reduction reactions.

20.5.3.1 Ligand-Field (LF) Transitions

The transition metals are in the middle part of the periodic table where the elements have partially filled $(n-1)d$ electron subshells (where n is the period or main shell number). There are five d orbitals in a given subshell, each with its

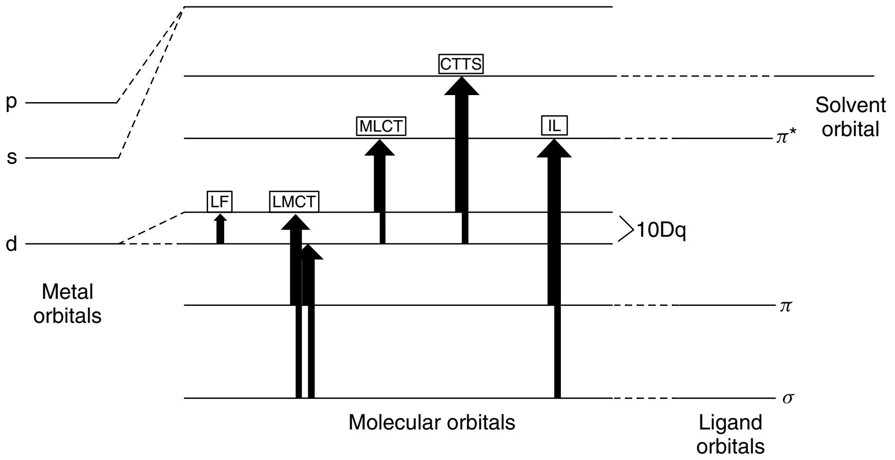

Fig. 20.7 Molecular-orbital diagram for an octahedral coordination complex and the various kinds of electronic excitation transitions that may occur between the orbitals.

own geometrical orientation in space, as shown in Figure 20.8.

In a neutral atom, the five d orbitals of Figure 20.8 are of the same energy, but in a metallic ion coordinately bound to electron-donor ligands there is a splitting of the energies, termed *crystal-field splitting*, caused by the interaction of the ligand electrons with the metal d orbitals. Which atomic orbitals undergo the strongest interaction with the ligands depends on the geometry of the complex: for an octahedral complex, the two e_g orbitals point in the directions of the incoming ligands, thus raising their energy, whereas the three t_{2g} orbitals point away from the ligands resulting in no change in energy. For a tetrahedral complex the situation is reversed, and for other geometries the splitting becomes more complicated. A molecular-orbital picture gives the same splitting patterns between metal orbitals, and these are shown for an octahedral complex in Figure 20.7 by the commonly used symbol for this difference, $10Dq$.

The split atomic orbitals of the metal ion give rise to electronic transitions resulting in LF or d–d bands. Since these transitions are Laporte-forbidden, they are rather weak such that extinction coefficients rarely exceed several hundreds, and the energies of the transitions are usually in the visible to near-IR region of the spectrum, giving a noticeable color to many transition–metal complexes.

For a transition to occur, the coordinating metal ion must have at least one d electron and there must be at least one unfilled orbital in the higher energy state to which an electron can be excited. Excitation of a metal center changes the geometrical distribution of electrons and hence may change the strength of the metal–ligand bond. Thus, LF transitions may result in ligand-exchange, isomerization, or rearrangement reactions without changing the oxidation state of the metal ion. A large number of photochemical reactions induced by LF transitions have been identified and are reviewed in the books by Balzani and Carassiti (1970), Adamson and Fleischauer (1975), Geoffroy and Wrighton (1979), and Ferraudi (1988).

20.5.3.2 Ligand-to-Metal (LMCT) and Metal-to-Ligand (MLCT) Charge-Transfer Transitions

Normally, charge-transfer bands are observed in the UV and short-wavelength visible region in complexes consisting of a donor and acceptor of electronic charge. If the donor is an electron-rich ligand, such as NH_3 or halo, and the acceptor a readily reduced metal, such as

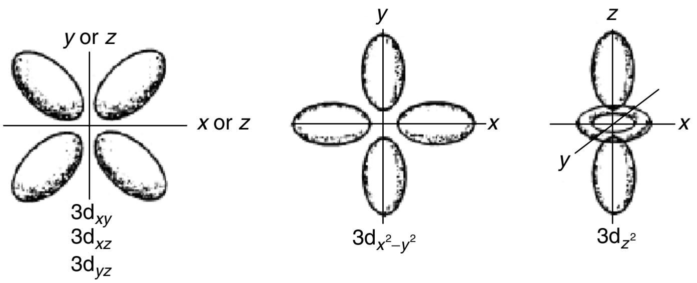

Fig. 20.8 Electron probability pictures of the three d orbitals of an atom.

Co(III) or Fe(III), the transition is LMCT; if the donor is an oxidizable metal, such as Cu(I) or Fe(II), and the acceptor an electron-poor ligand, such as 1,10-phenanthroline or bipyridine, the transition is MLCT. Such bands are Laporte- and (usually) spin-allowed yielding absorption coefficients on the order of 10^4.

One should expect that the excited species following charge-transfer absorption is at once a stronger oxidizing and reducing agent than the ground state because of the shift in electron density between metal and ligand. Thus, the photochemistry resulting from such transitions should involve redox processes of metal and ligand. This certainly seems to be the case following MLCT absorption, as exemplified by the well-known tris(bipyridyl) ruthenium (II) system (Gafney and Adamson, 1972), which has been heavily researched as a possible photocatalytic agent for water splitting (Creutz and Sutin, 1976) since the transitions occur in the visible portion of the spectrum. In addition to redox processes, MLCT transitions often result in reductive elimination.

In general, MLCT transitions usually result in processes that maintain the integrity of the metal–ligand bonds because they originate in filled or nearly filled metal d orbitals, which do not have much effect on the bonding, and they terminate in ligand-localized orbitals, which also are not usually involved in the metal–ligand bond.

By contrast, LMCT transitions often occur between ligand orbitals involved in the ligand–metal bond and a metal in a higher oxidation state with unfilled d orbitals, resulting in a coordinatively unstable, reduced metal–radical ion pair, which usually decomposes further to a complicated array of products. A useful list, prepared by Endicott (1975), tabulates the primary reduced metal and radical formed from the LMCT excitation of each of some 39 complexes of Co(III), Rh(III), Ir(III), Pt(IV), Fe(III), and Ru(III) in aqueous solution.

20.5.3.3 Charge-Transfer-to-Solvent (CTTS) Transitions

CTTS transitions are favorable when the irradiated species is easily oxidized and electron-rich, and there is some low-lying unoccupied orbital on the solvent molecule in the first or second coordination sphere of the complex. Since the first criterion for such transitions is the same as that which favors MLCT transitions, it is common for the lower oxidation states of such metals as Cu, Ru, and Fe to exhibit both MLCT and CTTS bands, sometimes with both types of transitions occurring in the same complex when an acceptor ligand is present, as has been observed, for example, in the case of the cyano complexes of copper(I) and iron(II). The most obvious indicator of a CTTS transition is the ejection by the excited species of a solvated electron into the bulk of the solvent.

20.5.3.4 Other Charge-Transfer Transitions

The number of di- and polynuclear complexes exhibiting metal–metal bonding has increased dramatically in the past few years. In such compounds, it is expected that there will be significant orbital overlap such that new metal–metal delocalized molecular orbitals will be formed. These molecular orbitals can then take part in transitions resulting in charge-transfer between the metals themselves, that is, metal–metal charge-transfer (MMCT) or between the metal–metal orbitals and ligand orbitals (perhaps labeled M_2LCT or LM_2CT, depending on the direction of the charge-transfer). For a detailed compilation of charge-transfer photochemistry of coordination compounds, see the book by Horváth and Stevenson (1993).

20.6
Conclusion

As this concise introduction demonstrates, photochemistry has great theoretical and practical significance in the natural sciences, industry, and nature. A multitude of phenomena, which have been observed and interpreted using photochemical theory and techniques, have strong connections to physics and biology, as well as to the material sciences. The development of more and more sophisticated experimental techniques in photochemistry makes possible the elucidation of the dynamics of elementary reactions. Perhaps even the energy needs of humankind will one day be met by an environmentally friendly photochemical solar energy conversion process.

Glossary

Absorbance: $\log_{10}(I_0/I)$, where I_0 is the incident light intensity falling on an absorbing sample and I is the transmitted light intensity.

Actinometry: Measurement of light intensities for quantum-yield determinations.

Bond-Specific Photochemistry: Photochemistry having products determined by a specific bond or combination of bonds set into vibrational motion.

Chromophore: Light-absorbing chemical group.

Cis: A molecular structural configuration in which two like functional groups are adjacent to each other on the molecular skeleton.

Concerted Reaction: A reaction in which bond-breaking and -forming occur essentially simultaneously.

Conformation: The (possibly unstable) arrangement of atoms inside a molecule.

Conformers: Different, relatively stable, arrangements of atoms, each consisting of identical numbers and types of atoms. A dissociating or rearranging molecule may pass through different conformers. Conformers need not be capable of being physically or chemically isolated.

Conjugation: Alternating double and single bonds within a molecular chain or ring, resulting in bond stabilization via electron delocalization.

Dipole Moment: A measure of the separation between centers of positive and negative charges in polar molecules.

Excimer: A complex formed from the excited state of a molecule with an identical molecule in the ground state.

Exciplex: A complex formed from an excited molecule and a different molecule in the ground state.

Extinction Coefficient: Specific absorbance of 1-cm pathlength of solution at 1 mol l^{-1} concentration.

Flash Photolysis: Experimental study of photochemical or photophysical processes initiated by a short pulse of light.

HOMO: Highest occupied molecular orbital.

Internal Conversion: Energy loss within a given electronic excited or ground-state manifold.

Intersystem Crossing: Transition of an excited electron from a given multiplicity (such as the singlet) to a different one (such as the triplet).

Isomers: Different molecular conformations, consisting of identical atoms, that are stable, or metastable long enough to be physically or chemically separated.

Lifetime: The time required for an excited species to decay to $1/e$ of its initial concentration.

LUMO: Lowest unoccupied molecular orbital.

Mechanism: Sequence of physical and chemical steps leading to a chemical change. Sometimes used to refer to the most unique or characteristic step of an overall mechanism.

Mode-Specific Photochemistry: Photochemistry having products determined by the vibrational mode set into motion.

Monomers: Low-molecular-weight molecules or atoms that can join together to form a polymer.

Multiphoton Absorption: Direct multiphoton absorption occurs when two or more photons are absorbed at once, mediated by higher order perturbation terms of the molecular Hamiltonian interaction with the radiation field. Sequential one-photon events are sometimes called by this name, but more properly may be called *multiple-photon absorption*.

Nonradiative Energy Transfer: Loss of energy from an excited state by any process that does not produce light.

Normal Mode: Classically, molecular vibration in which (nearly) all atoms move concertedly and periodically with the same frequency, but possibly not with the same phase. Quantum mechanically, eigenfunction of the vibrational Hamiltonian.

Organometallic: A compound containing organic carbon and metal atoms.

Oscillator Strength: A measure of the area under an absorption band, or the degree to which a transition is allowed.

Pericyclic Reactions: Concerted reactions proceeding via a cyclic transition state.

Photodetachment: Ejection of an electron from a negative ion by the effect of light.

Photodissociation: Fragmentation of a molecule into two or more pieces by the effect of light.

Polarizability: The measure of charge displacement by an externally applied electric field.

Radiative Energy Transfer: Loss of energy of an excited state by emission of light.

Sensitizer: Compound that absorbs light at the irradiation wavelength, then transfers its excited-state energy to a substrate that cannot be directly excited.

Singlet: An electron configuration in which the sum of the electron-spin quantum numbers is 0, that is, all the electrons are paired with respect to their spins.

Spin–orbit Coupling: Interaction of the orbital and spin angular momenta of an electron in an atom or polyatomic species.

Trans: A molecular structural configuration in which two like functional groups are opposite to each other on the molecular skeleton.

$u \longrightarrow g$ or $g \longrightarrow u$ Transitions: Laporte-allowed transitions between wave functions that are even (gerade or *g*) or odd (ungerade or *u*) with respect to inversion about a center of symmetry.

Triplet: An electron configuration in which the sum of electron-spin quantum numbers is 1, that is, there are two unpaired electrons of parallel spin.

Vibrational Relaxation: Loss of internal vibrational energy into other modes of motion.

INTRODUCTION

People since prehistoric ages have been managing to create various methods of recording to store and communicate information. Varieties of media were utilized such as rocks, bones and skins of animals, trunks and skins of trees or plants including the pith of the papyrus cut and pressed into sheets, etc. Recording was performed by putting a mark upon them by carving or painting. The inventions of paper and typography were indeed epoch-making in the history of recording technology. However, with the progress of electronics, recording technology has made a huge advance in its performances such as quality, capacity, speed, etc., and its progress is still being accelerated in accordance with the ever-increasing demand of the present information-technology era. This article focuses on magnetic and optical recording devices that will play a decisive role in the information processing, although there exist several key technologies in recording such as pen recorders, phonograph-type records, and photographic recording, about which the readers may be referred to the articles LABORATORY INSTRUMENTATION, SOUND REPRODUCTION, and RECORDING PHOTOGRAPHIC, respectively.

Magnetic recording has a history of almost one century, during which enormous development has been made in all aspects, starting from a steel wire recorder. The inventions of magnetic-powder–coated medium and the ring-type head especially have promoted surprisingly great progress in this technology, resulting in various kinds of systems such as audio and video tape recorders, disk memories of both rigid and flexible types, card systems, etc., which are all now indispensable in human life. On the other hand, it has not been much longer than fifteen years since optical recording systems were brought into market as video disk and compact disk (CD) players right after the mass-production technology for laser diodes had been accomplished. In the following, brief concepts of both magnetic and optical recordings will be given with some emphasis on the materials used recently and some idea

about future trends rather than historical ones.

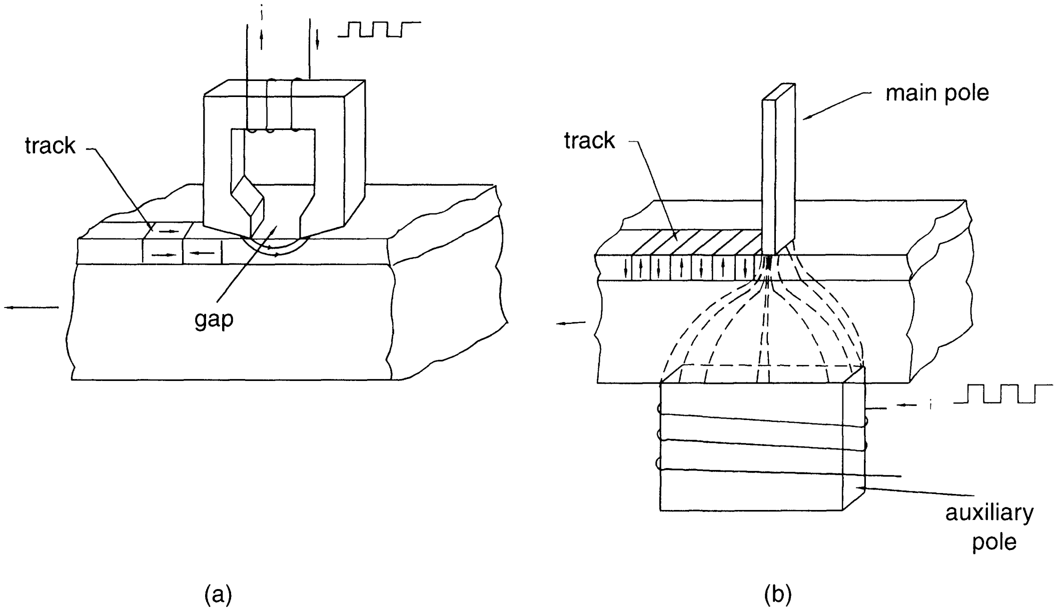
1. MAGNETIC RECORDING

1.1 Principles and Modes of Magnetic Recording

Magnetic recording devices basically consist of two parts: a medium on which information is written in the form of magnetic patterns corresponding to the information, and a head by which the information is written and/or read out. The medium, therefore, has a magnetic layer, which is usually coated on a substrate—rigid or flexible depending on the devices in which it is used. The write head is composed of a magnetic core and a coil wound around it and is designed to generate a magnetic flux in a restricted tiny portion, the strength of which is controlled by an electric current applied to the coil. The read head can be the same write head, or a specifically designed one that is sensitive to a magnetic flux coming out of the recorded medium.

In Figs. 1(a) and 1(b) are illustrated schematically the write processes of the two typical modes (longitudinal and perpendicular; Iwasaki and Nakamura, 1977) of magnetic recording. A magnetic head having (a) a small gap or (b) a thin main pole accompanied by an auxiliary pole is put close to a recording medium, with the gap or the pole tips facing it. During writing, the head moves relative to the medium, and a current modulated according to the information to be written is applied to the coil wound around the head core (or pole), making magnetic flux flow out of the gap (or the pole tip). This flux creates a track of magnetic pattern carrying the information in the form shown in the figures, with the head width determining the track width. For readout, the track is traced by the head. This time, the leakage flux from the magnetic pattern flows into the head core or the poles passing through the coil inducing a voltage in the coil, from which the information embedded in the magnetic pattern is reproduced.

Figure 2 illustrates the principle of the magnetic recording process by use of hysteresis curves (curves of magnetization M vs field H) of the magnetic layer of a medium, taking a pulse recording as an example. Here, H is the sum of all the fields applied to the relevant spot, i.e., the head field, the leakage field from the surroundings H_{srd}, and



(a) (b)

FIG. 1. Write process of magnetic recording: (a) longitudinal and (b) perpendicular recording.

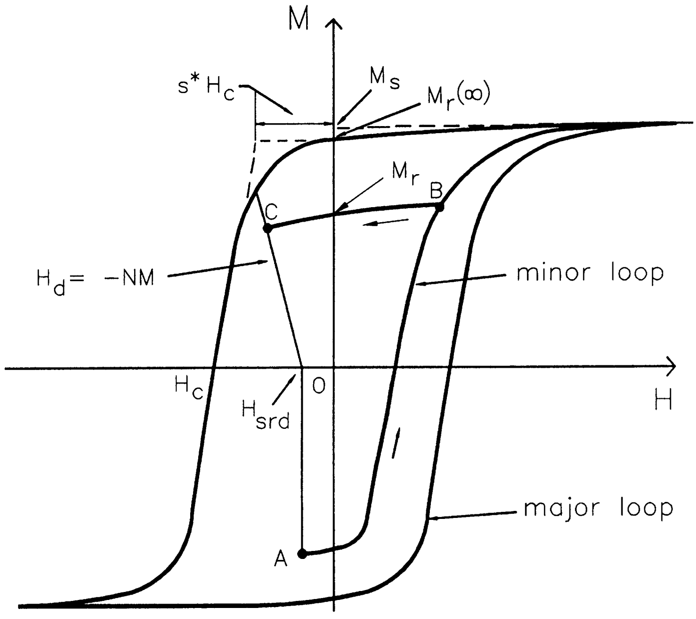


FIG. 2. Recording process on the *M–H* curves (pulse recording). *A*, initial state; *B*, maximum point (corresponding to the maximum write field), *C*, final state (recorded state); H_{srd}, field from the surroundings; H_d, demagnetization field; *N*, demagnetization factor. The saturation magnetization M_s, remanence M_r, squareness ratio M_r/M_s, coercive field H_c, and s^* (which is defined as shown in the figure) are the fundamental factors determining the recording characteristics.

the demagnetization field H_d, which is expressed as

$$H_d = -NM, \tag{1}$$

where N is a coefficient determined by the shape of the written bit and called "demagnetization factor." The recording starts from the initial point *A* and is completed at the final point *C* as is indicated by the arrows. The hysteresis curves represent the magnetic properties inherent to the medium and depend on the materials and fabrication conditions, and proper properties should be chosen for each specific device.

The modes of writing are classified basically into longitudinal and perpendicular recording and also into analog and digital recording according to the direction of the magnetization upon which signals are loaded and the nature of the signals to be recorded, respectively.

Although perpendicular recording is expected to show an excellent characteristic especially in the very high recording density, all practical systems have historically employed the longitudinal mode, with the exception of the evaporated tape case, which can be called "intermediate mode." Figures 3(a) and 3(b) show examples of the cross-sectional view of the recorded pattern of three different recording densities obtained by simulations for each mode of recording upon media having typical magnetic properties suitable for high-density recording for each case (for instance, the thickness for longitudinal recording is chosen much thinner than for perpendicular recording). The scaling ratio of the magnetization vectors for the longitudinal and perpendicular recordings is set as 3. Thus, it is seen that for the highest recording density shown here [300 kbpi (bpi: bits/inch)] the maximum recorded magnetization at the surface in perpendicular recording is much greater than that in longitudinal recording. Analog signals are recorded either by the ac bias method or by the frequency-modulation (FM) method, while digital signals are recorded by the pulse-coding method. The ac bias method was invented in order to improve the linearity of the recording response to the input head current, in which a high-frequency current (bias current) is added to the signal current. The FM method is rather similar to digital recording in the nature of the current wave form. The only difference is that in the FM method, the zero-crossing points are modulated in the analog manner, while in digital recording, they appear with intervals of integers times the predetermined minimum interval. The digital recording method

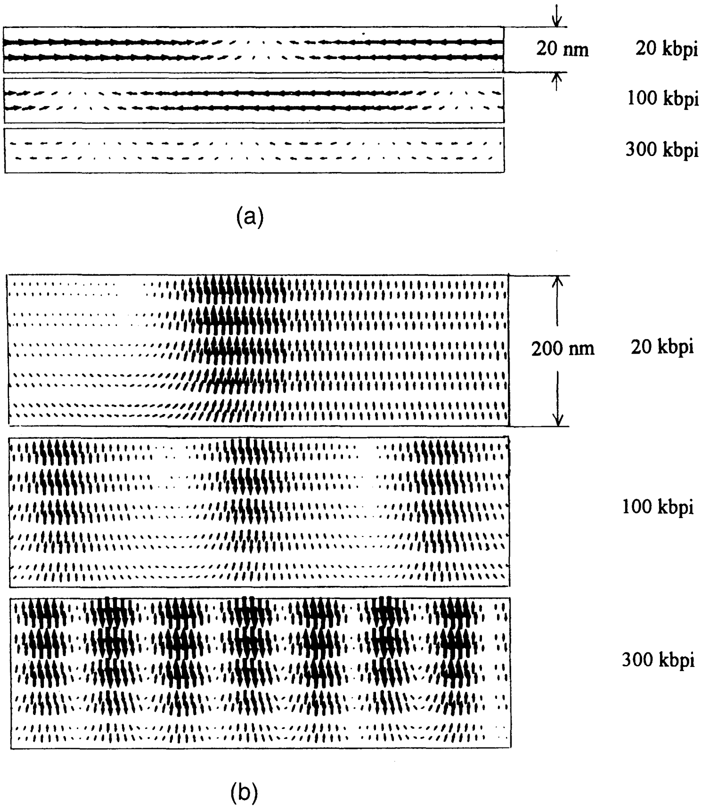

FIG. 3. Cross sections of recorded patterns for (a) longitudinal and (b) perpendicular recording at various recording densities obtained by simulation. The scaling ratio of the magnetization vectors for (a) and (b) is 3:1. (Courtesy of Dr. K. Yoshida and Mrs. F. Akagi, Hitachi.)

was first started from digital computer use. However, it is now being applied widely for all kinds of devices because of its potential perfectness in the reconstruction of the original signals by use of error-detection and -correction schemes.

1.2 Magnetic Recording Devices

A variety of devices exist that are designed to match various applications in the forms of a tape, drum, disk, card, sheet, etc. Among them, audio-video recording and digital-data storage for computers and instrumentation are the major applications. In Fig. 4, some typical magnetic recording devices are shown schematically.

1.2.1 Audio Tape Recorders Originally, audio tape recorders started from an open-reel type, in which two reels were set on a deck equipped-with a fixed read/write head and the tape was transported from one reel to the other during the read/write processes. However, they have been almost completely replaced by the two-reel "compact cassette" type, especially for consumer use, in which two stereo tracks are recorded on a 3.8-mm-wide tape.

In order to provide better sound quality and duplicability, digital tape recorders have been developed, which are divided into two categories; rotary-head type and stationary-head type. The rotary-head type recorder of the standard type is called R-DAT (3.8-mm tape), which is a modification of the VCR (video cassette-tape recorder) in which a helical-scan rotary head and a cassette tape are employed. The format called DASH (digital audio stationary head) was the first adopted for the stationary type. It is of an open-reel type carrying 2-in. tape and uses 24 or 48 heads in parallel. The plurality of heads allowed reducing the tape speed, which must have otherwise been made greater than 10 m/s. Another format of 32 channels using 1-in. tape is now also available. Recently, a stationary-head–type digital tape recorder

FIG. 4. Schematic illustration of typical magnetic recording devices (after Mee and Daniel, 1989).

named DCC (digital compact cassette) equipped with 18 parallel thin-film heads has been developed for consumer use. The cassette has the same basic dimensions as the conventional "compact cassette" providing read compatibility with the conventional one. The heads used for each of the above devices are designed differently from each other as will be seen in Fig. 7. In Table 1, recording characteristics and some other parameters are listed for typical audio tape recorders described above.

1.2.2 Video Tape Recorders Video signals usually carry more than two orders of magnitude wider frequency bandwidth (several megahertz) than audio ones. The frequency response of magnetic recording is not good enough to record directly such wide-band signals, and several modulation methods have been explored. Among them frequency modulation (FM) was proved to be most appropriate because of its insensitivity to the low-frequency noise inherent to electronics.

The first video recording system for broadcasting was accomplished in the form of the so-called "quadruplex head" scheme, in which a rotary drum carrying four heads that scanned a 2-in.-wide tape transversely was employed. One of its drawbacks was that a picture field was divided into 16 tracks making the electronics for reconstructing the field exceedingly complex. The "helical-scan" rotary head was thus invented to solve this problem, first using a 1-in. tape, and subsequent downsizing has continued via $\frac{3}{4}$-in. (U format) to $\frac{1}{2}$-in. (L and M formats).

On the other hand, the consumer-use video tape recorders started with the helical-scan type from the beginning. Although some of the U format were used for some time, they were soon replaced by $\frac{1}{2}$-in. video cassette-tape recorders (VCR) of β format and VHS format. The 8-mm video tape recorder was later developed for portable video cameras.

Digital video tape recorders called D-1 to D-5 have been successively developed for professional use within the past ten years. A number of experimental works have also been performed for the application of the

digital technology to consumer use, where an 8-mm cassette is expected to be employed. However, in order to make it compatible with high-definition television (HD-TV), a bit rate as high as 130–160 Mbits/s is required, claiming the bit size as small as 1 μm^2, which is almost one order of magnitude smaller than that for D-5 (6 μm^2).

In Tables 2 and 3, the characteristics of typical analog and digital video tape recorders are listed, respectively.

1.2.3 Digital-Data Recording Tape recorders are also used for the recording of digital data. However, the demands for very quick access to the stored data gave birth to a magnetic drum, followed by the magnetic rigid disk that is now employed for the major on-line file memories for almost all computers. The head is mounted on a slider supported by a suspension that is carried by an arm. The slider is designed to float extremely close (a few thousand angstroms) to the

smoothly finished magnetic surface of the disk. The data tracks are recorded circumferentially, and high-speed access to each track is achieved by moving the arm quickly either by a linear or by a rotary actuator bestowed with a precise servoing accuracy. The disks at the early stages were as large as 24-in. in diameter, with their capacities being only 10 MB (megabytes)/disk. Downsizing has also been performed in this field through 14-, 10.8-, 8.3-, 5.25-, 3.5- to 2.5-in., and now even a 1.8-in. disk is also available. Their typical characteristics are listed in Table 4. The rigid disks are in most cases used in a stack of 2 to 10 disks set on a spindle, to each surface of which one or a plurality of heads is assigned. This allows the achievement of much higher access speed for high-capacity file memories than a single disk drive.

The flexible disk called "floppy disk" is another major digital-data storage means. The medium is a flexible plastic disk coated with magnetic paint and is put in a soft jacket or a hard cartridge removable from the disk drive. The head comes in contact with the disk surface, except for the Bernoulli-type floppy-disk drive, and is driven by a step motor. The track density is designed much lower than that for the rigid disk. These design concepts have resulted in low-cost media and drives meeting a demand in the low-end uses. The disk size started as 8-in. followed by 5.25- and 3.5-in, successively, and the capacity has been increased from 0.4 to 2 MB. Even 3.5-in. disks of 4 and 12.5 MB have already been developed. In order to attain more than 20-MB capacity on a 3.5-in. disk, an optical-servoing–type floppy disk called "floptical disk" has been developed, in which the magnetic coating is set upon a PET (polyethylene terephthalate) substrate the surface of which is embossed so as to facilitate optical tracking. Very recently, a 3.5-in. floppy-disk drive of 100 MB in which a flexible disk of ultrathin metal particle coating (several hundred nanometers thick) is employed has been announced. In Table 4, the characteristics of typical floppy disks are also listed.

1.3 Magnetic Heads

A magnetic head must be endowed with "write" and/or "read" functions. The basic structures of write heads are seen in Fig. 1. The longitudinal recording head is essentially composed of a high-permeability magnetic core that forms a ring having a narrow gap and a coil wound around the core, thus being called a "ring head." For the perpendicular recording, on the other hand, a specific head consisting of a main pole with a narrow tip at one end and an auxiliary pole wound by a coil has been proposed, which may best be called a "probe head," although a ring head is also applicable. Since both types of heads are inductive in their nature, they are called "inductive heads." Inductive heads are also used as read heads, but some

read-only heads, such as a Hall head and a MR (magnetoresistive) head, have been developed to obtain higher field sensitivity. The Hall* or MR element is set at the front end of a head tip or in a gap of the magnetic core (either the front gap or a gap especially made at a recessed portion of the core in order to provide a wider space for it) or to avoid direct contact of the sensor with the medium.

1.3.1 Inductive Heads In order to obtain a distribution of the head field quantitatively in the vicinity of the head gap or the pole tip, it is generally required to solve a Poisson's equation regarding a vector potential, which can only be solved numerically in most cases (see Fig. 5). However, analytical expressions obtained under some simplified but reasonable assumptions are often useful. For an infinite-permeability ring head having a sufficiently high ratio of the track width to the gap length, the field components H_x and H_y along the center of the track width are well expressed by

$$H_x = \frac{H_0}{\pi}\left(\tan^{-1}\frac{g/2 + x}{y} + \tan^{-1}\frac{g/2 - x}{y}\right), \tag{2a}$$

$$H_y = -\frac{H_0}{2\pi}\ln\frac{(g/2 + x)^2 + y^2}{(g/2 - x)^2 + y^2}, \tag{2b}$$

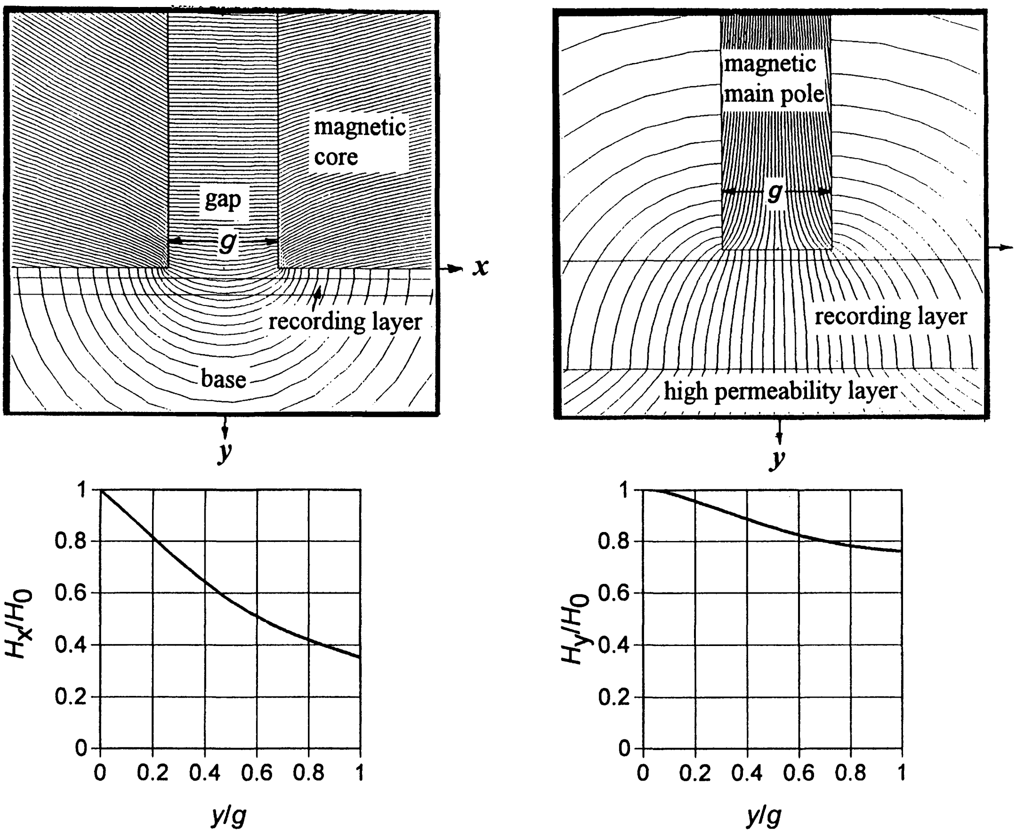
where the head is supposed to be placed with respect to the coordinate as shown in Fig. 5(a); g is the gap length and H_0 is the field at the center of the gap at $y = 0$. These formulas are well known as the Karlqvist expressions. For the probe head, no such simple expressions have been given, but qualitatively, H_x and H_y of the probe head have the nature of $-H_y$ and H_x, respectively, of the ring head, as is seen in Figs. 6(a) and 6(b) in which they are plotted as functions of x.

The readout voltage e to be obtained by using an inductive head is given, by applying the reciprocity law,† as follows, in terms of

---

*For increasing the recording density, narrowing the gap length is essential. However, the semiconductor film of the Hall element is difficult to make thin enough to put into the narrow gap. Therefore, Hall heads have almost been discarded from present-day magnetic recording devices.

†The reciprocity law between two coils can be applied for the system of the coil of the head and the magnetization in the medium because a magnetic moment is equivalent to a circular current.



(a) (b)

FIG. 5. Magnetic flux distribution: (a) at the head gap of a ring head and (b) at the pole tip of a probe head, calculated by simulation. The head fields at the center of the gap or the pole tip are also plotted as a function of the distance along the y direction. (Courtesy of Dr. Y. Yoshida and Mrs. F. Akagi, Hitachi.)

the magnetization distribution $M(x,y,z)$ in the medium and the head field distribution $H(x,y,z)$ that would be generated in the medium if a unit current be applied to the coil:

$$e = \mu_0 v \int H(x,y,z) \frac{dM(x,y,z)}{dx} d\tau, \tag{3}$$

where μ_0 is the permeability of the space, v is the relative speed of the head and the medium in the x direction, and the integration is performed for the whole volume of the medium. Since the permeability of the core or the pole materials has a finite value, the efficiency η of the head is generally reduced from that expected for the infinite-permeability case. Thus it is highly required that the core (pole) materials possess a high permeability. The following expression regarding the efficiency explains this situation:

$$\eta = \left[1 + \frac{g/\mu_0 S_g + l_c/\mu S_c}{R_l}\right]^{-1}, \tag{4}$$

where g and S_g are the length and area of the gap, l_c, S_c, and μ are the length, area, and permeability of the core, respectively, and R_l is the reluctance of the flux leakage paths.

The attainable maximum H_0 that appears in Eq. (2a) or Eq. (2b) is proportional to the saturation induction B_s of the pole material, especially in the vicinity of the head gap or the pole tip. Therefore, high B_s is another

FIG. 6. important characteristic that the core/pole materials are required to assume.

Inductive heads are constructed in many ways by using bulk magnetic materials and/or thin films. In Fig. 7, the structures of typical heads are schematically illustrated. The audio heads are mostly composed of laminated Permalloy cores, the layers of which are insulated from each other to avoid eddy-current losses at high frequencies. The video heads for professional use were first composed of two parts, the back core and the front core. In order to match the video frequencies, sintered ferrite was chosen for the back core. For the front core, a mechanically hard Al–Fe–Si alloy called "Alfesil" or "Sendust"* was chosen because of its excellent precise machinability and abrasion durability. When the VCRs for consumer use were developed, single-crystalline Mn–Zn ferrites were available and were utilized as the core materials. The choice of specific crystalline orientations has been confirmed essential for obtaining both high read/write performances and a high wear resistance (Fujiwara *et al.*, 1982). A typical choice of the crystalline ori-

entations is shown in Fig. 7. For rigid disk heads, polycrystalline Ni–Zn ferrites had long been used. This was because Ni–Zn ferrite had been believed to possess better characteristics at high frequencies than Mn–Zn ferrite on account of its very high resistivity. However, it was later confirmed that the machining effect improves the high-frequency characteristics of Mn–Zn ferrite and its higher saturation induction is more beneficial than Ni–Zn ferrite. The head cores are imbedded in a slider designed to float upon the disk surface hydraulically, the slider itself often making a part of the magnetic flux path. Floppy-disk heads are usually made of sintered polycrystalline ferrite and are imbedded in a slider.

In order to match the higher coercivity of the medium, heads having a metal gap have been developed for video tape recorders (see Fig. 7). Some of them are called MIG (metal-in-gap) or composite head as the core is mostly constructed by a ferrite and the gap portion is made of magnetic metals such as Permalloy, Sendust, and amorphous magnetic materials.

The thin-film head was introduced into disk systems first. Its chief merits are in the simplicity of its manufacturing process beneficial to mass production and in the characteristics of high permeability at high frequencies and high B_s (saturation induction). A typical structure of the thin-film head is shown in Fig. 7. Permalloy (a Ni–Fe alloy) is usually employed as a core material. The patterning of the head core and coils is performed by utilizing various fine lithography methods such as photolitography, electron lithography, and ion milling. Magnetic domain-wall stabilization or elimination is one of the principal concerns, which makes it possible to avoid the Barkhausen noise.

The demand for higher recording density, in which very high coercivity is to be employed, has stimulated the development of high-B_s head core materials. Fe-based alloys had been known as high-B_s materials, but their high crystalline anisotropy was preventing them from becoming magnetically soft enough to be employed as head core materials. The control of the grain size small enough to average out the crystalline anisotropy, which is recently referred to as nanocrystalline technology, was the breakthrough for that. This was first tried by multilayering and then by adding nitrogen and other ele-

ments that prevent excessive grain growth. In Table 5, properties of typical head core materials are listed.

1.3.2 Magnetoresistive (MR) Heads

The key element in MR heads is a MR element that consists of a narrow magnetoresistive thin-film stripe having a uniaxial magnetic anisotropy and current leads connected at each end of the stripe through which a current is supplied (see Fig. 8). The resistivity ρ changes as a function of the angle θ be-

tween the current and the magnetization of the element, according to the expression

$$\rho = \rho_0 + \Delta\rho \cos^2\theta, \tag{5}$$

where ρ_0 and $\Delta\rho$ depend on the material of the element. In most cases the easy axis of the element is set parallel to the stripes. Therefore ρ is expected to change quadratically with the field H as

$$\rho = \rho_0 + \Delta\rho[1 - (H/H_k)^2], \tag{6}$$

since

$$\sin\theta = H/H_k, \tag{7}$$

with H_k denoting the anisotropy field. However, because of the demagnetization field the magnetizations lying close to the edge do not deflect so much as the center, giving rise to the characteristic inflection points and the skirts in the response curve as is illustrated in Fig. 8 (Markham and Jeffers, 1990). Thus, in order to obtain a linear response, various kinds of biasing methods have been explored, typical examples of which are shown schematically in Fig. 9. The elimination of Barkhausen noise is another important issue in practical use. Therefore, some measure has to be taken to avoid the generation of reverse domains at the edges, such as putting hard magnetic or antiferromagnetic films at the ends of the element or making the element double-layered, etc.

A magnetic shield is usually used to obtain a fine resolution as shown in Fig. 10. The reciprocal relation in this case is formally expressed as

$$e \sim \phi = \mu_0 \int \mathbf{H}(x,y,z) \cdot \mathbf{M}(x,y,z) d\tau, \tag{8}$$

where ϕ is the flux entering the MR element and $\mathbf{H}(x,y,z)$ is the field distribution in the space when a unit current is applied to an imaginary coil supposed to be wound around the MR element. Analytical expressions for $\mathbf{H}(x,y,z)$ can be obtained for the infinite track width almost in the same way as the Karlqvist expressions:

$$H_x = H_{rx}(x + (b + t)/4, y) - H_{rx}(x - (b + t)/4, y), \tag{9a}$$

and

$$H_y = H_{ry}(x + (b + t)/4, y) - H_{ry}(x - (b + t)/4, y), \tag{9b}$$

where by H_{rx} and H_{ry} the Karlqvist's expressions for the ring head are denoted, with b and t denoting the gap length between the shield cores and the thickness of the MR element, respectively. The problem is, however, that the relation between e and ϕ is not usually simple. Therefore, the theoretical evaluation of the sensitivity requires some numerical calculations.

For MR heads, a high magnetoresistive ratio ($\Delta\rho/\rho_0$) is one of the basic requirements for the material. Although Permalloy has $\Delta\rho/\rho_0$ of only 2% to 3%, it has been the only material employed for practical use. The ρ_0 of Permalloy is about 20 $\mu\Omega$ cm and the applicable current density is almost 10^7 A/cm^2, leading to the maximum electric field of about 200 V/cm. This implies that for a track width of 10 μm, the signal output of 2–3 mV can be obtained taking into account the reduction of the usable amplitude to half of the maximum obtainable amplitude because of the nonlinearity in the transfer curve (Markham and Jeffers, 1990). This is almost an order of magnitude higher than the output obtainable by the inductive head at a bit density of 60 kfci (fci: flux changes per inch) and a relative speed of 1 m/s (MR heads are relatively speed insensitive by their nature). Some Ni–Co alloys show 6% to 7% $\Delta\rho/\rho_0$ ratio, but because of their high crystalline anisotropy and high magnetostriction, they have not been made applicable to magnetic heads.

In 1988, a new phenomenon called "the giant magnetoresistive (GMR) effect" was discovered in antiferromagnetically coupled multilayered films composed of a number of magnetic layers with nonmagnetic layers in between, each having the thickness of a few nanometers (Baibich *et al.*, 1988). This phenomenon comes from the spin-dependent resistivity at the interface and in the bulk of the magnetic layers and is isotropic with respect to the current direction, and is expressed as

$$\rho = \rho_0 + \Delta\rho \cos\phi, \qquad (10)$$

where ϕ is the angle between the magnetizations of the adjacent layers, in contrast to the case for the conventional MR, which is now called anisotropic MR because of its dependence on the angle of the magnetization and the direction of the current.

The GMR was first found in Fe/Cr systems at very low temperature, but soon it was observed even at room temperature in Co/Cu systems, showing MR ratios as high as 65% (Parkin *et al.*, 1991). At first, to obtain this high ratio, a magnetic field of the order of 10 000 Oe was needed, but a lot of efforts have made it possible to reduce the field drastically. Recently, a structure that gives a substantial sensitivity in fields as low as several oersteds has been proposed in which a granular nature is introduced into the magnetic layers (Hylton *et al.*, 1993). It has been made clear that the antiferromagnetic coupling between the adjacent layers is not essential to the GMR effect. Thus, any metallic magnetic bilayer structures in which the magnetization of one layer is pinned and that of the other is free exhibit the GMR effect (Shinjo and Yamamoto, 1990; Dieny *et al.*, 1991). They are now called spin valves and are expected to be applied for read heads before long.

1.4 Magnetic Recording Media

It may safely be said that the history of magnetic recording media is finding ways of increasing the recording density. This is especially true with digital recording. For longitudinal recording, assuming the magnetization function at the bit transition with a transition length a_T as

$$M_x(x) = (2/\pi)M_r \tan^{-1}(x/a_T), \tag{11}$$

where x refers to the track direction, the output voltage with use of a ring head is given by

$$e_x(x) = -2\mu_0 v w M_r t H_x(x, a_T + h), \tag{12}$$

where v is the relative velocity of the head and medium, w is the track width, M_r is the saturation remanence of the medium, and H_x is given by Eq. (2a) (h: head-to-medium spacing). Then the output pulse width p_{50} (the width at 50% of peak amplitude) is given by

$$p_{50} = 2[(g/2)^2 + (a_T + h)(a_T + h + t)]^{1/2}, \tag{13}$$

where t is the thickness of the medium. This tells that a small gap g, spacing h, thickness t, and transition width a_T are essential to obtain a high resolution. Among those factors, a_T, t, and h in part are related to the medium properties. It should be noted that the above expressions are derived by assuming that the recording is perfect from the top to the bottom, which is the case only for very thin-film media relative to g. A lot of experiments have been performed and an empirical relationship between p_{50} and M_r, H_c, and t of the medium has been obtained for the longitudinal recording as follows:

$$p_{50} \sim (M_r/H_c)^a t^b, \quad a = 0.3\text{–}0.5, \quad b = 0.3\text{–}0.8, \tag{14a}$$

while Nakamura (1991) has obtained by simulation

$$p_{50} \sim (M_r/H_c)^{0.4} t^{0.4}. \tag{14b}$$

Thus, it is concluded that in order to obtain a high resolution, H_c of the medium should be made as high as possible within the limit of the writing capability of the head, although some compromise is necessary between the resolution and output in terms of M_r and t. The surface roughness is another critical factor that should be minimized from the viewpoint of both output and resolution.

The magnetic characteristics of the medium are mostly expressed by its B–H curves, schematic illustration of which was given in Fig. 2. Other than M_r and H_c, the squareness ratio, which is defined as shown in the figure, is also critical to the resolution.

Noise reduction is another important issue. The key point is to reduce the factors that cause inhomogeneity in the medium. Among them, the reduction of the particle size (or the effective size of magnetization switching unit), their homogeneous dispersion, and the smoothing of the surface are most critical.

In accord with the guidelines stated above, varieties of recording media have been developed and brought into practical use. Historically, the first medium was a steel wire, meanwhile replaced by tapes constituted of a plastic base and iron-oxide particles coated upon it with an organic binder. A plated medium was introduced for drum devices but they were soon replaced by rigid disks of particulate coating and now thin-film media are beginning to replace them, starting with disks such as 5.25-in., 3.5-in., or smaller-sized ones. Floppy disks are again of particulate coating.

1.4.1 Particulate Media A particulate medium is basically composed of a base, with a magnetic coating and lubricant coated upon it. As base materials, biaxially oriented polyethylene terephthalate (PET), in some cases with some fillers embedded to reduce the friction coefficient, is mostly employed for flexible media, and mirror-finished Al–Mg(4%–5%) alloys for rigid disks. Other than these, polyimides, polyamides, hard glass, ceramics, etc., are now under development. For most particulate media, acicular magnetic particles are used on account of their high coercivity. For tapes and disks, the particles are aligned in the track direction by applying a magnetic field during the coating process in order to give a higher squareness ratio, while in floppy disks, they are not. This is because the floppy disks are produced by punching out of a wide plastic sheet with a magnetic coating on it. As a lubricant, fluoro resins such as perfluoropolyether are used. The typical thickness of the coatings is a few micrometers for flexible media and several hundred nanometers for rigid disks, respectively, with some exceptions such as double-coated media in which less than 300-nm thickness has been attained for flexible media (Inaba *et al.*, 1995).

The magnetic paint (or dispersion) for coating is prepared by mixing the magnetic powder, a small amount of nonmagnetic powder (α-Al_2O_3, Cr_2O_3, etc., for strengthening the durability, graphite for preventing electrostatic charging), an organic binder, and some organic solvent by use of a sand mill and/or a kneader, though some waterborne paints are under development from the environmental point of view. The binder is designed to be composed of hydrophilic and hydrophobic segments so that it may prevent the particles from aggregation. Figure 11 illustrates the function of the binder. The hydrophilic segments work as an anchor and the hydrophobic ones as a repeller. For flexible media, thermoplastic compositions such as vinyl resin and/or urethane resin are employed, while for rigid disks, thermosetting ones such as epoxy resins or phenolic resins are used. Those have been chosen to facilitate each coating process: roll coating for flexible media and spin coating for rigid disks. The volume fraction of the magnetic particles in the coatings is limited to not much greater than 35% (25% for rigid disks) in order to endow the media with sufficient durability and smooth surfaces.

Magnetic particles in practical use are listed in Table 6. Acicular γ-Fe_2O_3 particles elongated in the [110] direction are prepared according to the processes shown in Fig. 12. The magnetic anisotropy of the particles thus prepared is the sum of the crystalline and shape anisotropies, the contribution of each being almost of the same order. The dehydration and reduction involved in the process are accompanied by a substantial material transport resulting in a more or less irregular shape containing many pores, which leads to a lower coercivity than expected. In order to overcome this drawback, a new process has been developed in which acicular γ-Fe_2O_3 particles are directly precipitated without passing through α-FeOOH (goethite). Thus their coercivity ranges from 250 to 450 Oe according to their preparation methods. CrO_2 is synthesized by hydrothermal synthesis (~400 °C) from Cr_2O_5 by using seeds having a rutile structure. The particles are mostly a single crystal of well-defined shape, which is beneficent for obtaining a coercivity as high as 700 Oe. However, there was a drawback to CrO_2 that toxic hexavalent Cr ions were to be treated during the preparation process. For its replacement, Co-

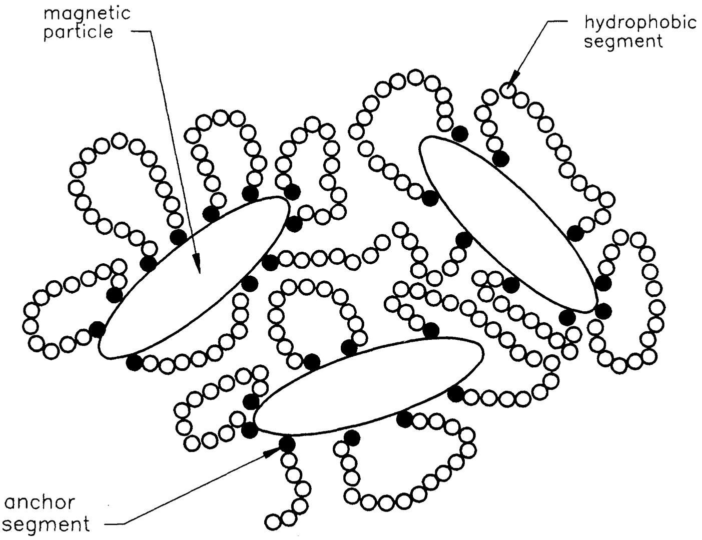

FIG. 11. Schematic model of the function of binder. The binder is composed of hydrophobic segments and hydrophilic segments located at the ends. The hydrophilic segments act as anchors to the magnetic particles.

modified γ-Fe_2O_3 has been developed. At first, replacement of a fraction of the Fe^{2+} by Co^{2+} was tried, which was expected to increase the crystalline anisotropy substantially resulting in an increase in coercivity. However, because of the drastic temperature dependence of its anisotropy, this trial was not successful. Instead, methods in which only the surface of the particle is modified, including epitaxial growth of Co-ferrite upon the surface, have been developed. Thus, coercivity as high as 900 Oe has become available. Figure 13 demonstrates the epitaxially grown Co-ferrite upon the surface of a γ-Fe_2O_3 particle. Acicular α-Fe particles were developed to obtain higher B_s particles than oxides. They are now being produced by the reduction of acicular precursors of α-FeOOH or γ-Fe_2O_3. In order to obtain chemical stability, the surfaces are passivated by mild oxidation, and some stable oxides such as Al_2O_3 and SiO_2 are coated, although the recently developed amine-quinone polymer

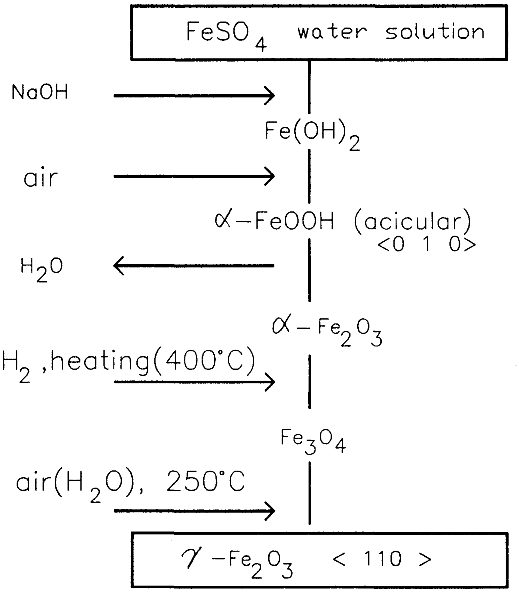

FIG. 12. Typical production process of acicular γ-Fe_2O_3 particles.

binder may relieve the necessity of protection coating through their corrosion-protecting capability (Nikles *et al.*, 1994). Typical magnetic properties are seen in Table 6. Barium ferrite ($BaFe_{12}O_{19}$) has a hexagonal crystalline structure and has a strong uniaxial anisotropy (3.3×10^5 ergs/cm^3) with its easy axis parallel to the *c* axis. This high anisotropy results in a very high coercivity (~2000 Oe), and as a material for magnetic recording, the use was limited up to now only to master tapes or magnetic cards for specific applications. However, the idea of its application to perpendicular recording promoted its adaptability to more general use. The primary concern was the reduction of the coercivity, although it is estimated that coercivity as high as 3000 Oe will be necessary for future high-density recording. The reduction was accomplished by replacing some fraction of Ba or Fe ions by divalent and tetravalent elements such as Co–Ti or Zn–Ti. The particles are prepared either by precipitation in glass flux or by hydrothermal synthesis.

Figure 14 shows electron microscope images of typical magnetic particles mentioned above.

1.4.2 Thin-Film Media As is evident from the expressions (14a) and (14b) for p_{50}, thinness of the medium is essential to high-density recording especially for longitudinal recording. This is the reason why thin-film technology has received strong attention. Another advantage inherent to the thin-film media is the binderlessness that enables achieving higher saturation magnetizations than the particulate ones. However, obtaining a sufficiently high coercivity in thin films was the primary challenge, which was eventually achieved by utilizing crystalline anisotropy, with the aid of shape anisotropy in some cases, of the grains constituting the films. Thus, in most of the thin-film media, cobalt-based alloys having a hexagonal structure, in which a high uniaxial crystalline anisotropy is inherent, have been used, although there have been some exceptions such as gamma ferric oxide and barium ferrite. In thin magnetic films, zigzag walls as shown in Fig. 15 are apt to be formed at the recorded bit boundaries where the magnetizations point head to head (or tail to tail) against each other, reducing the magnetostatic energy at the expense of exchange and anisotropy energies. Their amplitude should be made as small as possible in recording. This can be attained by the reduction of the exchange interaction between the grains. Thus, by taking advantage of the ease of obtaining much smaller grains than in the particulate coatings, very low-noise thin-film media are now available. Protection from abrasion or mechanical damage is also important, a typical example of which is a carbon coating of the order of 10 nm thick.

Thin-film media are produced by plating, sputtering, or evaporation, the appropriate one of which is chosen according to its application: for tapes, evaporation because of its mass productivity and the ease of obtaining a high coercivity and high squareness ratio along the tape direction by making use of the oblique incident evaporation method, and for rigid disks, plating or sputtering because of its ease in producing films with isotropic high coercivity (in some cases, circumferential anisotropy is attached to the

disk by making scratched trails on the substrate in that direction). In Table 7, the properties of some typical thin-film disks are also listed.

Plated disks are produced by electroplating or electroless plating of Co–Ni(P) upon an Al-alloy substrate covered with an electroless-plated nonmagnetic Ni(P) layer. The Ni(P) layer here facilitates obtaining a smooth finish by virtue of its hardness. The coercivity can be controlled by the composition of Co–Ni, additives, the *p*H of the plating solution, and the current density in the case of electroplating. For films having a rel-

atively high coercivity it has been confirmed that they have an hcp structure with its *c* axis preferentially aligned in the in-plane direction forming a networklike structure or that they are composed of a mixture of hcp and fcc structures. It has been also made clear that the control of *p*H and addition of some elements such as Zn and Mn facilitate the reduction of grain sizes, leading to obtaining low-noise media (Goto and Osaka, 1993).

The γ-Fe_2O_3 sputtered disk is mostly made by reactive sputtering of Fe in an Ar–O_2–H_2 atmosphere to obtain a Fe_3O_4 film and then heat-treating it in H_2. Addition of Co increases the crystalline anisotropy. In some films of the media that show good high-density recording characteristics, it has been confirmed that the films are composed of two kinds of columns (several tens of nanometers in diameter); one is of a single crystal with the (111) plane oriented parallel to the plane of the substrate and the other is an assembly of fine grains separated by amorphous materials (Takagaki *et al.*, 1987). Co-based–alloy sputtered disks are made by depositing the alloy upon a polycrystalline Cr underlayer mostly with the (110) or (100) planes preferentially oriented parallel to the substrate surface, upon which Co alloys are epitaxially grown resulting in the *c* axis of the Co-alloy grains oriented parallel to or at a small angle with the disk surface. Circumferential trails are sometimes introduced to obtain a circumferential easy-axis orientation. As Co-based alloys, first CoNi and then CoCr, CoCrTa, and CoCrPt have been explored to obtain a higher and higher coercivity. It is now understood that Cr and Ta are likely to precipitate at the grain boundaries and give a desirable effect of the reduction of the exchange coupling between the grains. Sputtering conditions that give a low mobility to the deposited atoms upon the substrate, such as high Ar pressure, low substrate temperature, and no biasing, are also effective to reduce the noise. Figure 16 shows a cross-sectional view of a typical Co-based–alloy sputtered disk. By utilizing Co-based thin-film media, recording densities of 1–3 Gb/in.^{2} have been successfully demonstrated.

Evaporated media are prepared by such a method as is illustrated schematically in Fig. 17. A Co(Ni) alloy is electron-beam deposited obliquely onto a 6–20-μm-thick PET base film running at a speed of 10–20 m/min over a rotating drum. The incident angle of the depositing atom beams is controlled by a shutter. During the deposition, air is blown

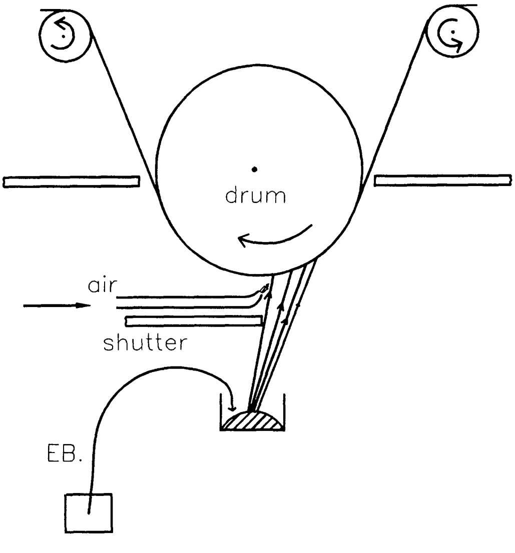

FIG. 17. Schematic illustration of the production process of evaporated metal (ME) tapes.

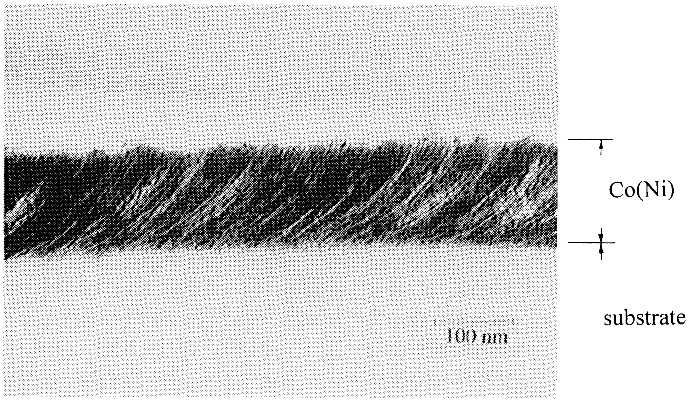

FIG. 18. Electron micrograph of a cross section of an evaporated metal (ME) tape (courtesy of Hitachi Maxell).

onto the substrate in order to form an oxide around each grain growing on the substrate. Figure 18 shows a cross section of a typical evaporated tape (ME tape). The oxide acts as a reducer or inhibitor of the exchange coupling between the grains and a protector against both corrosion and abrasion. The inclination of the grain growth with respect to the substrate surface makes the role of the perpendicular component of the magnetization greater, especially in high–recording-density regions. The optimization of the inclination angle is one of the present primary concerns.

1.4.3 Perpendicular-Recording Media

Investigations on perpendicular recording were first started by using CoCr films (Iwasaki and Nakamura, 1977). Although various other Co-based alloys (CoV, CoMo, CoW, etc.) and barium ferrite have been explored, no better recording characteristics have been obtained than with CoCr media. One of the important criteria the media should satisfy is that the quality factor Q, which is defined as the ratio $K_{\perp}/2\pi M_s^2$, be almost equal to or greater than unity, with $K_{\perp}$ denoting the intrinsic perpendicular anisotropy. For CoCr, this criterion can be satisfied in the Cr-content region greater than 15 at. %, with the limit at about 25% at which M_s tends to vanish. CoCr films with a definite perpendicular anisotropy can be formed either by sputtering or by evaporation. They are composed of very fine columnar crystallites of hcp structure with their c axes aligned almost perpendicular to the film surface. Morphological analysis has revealed that each column has a microstructure such that there exist Co-rich areas and Cr-rich areas if observed from the top of the film, an example of which is shown in Fig. 19, which facilitates high-density recording. Co-based–alloy films with a good quality factor can also be made by electroless plating in a Co–Ni–Zn–P bath with a relatively high concentration of $NiSO_4$ compared with that for the longitudinal recording media (Goto and Osaka, 1993). Barium-ferrite films have been reported successfully prepared on ceramic substrates by the sputtering/heat-treating method. A drawback of this method is that they require a high-temperature (almost 500°C or higher) heat treatment, although some breakthrough is being developed by using laser flash annealing.

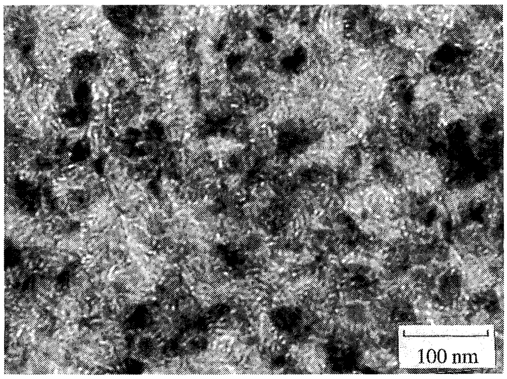

FIG. 19. Transmission electron micrograph of an etched Co–Cr film. Bright area, Co-rich; dark area, Cr-rich (courtesy of Drs. Y. Maeda and S. Hirono, NTT).

In order to match the medium to the one-sided probe-type head system, the recording layer should be formed upon a several hundred nanometers thick soft magnetic (under)layer, which acts as a flux path from the main pole to the auxiliary pole or vice versa. In most cases, Permalloy is used for that purpose. It is noteworthy that even for the ring-type head system, a very thin, rather soft magnetic underlayer (several to several tens of nanometers) improves the recording characteristics substantially (Kitakami *et al.*, 1988; Iwasaki and Ouchi, 1989)

2. OPTICAL RECORDING*

2.1 Concept of Optical Recording

The concept of optical recording is not much different from that of magnetic recording. The only primary difference between the two is that a light beam is utilized to write and read a bit in the former, a magnetic flux in the latter. Therefore, the setup for optical recording devices is quite similar to that for magnetic ones. Optical recording devices basically consist of a medium upon which signals are written and an optical head that applies an optical beam to write and/or read the signals. One of the prominent characteristics of optical recording is its extremely high-density recording capability due to the fact that the light can be focused down to the limit of the wavelength, say less than 1 μm. Other features especially to be mentioned will be the facts that the spacing between the medium and the head can be set wide enough to keep them from contact with each other and that each bit is accessible by the light beam through the transparent substrate at the surface of which the beam diameter can be made as large as about 1 mm. This provides the system with high endurance against dust, enabling the media to be made detachable from the drive and portable, with a much higher recording density than floppy disks.

Figure 20 illustrates the optical recording system schematically. An optical disk is rotated at a high speed and a head is set under the disk and is driven by an actuator so that the light beam may access each track of the disk transversely. The head system is provided with both autofocusing and autotracking functions in order to take full advantage of the high-density recording capability.

2.2 Optical Recording Devices

Optical recording is classified into three categories: read only, write once, and rewritable (erasable), according to the mechanism for recording the information. Just like magnetic recording, the medium can assume any

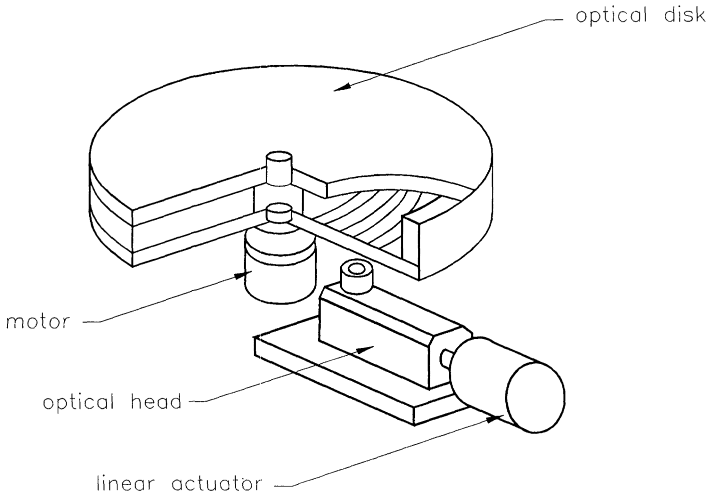

FIG. 20. Conceptual illustration of an optical disk system (after Terao *et al.*, 1990).

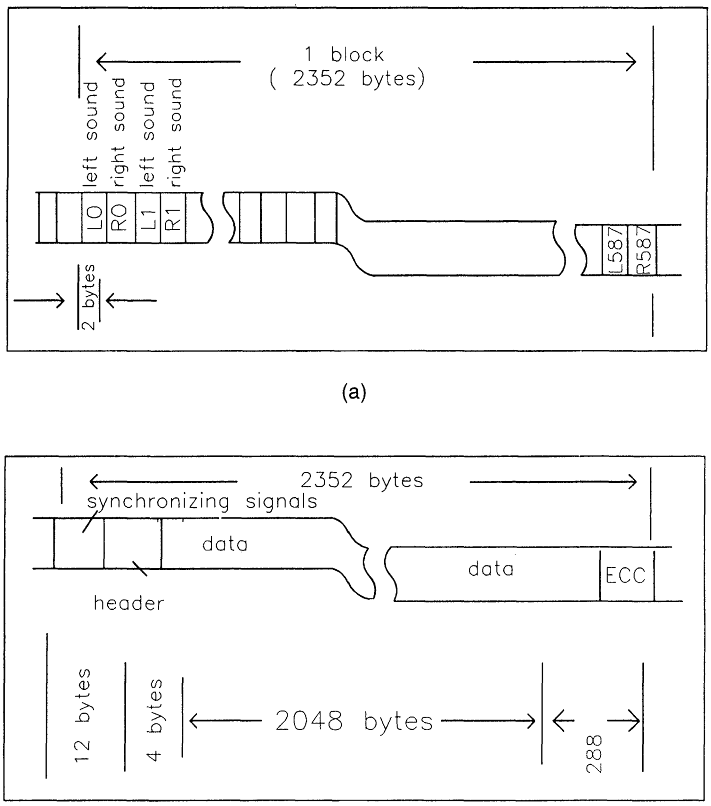
---

*A substantial part of this section is based on "Optical Recording" (in Japanese) (Terao *et al.*, 1990).

style—a disk, card, or tape, to meet various usages, disk being the most popular.

Among the read-only devices are video disk (VD), CD (compact disk), and its derivatives CD-ROM, CD-I (CD-interactive), CD-ROM.XA, and CD-V (CD-video). Video disks employ the FM method to record images. They are either double-sided or single-sided with diameters 200 mm (8 in.) or 300 mm (12 in.), with the playing time ranging from 20 to 120 min. The CD has a diameter of 120 mm and has been developed for recording music by the PCM (digital) method with playing time more than 60 min. An 80-mm CD has also been developed recently with the name "CD single." The CD is rotated at a constant angular velocity (CAV) whereas the VD has two types, CAV and CLV (constant linear velocity). The CD-ROM is a "read-only memory" of any data or software for digital information processors, having the same geometrical, mechanical, and optical specifications for the read procedures as those for the CD. The data structures are also made similar to each other as shown in Fig. 21. On CD-I and CD-ROM.XA are recorded both image and sound by means of a time-division multiplexing method, the latter being standardized for PC use. The CD-V has also both image and sound recordings but they are recorded separately from each other, image data on the outside and sound data inside. All the VD's and CD's have a single spiral track per surface.

Write-once [W-O or WORM (write once and read many)] and rewritable types are both intended to be used for digital information files of a huge capacity, having either a single spiral track or a large number of concentric circular tracks on each surface. Various sizes of W-O–type disks are now on the market such as 356 mm (14 in.), 300 mm (12 in.), 200 mm (8 in.), and 130 mm (5.25 in.), with various kinds of recording media. As for the rewritable ones, 130-mm (5.25-in.) and 85-mm (3.5-in.) magneto-optic



(a)

(b)

FIG. 21. Data recording schemes of (a) CD and (b) CD-ROM (after Otomo, 1988).

(MO) disks are now commonly used, although a 300-mm (12-in.) MO disk has also been developed for special applications such as video editors for broadcasting uses. The number of possible write repetitions exceeds 10^7. Phase-change–type optical disks are now also beginning to be put on the market, which will provide disks of lower cost with lower write repeatability. In Table 8 are listed the specifications and characteristics of typical optical disks and drives.

2.3 Optical Heads

In Fig. 22 is illustrated the basic system of an optical head. The beam from the laser is made parallel through the coupling lens and is shaped into a circular beam by the first prism. After passing through the polarized beam splitter, the linearly polarized light emitted from the laser is transformed into a circularly polarized beam through the $\frac{1}{4}\lambda$ (wavelength) plate, reflected by the mirror toward the medium, and focused upon the surface of the recording layer of the medium by the condenser lens mounted upon a fine positioner (not shown). The reflected beam from the medium comes back to the beam splitter after being changed into linearly polarized light by the $\frac{1}{4}\lambda$ plate and forwarded to the light detectors of the autofocusing and autotracking signals as well as the data signals. For MO recording, the $\frac{1}{4}\lambda$ plate is omitted because the linearly polarized light is utilized to read the signals.

As a laser, GaAlAs laser with 780- to 830-nm wavelength is now adopted, although, for a further increase of the recording density, light sources with shorter wavelengths are under development such as the InGaAlP laser (670 nm), the ZnSe laser (600 nm), and second-harmonic generators that generate the light of a wave length $\frac{1}{2}$ of that of the incident beam (when using a YAG laser, 532-nm light is generated).

It is well known that the diameter of the focal point (measured between points of $1/e^2$ times maximum intensity) is expressed by λ/NA and the focal depth by λ/NA^2, where λ is the wavelength of the light and NA is the numerical aperture of the condenser lens. In order to make the focal diameter small, it is necessary to employ a lens of a large NA, which makes the focal depth extremely small. Therefore, in the optical recording

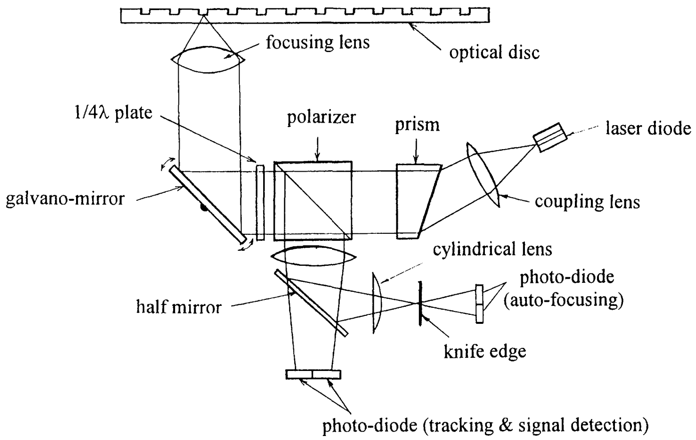

FIG. 22. Basic system of an optical head (after Terao *et al.*, 1990).

system, autofocusing is inevitable. Autofocusing is performed by detecting the change of the focus of the reflected beam condensed through a condenser system set in front of the light detectors. Several methods are proposed for it:

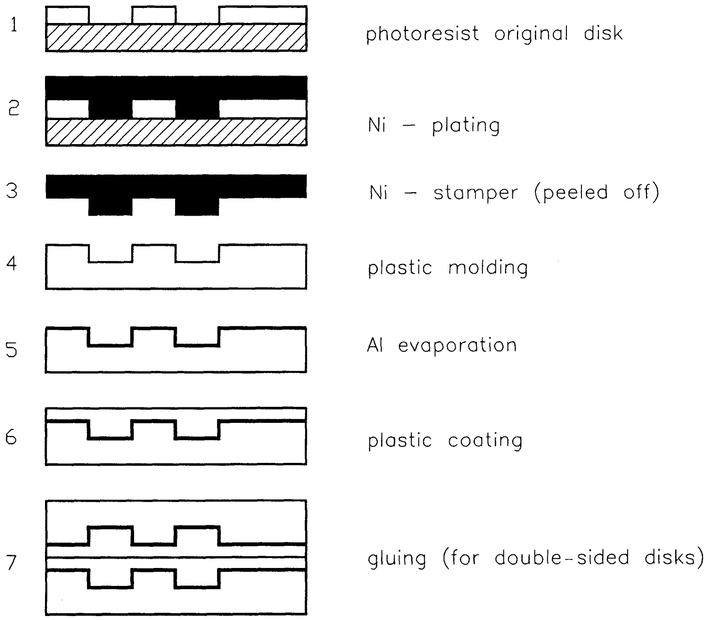
1. two detectors, set before and behind the nominal focal point;
2. a knife-edge shutter set at the nominal focal point and detection of the change of angular distribution of the light;
3. astigmatism method; and
4. astigmatism method with a knife edge.

In the astigmatism methods, a cylindrical lens is combined with a condenser lens in the condenser system to provide an elongated beam cross section in the straight and curved direction of the cylindrical lens right before and after the average focal point of the system, respectively. In method **3**, four detectors are set at the average focal point for the normal position, and by adding/subtracting the four outputs, the amount and the direction of the defocusing are sensed. In method **4**, a knife-edged shutter is set at the spot where the detectors are set in **3**, having its edge at 45° with the principal axis of the cylindrical lens, providing a semicircular beam cross section behind the shutter. The semicircle rotates clockwise or counterclockwise according to the defocusing direction. Therefore, by sensing the rotation direction, the current to be applied to the electromagnetic coil is determined to control the position of the condenser lens.

Autotracking methods are classified into two: continuous servoing [differential diffraction (push-pull) method and three-beam method] and sample servoing (SS). The differential diffraction method is employed when disks having guide groves are used. In this case, a two-division detector is set to receive equal zeroth- and first-order diffracted light when the beam is right on the track, and the off-tracking is sensed by the difference between the first-order diffracted beams. In most of the read-only disk drives, the three-beam method is adopted, in which the beam is split into three by a grating before entering the condenser lens and the light spot is divided into three, one main spot and two subspots aligned in a line tilted a little with respect to the data track direction. The off-track condition is sensed by the difference between the two signals detected through the two subbeams. In the sample servoing method, a number of marks are put periodically on each track (say 1000/track), each mark typically having a pair of dots aligned across the center of the track located a little before and behind in the track direction, and the data are recorded between the marks. Thus the off-track signals are obtained through the read beam.

2.4 Optical Recording Media

2.4.1 Read-Only Disks Read-only disks are produced by stamping. Figure 23 illustrates schematically the stamping process. The first three steps are those for preparing a stamper. First, an original disk in which the information is recorded as a series of



1
photoresist original disk

Ni – stamper (peeled off)
4
plastic molding
5
Al evaporation
6
plastic coating
7
gluing (for double-sided disks)

FIG. 23. Production process of W-O–type optical disks (after Terao *et al.*, 1990).

pits is prepared by means of a laser-beam recording upon a photoresist-coated glass disk, then nickel is first sputtered (several micrometers) and then electrodeposited (about 0.2 mm thick), and finally the deposited nickel layer is peeled off making a mother stamper. Although not shown in the figure, actually, working stampers are made by repeating the Ni deposition and peeling similarly to the above with the aid of peeling agent, using the mother stamper. Then, plastic materials, such as polycarbonate (PC) and polymethyl methacrylate (PMMA), are compressed or injection-molded upon the stamper. After being peeled from the stamper, the mold is finished with aluminum coating for reflection and resin coating for protection (and adhered face to face when making a double-sided disk).

The signals are recorded as a series of pits having a width smaller than the read beam diameter ($\sim\lambda/\mathrm{NA}$) and a depth equal to $\lambda/4n$ (n: refractive index of the substrate). In the read process, the reflected light from a pit and its surrounding land cancel each other through interference, which gives a weaker return beam than from the land area, providing the pit signal.

2.4.2 Write-Once (W-O) Disks There are various kinds of W-O disks in terms of the mechanism of recording: deformation (hole, dip, or bubble formation), phase change, alloying, and color developing, with the deformation type, especially the hole-formation type, being the most common.

The mechanism of hole or dip formation by irradiation with a laser beam is explained as follows: When the disk is irradiated, the viscosity of the recording layer at the spot is decreased because of the elevation of the temperature, and a viscosity gradient appears with a minimum at the center, which in turn generates a gradient in the surface tension. The surface tension increases toward the perimeter, causing material to gather toward the perimeter, which makes a banklike bulge (or mound) leaving a dip inside as is schematically shown in Fig. 24; and when the viscosity becomes sufficiently low, a hole is formed at the center. There-

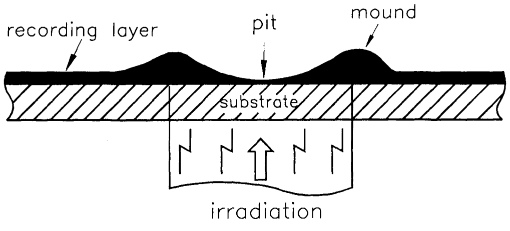

FIG. 24. Pit formation in W-O–type recording (after Oba *et al.*, 1985; Terao *et al.*, 1990).

fore, it is desirable that the materials for the recording layer possess a steep temperature dependence of the viscosity as well as a low melting point, high light-absorption coefficient, and low thermal conductivity in order to obtain high resolution and high light sensitivity. Of the many materials explored thus far, tellurium alloys such as (Pb–)Te–Se and Te–C are outstanding among inorganic materials, although there have been developed a lot of potential organic materials such as cyanine dyes, azulenium dyes, phthalocyanines, naphthoquinone dyes, etc., which have a high absorption coefficient for the light emitted from the laser diode. Generally, those dye polymers are rather apt to be deteriorated by the read beam or even by natural light, and their disk life cannot be expected to be as long as that of the inorganic ones. However, some of them show a read durability of more than 10^6 times and they are acceptable for low-cost disks.

There is another type of deformation by irradiation, in which the surface of the substrate itself is deformed through the heating up of the light-absorbing layer coated directly upon it. Au–Sn alloy on PC (polycarbonate) substrate is one of the most noticeable examples because it can provide a reflectivity contrast that is compatible with the CD's.

Te–O–Pd is known as an excellent material for phase-change–type media, in which fine Te particles of several nanometers are dispersed in the amorphous TeO_2 matrix. Without Pd, the heat/cool process under irradiation causes the recrystallization of Te in the form of long chains, which makes the spot shape irregular; Pd prevents this phenomenon. As alloying-type media, the $Sb_2Se_3/Bi_2Te_3/Sb_2Se_3$ triple-layered film coated with an Al reflection layer is well known. By irradiation, the Bi_2Te_3 layer absorbs the light and the temperature is elevated, which causes selective mutual diffusion of Bi and Se because of their strong affinity. A color-developing–type recording layer consists of a colorless dye layer and a developer layer mostly having a light-absorbing layer in between, an example being the combination of crystal violet lactone (dye), phenolphthalein (developer), and vanadyl phthalocyanine (absorber).

2.4.3 Rewritable (Erasable) Disks Although several methods have been investigated for rewritable optical recording, such as magneto-optic (MO), phase change, deformation, photochromic, liquid crystal, etc., most rewritable disks now on the market are MO disks, with some of the phase-transition types being also put into practical use.

2.4.3.1 MO (Magneto-optic) Disks. Figure 25 illustrates the principle of the write process. The recording layer is composed of a magneto-optic material of several tens of nanometers thickness, having a magnetic anisotropy with its easy axis perpendicular to the plane. Initially, the magnetization of the layer is saturated in one direction, say upward. When a spot is irradiated by a laser beam (<10 mW), the temperature of the spot is elevated and the coercive force decreases to almost zero near the Curie temperature. Thus the magnetization of the spot is reversed by the effect of the reverse field H_{srd} from the surroundings or, in most cases, by a field H_a (typically several hundred oersteds) applied through a coil set close to the condenser lens through which the beam is applied. After irradiation, the spot begins to cool accompanied by an increase in the coercive force, which sustains the small reverse domain (reversed magnetization region) even if the applied field is removed. Erasing is

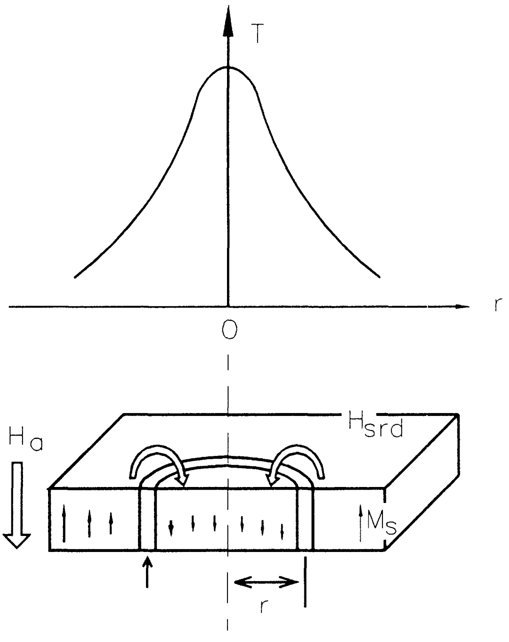

FIG. 25. Mechanism of magneto-optical (MO) recording (after Terao *et al.*, 1990).

performed before the rewrite process by applying an opposite field while irradiating. For reading, a magneto-optic effect called the polar Kerr effect is utilized. When linearly polarized light (2–3 mW) is reflected at the surface of a magnetic body, the polarization plane rotates clockwise or counterclockwise (a few tenths of a degree) according to the direction of the magnetization, which enables the sensing of the magnetization direction. Thus the magneto-optic materials for a recording layer should have

1. a high Kerr rotation angle,
2. appropriate Curie temperature (150 to 250 °C), and
3. low thermal conductivity and heat capacity, as well as sufficiently high perpendicular anisotropy $K_\perp$ to keep the magnetization perpendicular to the film plane, and high coercive force H_c, which sustains the written bit in the ambient conditions including reading.

More specific conditions that $K_\perp$ and H_c should satisfy are

$$K_\perp > 2\pi M_s^2, \tag{15}$$

$$H_c > (AK_\perp)^{1/2}/2\,M_s d, \tag{16}$$

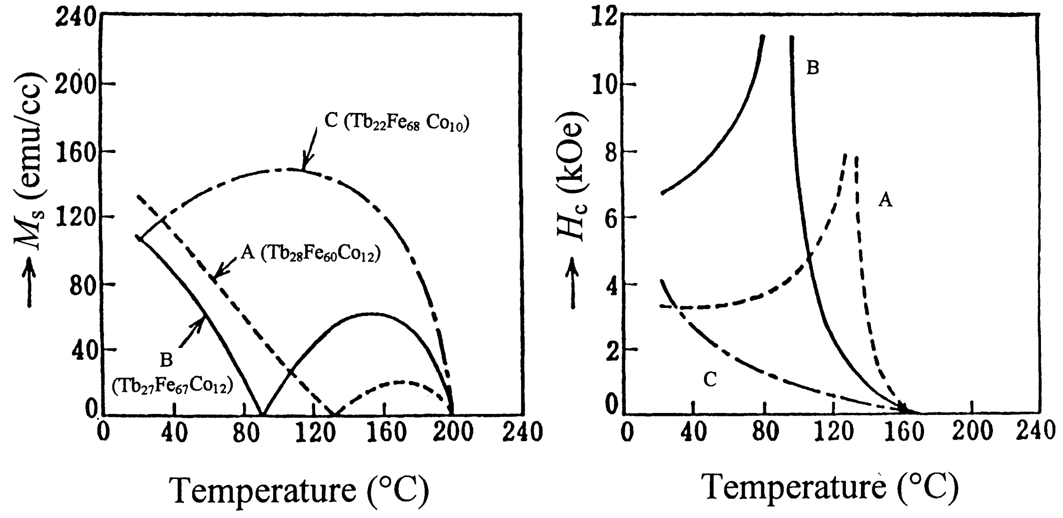
where A is the exchange constant of the material and d is the diameter of the written spot. The readout signal-to-noise ratio is given by

$$S/N \sim R^{1/2}\theta_k \tag{17}$$

where R is the reflectivity and θ_k is the Kerr rotation angle. Therefore, the reflectivity and absorption should be appropriately compromised.

A lot of materials have been explored, and at present amorphous RE–TM (rare-earth–transition-metal) alloys are regarded as the most favorable (Imamura and Ota, 1980), although a lot of work has been devoted to manganese chalcogenides such as Mn(Cu)Bi, and to rare-earth iron garnets. This is because the RE–TM alloys have much flexibility in material designing, and their amorphousness is thought to be advantageous in making the written-spot perimeter smoother, leading to less noise than polycrystalline materials like MnBi and garnets.

Among RE–TM alloys, TbFeCo alloy is the most common, although GdTbFe with a greater Kerr effect and low-cost DyFeCo and TbDyFeCo are now also in practical use. In Fig. 26, curves of the saturation magnetization M_s and coercive force H_c vs temperature



(a) (b)

FIG. 26. Temperature dependence of the saturation magnetization M_s and the coercive field H_c of typical TbFeCo magneto-optical (MO) recording films (after Takahashi *et al.*, 1988).

are shown for three typical kinds of TbFeCo alloys with different compositions. Figure 27 shows the written spots on each of the three kinds of disks for various applied fields during recording. It is seen that disk B is the most insensitive to variation of the field between 100 and 400 Oe, giving an almost constant size to the written spots. This behavior is explained by considering the balance of the forces acting on the domain wall during the write process: the forces through the applied field H_a, leakage flux of the surroundings H_{srd}, the surface tension and potential energy of the wall, and the coercive force taking into account the temperature distribution during recording:

$$H_c(r) = H_a + H_{\text{srd}} - \frac{\sigma_w}{2rM_s} - \frac{\partial M_s}{\partial r}(2M_s)^{-1}, \qquad (18)$$

where r is the radius of the written domain and σ_w is the wall energy.

For the next-generation MO disks increases in speed and recording density are now being explored. Higher speed will be attained by introducing overwritability, lighter heads, and multichannel heads. Typically, two schemes are under development to obtain overwritability: the field-modulation type and the beam-modulation type. In the former scheme, a small magnetic head is used for providing high-frequency modulation fields. To make the head small enough, the field necessary to write/erase is required to be weak. The coating of a very thin (several nanometers or less) ferromagnetic capping layer upon the recording layer is known to be extremely effective for field reduction (Ohnuki *et al.*, 1991). On the other hand, in the latter, exchange-coupled double-layered films consisting of a memory layer and an auxiliary layer or their modifications are being investigated (Saito *et al.*, 1987). Figure 28 illustrates how it works. One way to decrease the head weight to be moved is to divide the head into two parts, one consisting of the condenser-lens systems and the other the light-source and detector systems. Another is making it up with thin films. The former is almost at a practical use level, although the latter is still at a research stage. Four typical methods are being explored for increasing the recording density;

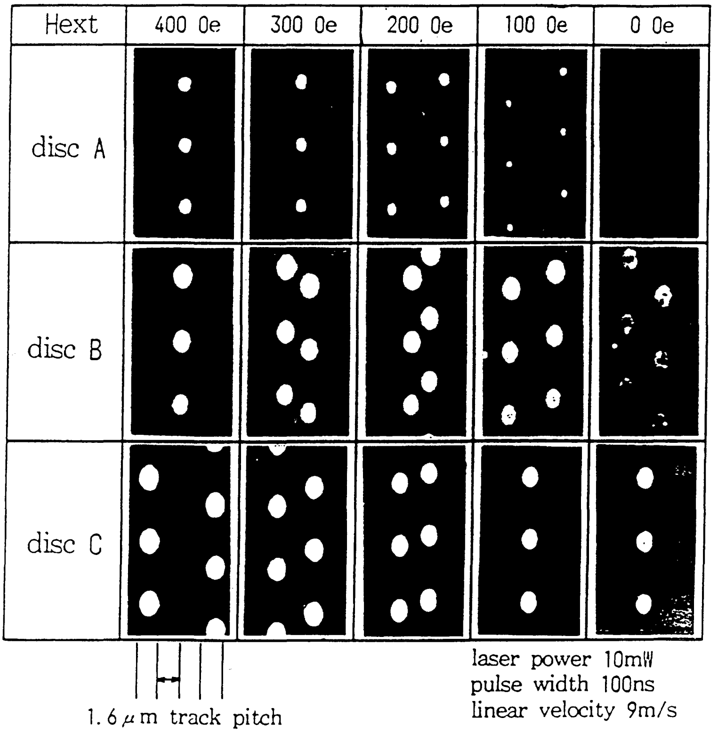


FIG. 27. Recorded patterns on the disks A, B, and C the magnetic properties of which are shown in the previous figure. The applied field was varied from 0 to 400 Oe, keeping the other conditions constant. (After Takahashi *et al.*, 1988).

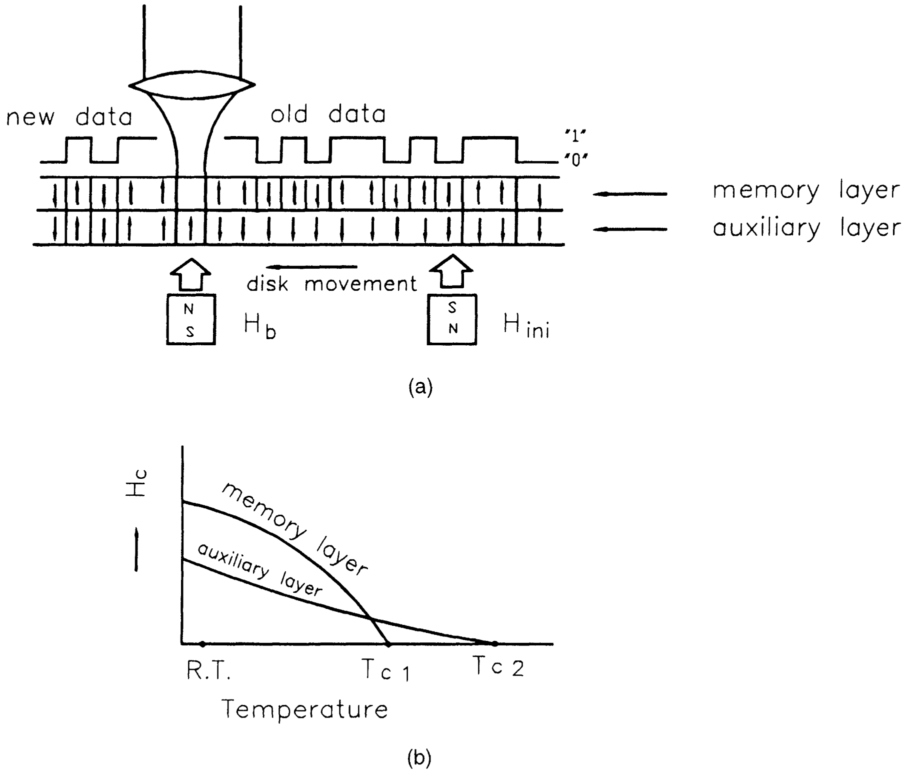

FIG. 28. Mechanism of overwritability in double-layered films for light (beam) modulation mode. The recording film consists of a memory layer and an auxiliary layer. The H_c vs temperature curve of each layer is shown in (b). Before overwriting, the auxiliary layer is initialized by a field H_{ini}. For overwriting, H_b is applied in the reverse direction. For the high-level beam ("1"), both magnetizations are aligned upward; for the low-level ("0"), the magnetization of the auxiliary layer does not change and the memory layer follows it by the exchange coupling. (After Saito *et al.*, 1987.)

1. reduction of the light wavelength λ,
2. mark-edge recording,
3. removal of track guard band, and
4. MSR (magnetically induced super resolution), described later (Ohta et al., 1991).

The reduction of λ basically depends on the development of short-wavelength laser diodes. However, materials for short wavelength are also being investigated, amorphous NdFeCo, garnets, and Co/Pt(Pd) multilayers (Zeper, *et al.*, 1989) being typical ones. Mark-edge recording, in which information is stored by the position of the edge of a recorded mark, can increase at least 1.5 times the conventional mark-position recording, and it is almost at hand. The three-beam method has been proposed for removing the guard band that enables cancellation of the crosstalk from the neighboring tracks. There are two typical types in the MSR method: front-aperture detection (FAD) and rear-aperture detection (RAD). The FAD method utilizes trilayered films exchange coupled when no beam is applied; the recording layer, a switching layer, and a readout layer (see Fig. 29). At room temperature, the recording layer has the highest coercivity and the coercivities of the readout layer and the switching layer are low enough for the magnetization of each layer to align in the same direction as that of the memory layer through exchange coupling. The Curie temperature of the switching layer is made lower than that of the other two layers. Thus, when a read beam is applied to a rotating disk while an erase field H_r is applied, the film is heated up to make a part of the

irradiated switching layer nonmagnetic, decoupling the readout layer from the recording layer and resulting in the erasure of the readout layer, which acts as a kind of mask in the spot providing an extremely high readout resolution. Regarding the mechanism of RAD, see Fig. 29(b).

Very recently, multilevel (four-level) recording has been achieved by using multilayered MO media, which will also be a candidate for a future high-density recording scheme (Shimazaki *et al.*, 1995).

2.4.3.2 Phase-Change–Type Disks. Amorphous materials have a glass point T_g above which atoms become rather easy to move around, and a melting point T_m above which they become liquids. If they are kept at a temperature between T_g and T_m for a sufficient time, they turn into crystallites, and if they are cooled rapidly from their liquid state, they become amorphous. The write/erase or overwrite in the phase-change–type disks utilizes this phenomenon. Figure 30 illustrates the recording process schematically. A series of light pulses corresponding to the signal to be written, having a sufficient height to melt the recording layer, are applied with a constant biasing power that elevates the temperature just above the crystallization temperature, thus leaving amor-

FIG. 30. Mechanism of phase-change–type recording (one-beam overwrite mode). (a) Form of three-level beam (amorphous, crystallization, and readout levels) applied. (b) Temperature profile generated by the irradiation. The spots where the temperature has exceeded the melting point become amorphous and the spots where the temperature has been raised a little higher than the crystallization temperature become crystallites. Thus the pattern as shown in (c) is recorded. (After Terao *et al.*, 1990.)

phous spots corresponding to the pulse peaks and crystalline spots corresponding to the valleys. Therefore, one of the crucial points to design the recording layer is to choose an appropriate rate of the phase change from amorphous to crystalline state in the range of the temperatures that the recording layers will experience.

The crystallization ratio x as a function of time t is generally given by the Avrami's formula,

$$x = 1 - \exp(-kt^n), \tag{19}$$

where n is an index called the Avrami index that takes on values from 1 to 4 according to the dimension of the crystal growth and whether the number of nuclei is kept constant or increases with time, and k is a function of the nucleation speed and the crystal-growth rate. The average crystallization rate $\langle \nu_0 \rangle$ from the beginning to the time when x becomes x_0 is given by

$$\langle \nu_0 \rangle = [-k/\ln(1 - x_0)]^{1/n}. \tag{20}$$

Reading the written bit is performed by detecting the change of the reflectivity as in the case of the write-once type.

The Ge–Sb(Co,Tl,Ag)–Te system is known as one of the most excellent material systems in terms of overwrite repeatability and erase characteristics (Akahira *et al.*, 1988; Ohta *et al.*, 1989). GeTe possesses a crystallization time as short as 30 ns and a high stability in the amorphous state because of its high crystallization temperature (Chen *et al.*, 1986). However, it is easily cracked during crystallization, as a substantial volume change takes place during the phase transition. On the other hand, Sb_2Te_3 has a long crystallization time of several microseconds but shows an excellent resistance to crack formation (Yagi *et al.*, 1987). The Ge–Sb–Te system is endowed with the compromised characteristics of those two. The addition of Co, Tl, and Ag controls the crystallization speed (Terao *et al.*, 1989). In–Se–Tl–Co, In–Sb–Te, and In–Sb have also been investigated extensively. However, none of them have surpassed the Ge–Sb–Te system in erasability and overwrite repeatability.

2.4.4 Multiplex Recording In order to obtain much higher recording density, multiplex recording methods have been investigated, such as multiwavelength recording and holographic recording, although a great deal of work is left to be done before they are put into practical use.

2.4.4.1 Hole Burning. Several media consisting of pluralities of dyes, such as multilayered LB (Langmuir–Blodgett) films of spiropirane compounds, have been shown to have the potential of being applied to multiwavelength recording. However the multiplexity number must be limited. "Hole burning," on the other hand, has demonstrated the possibility of attaining multiplexity of almost 1000 (Bjorklund *et al.*, 1988). The recording medium is composed of a host material with a guest material dispersed in it. The guest must be or must possess a light-absorption center, the spectrum of which is modulated by the inhomogeneity of the surroundings, resulting in a broad dispersion in the absorption spectrum of the medium. Recording is performed by applying a monochromatic light with a sharp spectrum making some of the absorption centers immune to the light of the same wavelength by exciting the electrons away. This generates a "hole" in the absorption spectrum of the irradiated spot, which enables reading out later. By changing the wavelength, a multiple of recordings can be done on the same spot.

A lot of materials have been investigated including both organic and inorganic materials, such as porphyrin, phthalocyanine, quinizarin, carbazole–boric acid, single-crystalline alkali halide with color centers or divalent ions, single-crystalline transition-metal oxide, glass doped with trivalent ions (Pr^{3+}, Nd^{3+}), etc. In terms of the multiplexity in recording, quinizarin/PHEMA(poly-2-hydroxyethylmethacrylate) and ABDAQ [4-amino-2,6-bis (4-butylphenoxy)-1,5-dihydroxy-anthraquinone]/PHEMA are known as outstanding. For a double-layered film of these two, 600 multiplex recording has been demonstrated successfully (Yoshimura *et al.*, 1989).

In order to obtain a reasonable signal-to-noise ratio and speed, however, the guest must simultaneously fulfill conditions with respect to both quantum efficiency and absorption cross section, which has not yet been attained. All the successful experiments have been performed at very low temperatures such as liquid He or N_2 temperatures. This is another drawback left to be overcome. At present, by reading, the record is

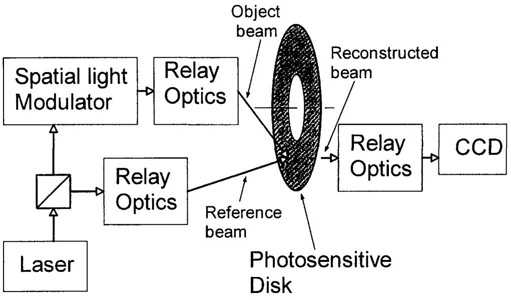

FIG. 31. Diagram of a holographic recording system (after Curtis, 1994).

substantially faded out, which is also one of the crucial issues to be improved.

2.4.4.2 Holographic Recording. Holography is a well-known image-recording technology in which both intensity and phase are recorded simultaneously in the form of interference patterns of the signal and reference beams. Figure 31 illustrates a possible system approach (Curtis, 1994). The spatial light modulator (SLM), which is either a liquid-crystal–based device or a deformable mirror, creates pages of data and multiple pages are recorded in the form of holograms (images of interference pattern) on the same area of the photosensitive recording medium by changing the wavelength or the incident angle of the reference beam. Reading is performed by applying the reference beam to generate a reconstructed beam, which is led to the light detector (CCD). Thus more than 10^5 parallel channel processing can be achieved. As recording materials, several photosensitive materials such as $LiNbO_3$, photorefractives, photopolymers, photorefractive polymers, and glasses are now under investigation. By using those materials, a recording density as high as 10^{10} pixels/cm^3 is expected to be available, 3×10^9 having been achieved experimentally by using $LiNbO_3$ (Heanue *et al.*, 1994). Although the necessary components now seem to be available, full evaluation of the total systems is still to be performed.

3. CONCLUSION

The history of recording technology has been and will continue to be, so to speak, a history of the increase in the recording density and rate. The basic trend in magnetic recording is the utilization of thin films both for heads and media. For the head, the development of high-permeability materials with a high saturation induction and the application of giant magnetoresistance will be major concerns, while for the media, thin-film media constituted of fine grains with high saturation moment and high anisotropy and the utilization of the inclined anisotropy will be. Perpendicular recording will also participate in ultrahigh-density recording in the long run. Although it was not mentioned above, it is worth pointing out that some recent studies imply that the switching speed of recording media will be a matter of serious concern when we go into the frequency range of a few hundred megahertz (He *et al.*, 1995). In optical recording, the development of shorter-wavelength laser diodes including SHG, and the media matching for them, and multilevel recording will be the main issues for increasing the recording density, although other multiplex recording technologies, such as holographic and hole-burning recording, give us an unlimited dream for the future.

GLOSSARY

Barkhausen Noise: In the magnetization process in which domain-wall motion takes place, the change in the magnetization becomes rather discontinuous because there exist a lot of wall pinning sites originating from various kinds of inhomogeneity such as holes, inclusions, crystalline boundaries, etc., generating noise. This effect was first observed by H. Barkhausen in 1919, who made an indirect verification of the presence of ferromagnetic domains in a magnetic body.

Demagnetization Field: A magnetic field that appears when a magnetic body is magnetized, due to the appearance of magnetic free poles mostly at the two ends of the body. As this field opposes the magnetization direction, resulting in some degree of demagnetization, it is called the demagnetization field. When a magnetic body is saturated in one direction with a saturation magnetization M_s, the demagnetization field H_d is expressed as $H_d = -NM_s$, where N is called a demagnetization factor.

GMR (Giant Magnetoresistance): A phenomenon found in magnetic multilayers each layer of which couples with the neighboring magnetic layers antiferromagnetically through a nonmagnetic layer in between, each layer having a thickness of a few nanometers (Baibich *et al.,* 1988). The resistance of the multilayers is changed drastically by applying a field that changes the angle of the magnetizations of the neighboring layers. This phenomenon comes from the spin-dependent resistance at the interface and in the bulk of the magnetic layers and is isotropic with respect to the applied current direction.

Inductive Head: A magnetic head consisting of a magnetic core and a coil wound around it. Because it operates through the phenomenon of inductance, it is called "inductive head." This term began to be used to distinguish the one from noninductive heads such as Hall head or MR (magnetoresistive) heads, which are used for reading only.

MR (Magnetoresistance): A phenomenon in which the resistance of a magnetic substance changes as a function of the magnetization direction with respect to the direction of the current applied. Since it is anisotropic in this sense in contrast to the giant magnetoresistive effect (GMR), it is called "anisotropic magnetoresistance."

Spin Valve: The metallic magnetic bilayer structure in which the magnetization of one layer is pinned and that of the other is free exhibiting the GMR effect. The magnetization in the free layer acts as if it were a valve for the electric current.

INTRODUCTION

The recrystallization that takes place *during* the high-temperature deformation of metals is known as dynamic recrystallization (DRX) and was initially a subject of considerable controversy. At the Sheffield conference on Deformation under Hot Working Conditions, for instance, it was still being claimed by Stüwe (1968) that the nucleation and growth of new grains (which involve grain-boundary migration) can only take place *after* straining, while the microstructural changes occurring *during* deformation are restricted to the rearrangement and removal of dislocations (dynamic recovery). It was, indeed, rather difficult to decide whether the new grains present in deformed and cooled samples were generated dynamically (i.e., during deformation) or statically, during the interval between hot working and quenching. As will be seen below, *postdynamic* restoration processes generally take place very rapidly, which makes it difficult to interpret metallographic data without ambiguity.

Because of these difficulties, the early references to DRX were based on the special shapes of the stress–strain curves sometimes observed under metal-working conditions. (Similar remarks apply to the unusual strain–time curves occasionally determined under creep conditions.) These were characterized by considerable amounts of strain softening, and more particularly by oscillations indicating that successive cycles of work hardening and flow softening were taking place. An early example of such wavy flow behavior is presented in Fig. 1, obtained from compression tests carried out on lead specimens at room temperature (Thomsen *et al.,* 1954). Since then, similar observations have been made on a large number of metals and alloys (copper, carbon steels in the austenite range, austenitic stainless steels, nickel, etc.) that have been subjected to hot-compression, tension, or torsion tests. DRX has also been reported to occur in nonmetallic materials, such as ice (Steinemann, 1958), and some minerals (Poirier, 1972).

Although the occurrence of DRX under laboratory testing conditions has now been amply assessed and analyzed, some doubt still remains about its importance during in-

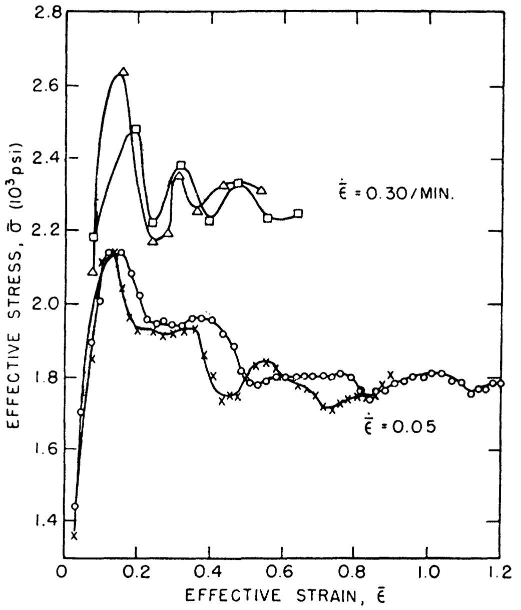

FIG. 1. Room-temperature stress–strain curves determined on lead specimens; the wavy flow behavior is an early example of the periodic softening produced by dynamic recrystallization (after Thomsen *et al.*, 1954).

dustrial hot-forming operations, as recently discussed by Jonas (1994). In processes where large strains are applied in a single operation (as in seamless tube piercing, extrusion, and planetary hot rolling), the material grain size during processing is clearly controlled by DRX. This also appears to be the case for multiple-pass processes such as hot rolling when the interpass times are short ($\leqslant 1$ s) so that interpass-restoration effects are negligible or absent, and the strain can accumulate. It will be seen later that such industrial forming conditions, which usually involve high strain rates (10 to 1000 s^{-1}), generally lead to *grain refinement* as a result of DRX and, therefore, to increases in yield stress and hardness, as well as in the resistance to cracking and fracture. No longer a "scientific curiosity," dynamic recrystallization is now becoming an industrial tool (Jonas, 1994).

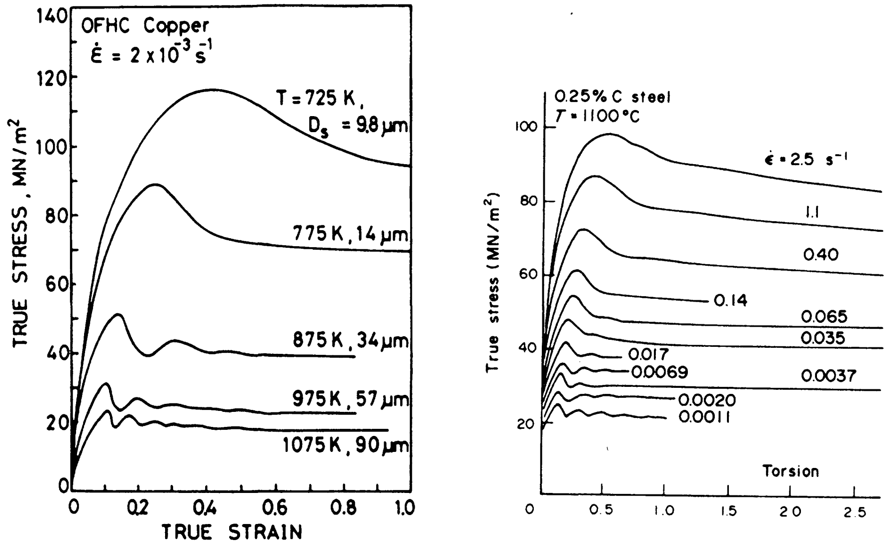
Careful analysis of the stress–strain curves obtained over various ranges of strain rate and temperature, together with that of the associated microstructures, has shown that two broad classes of DRX can be distinguished. The first, usually referred to simply as "dynamic recrystallization" in the literature, involves the nucleation and growth of new grains within a strained matrix; it will be categorized here as *discontinuous dynamic recrystallization.* The second type results solely from the operation of dynamic recovery and grain-boundary migration; i.e., it does *not* involve nucleation. This mechanism can also produce "new" grains at large strains. Because of the absence of nucleation, it will be referred to here as *continuous dynamic recrystallization.*

1. DISCONTINUOUS DYNAMIC RECRYSTALLIZATION

The most striking microstructural feature of discontinuous DRX is the formation of dislocation-free nuclei, which grow during further straining. This leads to the appearance of equiaxed grains that, unlike those produced by *static* recrystallization, contain dislocations as a result of the continued straining.

1.1 Flow Curves Associated with Discontinuous DRX and the Critical-Strain Model

Some stress–strain curves that are typical of DRX are illustrated in Fig. 2(a); these were obtained from hot-compression tests of OFHC (oxygen-free high-conductivity) copper specimens at various temperatures (Blaz *et al.*, 1983). Here, the shape of the curve changes from the *multiple-peak* variety to the *single-peak* type when the temperature is decreased. A similar transition is observed when the strain rate is increased, as shown in Fig. 2(b) for the case of a 0.25% C steel (Rossard and Blain, 1959). Such equivalence between the effects of decreasing temperature and increasing strain rate is associated with the occurrence of thermally activated processes and has long been recognized in the study of hot working. It arises because an increase in strain rate decreases the time available for thermal activation (and therefore the probability of successful activation), while a decrease in temperature has an equivalent effect on successful activation by decreasing the amplitude of the thermal fluctuations. The equivalence permits use of the



(a) (b)

FIG. 2. Stress–strain curves typical of discontinuous dynamic recrystallization obtained on (a) OFHC copper at various temperatures (after Blaz *et al.*, 1983) and (b) 0.25% C steel at various strain rates (after Rossard and Blain, 1959).

temperature-corrected strain rate, or Zener–Hollomon parameter (Zener and Hollomon, 1944):

$$Z = \dot{\epsilon}\exp(Q/RT), \qquad (1)$$

where $\dot{\epsilon}$ is the strain rate, T the absolute temperature, R the gas constant, and Q the apparent activation energy of deformation. Thus when Z is less than a critical value Z_c, multiple peaks are present, whereas when $Z > Z_c$, single-peak flow occurs.

The positive-slope portions of the oscillations (when $Z < Z_c$) can be intuitively understood as resulting from strain hardening, whereas the negative-slope regions can be associated with softening by recrystallization. Such softening can only be reflected in the flow curve when recrystallization is "synchronized" throughout the sample. Conversely, in the single-peak type of curve ($Z > Z_c$), work hardening and softening by recrystallization take place concurrently in different parts of the specimen, so that recrystallization is now "asynchronized." Starting from this very simple idea, a first model of discontinuous DRX was proposed by Luton and Sellars (1969). They introduced two characteristic strains associated with the flow curves (Fig. 3): ϵ_p, the strain to the first stress peak,* and ϵ_x, the recrystallization

FIG. 3. Schematic definitions of the peak and recrystallization strains, ϵ_p and ϵ_x, respectively, in the single- (left) and multiple-peak (right) cases. ϵ_s is either the minimum strain required to attain steady-state flow or the strain at which the mean value of the flow stress is attained during the second cycle of work hardening. (After Luton and Sellars, 1969.)

---

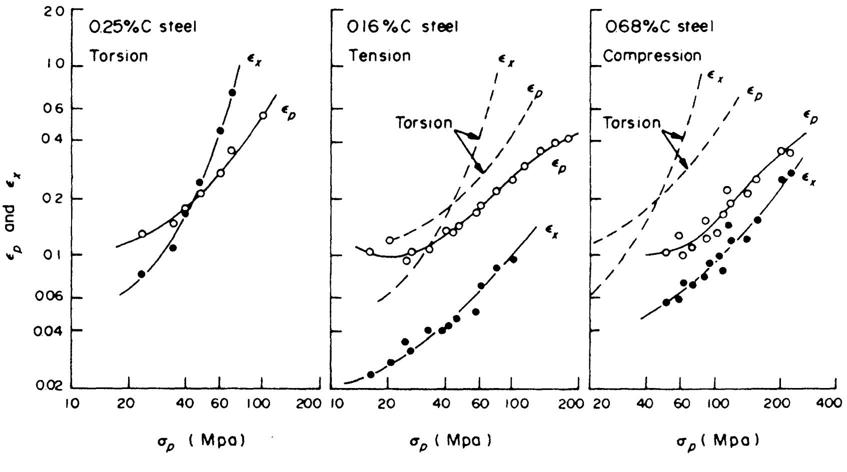
*A more physical quantity, viz, the critical strain ϵ_c, has also been used. It refers to the strain required to initiate DRX, which is less than ϵ_p [$\epsilon_c \approx (0.6 \text{ to } 0.8)\epsilon_p$]. As ϵ_c cannot be readily determined from stress–strain curves, the "nucleation" strain is frequently specified in terms of ϵ_p rather than ϵ_c.

strain. The latter was defined as $\epsilon_s - \epsilon_p$, where ϵ_s is the minimum strain required to attain steady-state flow in single-peak curves, and the strain at which the mean value of the flow stress is attained during the second cycle of work hardening in multiple-peak curves. On the basis of their results for the torsion testing of nickel, the authors showed that when $\epsilon_p > \epsilon_x$ (low Z), DRX is synchronized, whereas when $\epsilon_p < \epsilon_x$ (large Z), asynchronized DRX takes place. By means of computer simulations, they were able to reproduce the two alternative shapes of stress–strain curves. This *critical-strain model* is consistent with the data obtained from numerous *torsion*-test investigations.

It has been shown more recently, however (Sakui *et al.*, 1977; Weiss *et al.*, 1984), that the critical-strain comparison does not apply to *tension* or *compression* experiments, at least in unmodified form. This is illustrated in Fig. 4, which shows the peak stress dependences of ϵ_p and ϵ_x for three plain carbon steels deformed in torsion, tension, and compression (Sakai and Jonas, 1984). In the case of *torsion* [Fig. 4(a)], the intersection of the two curves identifies the peak stress that corresponds to the critical value Z_c of the Zener–Hollomon parameter introduced above. The latter defines the transition from multiple-peak to single-peak flow. However, unlike the behavior displayed by the torsion results, the ϵ_p and ϵ_x curves do *not* intersect in the case of the tension [Fig. 4(b)] or compression [Fig. 4(c)] experiments, although the flow-curve–shape transition is still observed within the σ_p range investigated.

Such an unexpected disagreement between the results of torsion tests on the one hand, and those obtained from tension or compression tests on the other, has been analyzed in detail by Sakai and Jonas (1984). Their main conclusions can be summarized as follows.

1. The determination of material stress–strain curves (σ-ϵ) from torque (T) versus twist (N) data determined on solid-bar torsion specimens is subject to error, because of the radial strain and strain-rate gradients that are present. Although the problem was solved by Fields and Backofen (1957) for a wide class of materials that undergo work hardening and display rate sensitivity, their method involves calculation of the partial derivatives of T with respect to the number of twists, N, and the rate of twisting, $\dot{N}$. This requires the processing of large amounts of experimental data, and is rarely carried out. The algebraic shortcuts taken instead by most experimenters lead to the overestimation of ϵ_p.
2. Because necking develops fairly rapidly in tension after the stress peak has been attained, ϵ_x values determined by this



(a) (b) (c)

means will generally be lower than those measured using other test methods [cf. Fig. 4(b) with Figs. 4(a) and 4(c)].

3. There is also an effect of *strain path* on the rate of work hardening and therefore on the strain required to attain ϵ_p. This is because the flow stress of a material can be written in the form

$$\sigma(\epsilon) = \bar{M}(\epsilon)\bar{\tau}_c(\epsilon), \qquad (2)$$

where $\bar{M}$, the average Taylor factor, is associated with the current crystallographic texture and $\bar{\tau}_c$ is the mean value of the critical resolved shear stress, a quantity that is closely linked to the current dislocation configuration. The strain dependences of these two factors are distinctly different for specimens deformed along different strain paths (Jonas *et al.*, 1982). In particular, the flow stress of samples strained at room temperature is generally lower in torsion than in tension or compression. Such strain-path effects also contribute to the different ϵ_p and ϵ_x dependences displayed in Figs. 4(a)–4(c).

The errors and discrepancies involved in determining ϵ_p and ϵ_x from mechanical test data thus led Sakai and Jonas (1984) to conclude that the critical condition $\epsilon_p = \epsilon_x$ associated with the transition from single- to multiple-peak flow only applies, strictly speaking, to solid-bar torsion experiments and then only in an approximate and perhaps fortuitous way.

1.2 Grain-Size Evolution and the Relative-Grain-Size Model

The critical-strain approach was principally concerned with the mechanical or macroscopic aspects of DRX. Little attention was paid to the characteristics of the actual microstructural processes taking place within the material. More recently, these have been studied in some detail, principally by Sakai and co-workers (Sakui *et al.*, 1977; Sakai and Jonas, 1984). To avoid the occurrence of postdynamic restoration, they used special tensile machines in which the specimen could be quenched at a cooling rate of about 2000 K s^{-1} at the end of the deformation. By this means, these authors were able to investigate the evolution of the average grain size during DRX. In particular, they compared the dynamic "equilibrium" grain size D_s present in the steady state (at large strains) with the initial grain size D_0.

The results obtained on a 0.16% C steel tested at 940 °C and a range of strain rates are presented in Fig. 5. The strains at which stress peaks were observed are identified as P_1, P_2, etc. It can be seen that, at low strain rates, multiple-peak behavior is displayed and either grain coarsening ($\dot{\epsilon} = 2.6 \times 10^{-4}$ and $2.0 \times 10^{-3}\ s^{-1}$) or slight refinement ($\dot{\epsilon} = 2.0 \times 10^{-2}\ s^{-1}$) takes place. Conversely, at high strain rates ($\dot{\epsilon} = 1.48 \times 10^{-1}$ and 18 s^{-1}), single-peak behavior is associated with a large decrease in grain size. The critical D_0/D_s ratio above which single-peak behavior occurs can be estimated to be about 2. This can be shown more quantitatively as follows.

It is well known that the equilibrium grain size D_s is a power-law function of the steady-state flow stress σ_s for a number of metals and alloys (Derby, 1991):

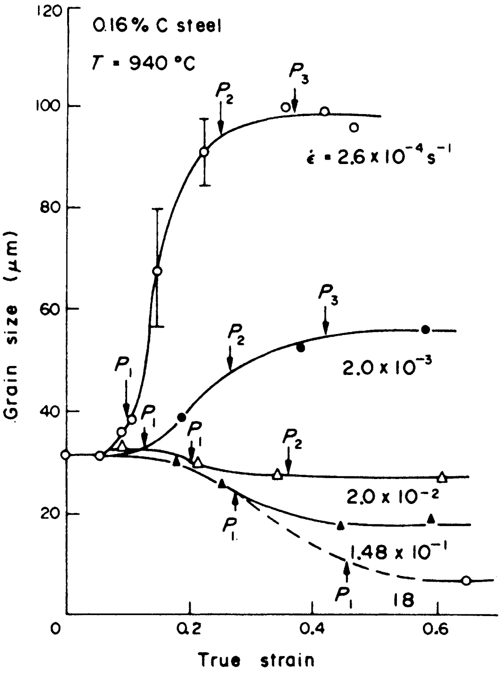

FIG. 5. Strain dependence of the average grain size during the tensile deformation of a 0.16% C steel at 940 °C. Whether grain coarsening or grain refinement takes place depends on the imposed strain rate. The strains at which stress peaks were observed are identified as P_1, P_2, etc. (After Sakui *et al.*, 1977.)

$$\sigma_s = k_1/D_s^{\alpha}. \tag{3}$$

Here, $\alpha \approx 0.66$–0.75 is an empirical constant and k_1 is a constant. Since σ_s is itself related to the Zener–Hollomon parameter Z by a power-law-relationship (provided that the strain rate and stress are not too high), viz.,

$$\sigma_s = k_2 Z^m, \tag{4}$$

Z can be expressed in the form

$$Z = k/D_s^{\alpha/m} \tag{5}$$

In the above equations, k_2 and k are further constants, and $m \approx 0.1$ to 0.2, so that $\alpha/m \approx 4$ to 8. Equation (5) essentially states that D_s depends solely on the temperature-corrected strain rate Z. This can be interpreted as signifying that the growth of new grains stops when the driving force for grain-boundary migration (the dislocation-density difference) decreases to zero, or drops below a critical level. The loss of driving force is caused by strain hardening, the rate of which must be balanced against the velocity of grain-boundary migration. It is the latter quantity that is directly related to the parameters of straining, via Z.

The relationship described by Eq. (5) is illustrated in the semilogarithmic plot of Fig. 6 for a 0.16% C steel. Here it can be seen that the dependence of the critical value of the Zener–Hollomon parameter Z_c on the initial grain size D_0 is *nearly parallel* to the Z-D_s dependence. Furthermore, the above authors showed that the Z_c vs $2D_s$ relation approximately coincides with the one pertaining to Z_c vs D_0 (Fig. 6). This means that $D_0 = 2D_s$ corresponds to $Z = Z_c$ and is thus associated with the transition from multiple- to single-peak behavior.

These experimental observations led to the *relative-grain-size model* described in Fig. 7. In this double-logarithmic plot, the Z_c-D_0 and Z-D_s relations are now represented by two parallel straight lines of slope $-\alpha/m$. The first divides the diagram into two parts, associated with single-peak (large initial grain size, high Z value) and multiple-peak (small initial grain size, low Z value) behavior, respectively. The Z-D_s line in turn distinguishes between the grain-coarsening and grain-refinement domains. From the diagram, the outcomes of two different types of tests can be predicted. "Vertical" experiments are carried out with a fixed initial grain size D_0 but at various values of Z, as in Figs. 2(a) and 2(b). According to Fig. 7, given an initial grain size D_{01}, stress oscillations will occur when a combination of relatively low testing strain rate and high tem-

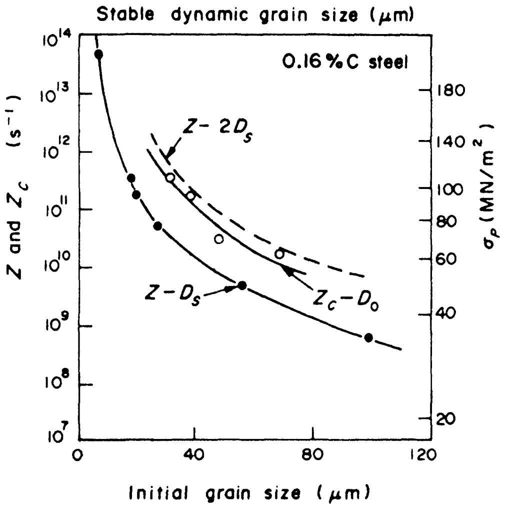

FIG. 6. Relationship between the steady-state grain size D_s and Zener–Hollomon parameter Z. The initial grain-size dependence of the critical value Z_c associated with the transition from single- to multiple-peak flow (and vice versa) is shown to be *parallel* to the latter curve. (After Sakui *et al.*, 1977.)

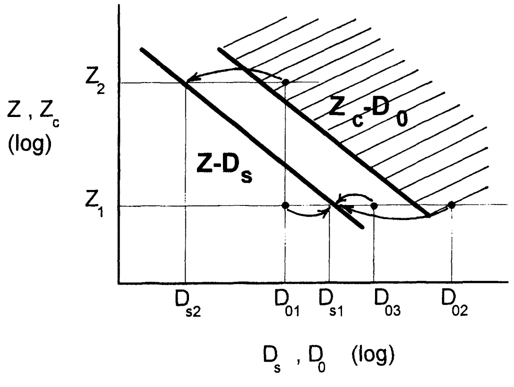

FIG. 7. Double-logarithmic plot illustrating the relative–grain-size model (see text). The Z_c-D_0 and Z-D_s relations are represented here by two parallel straight lines. The cross-hatched area corresponds to the temperature-corrected strain rate and initial grain-size conditions associated with single-peak dynamic recrystallization.

perature, e.g., $Z_1 < Z_{c1}$, is used. Each cycle of recrystallization then produces *grain coarsening* until the stable grain size D_{s1} pertaining to Z_1 is attained. Conversely, if a combination of a relatively high testing strain rate and low temperature, e.g., $Z_2 > Z_{c1}$, is used, a single peak is observed and *grain refinement* occurs until the stable grain size D_{s2} is reached.

The "horizontal" tests are carried out, in turn, at a fixed value of Z (generally with both the strain rate *and* temperature held constant) but at various values of D_0, as illustrated in Fig. 8. Thus for $Z = Z_1$, when the initial grain size D_{01} is finer than D_{s1}, multiple peaks and grain coarsening are called for, persisting until D_{s1} is attained (Fig. 7). Alternatively, when the initial grain size D_{02} or D_{03} is larger than D_{s1}, the occurrence of grain refinement is predicted; this can be associated with either single- (for $D_{02} > 2D_{s1}$) or multiple-peak (for $D_{s1} < D_{03} < 2D_{s1}$) flow. The grain size decreases in this case until it attains D_{s1} and a steady state of flow is achieved.

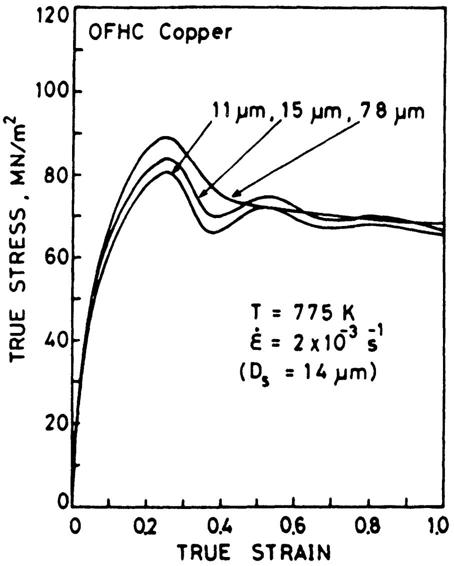

FIG. 8. Hot-compression stress–strain curves for OFHC copper specimens with various initial grain sizes, illustrating the transition from multiple- to single-peak dynamic recrystallization (after Blaz *et al.*, 1983).

1.3 Nucleus-Density Condition

A physical basis for the microstructure-mechanism map of Fig. 7 will now be considered. It is first assumed that the nucleation of new grains occurs only at or near existing grain boundaries. This is because the stored energy (dislocation density) is greater in these parts of the crystals, and also because less additional surface area need be created when a nucleus is formed. The relations between nucleus density N and grain size D are thus

$$N_0 = \beta P_0/D_0 \quad \text{and} \quad N_s = \beta P_s/D_s \qquad (6)$$

in the initial and steady states, respectively, where β is a geometrical constant. P_0 and P_s are the probabilities per unit surface area that a grain-boundary site is activated to form a nucleus. Since some recently recrystallized parts are unable to supply nuclei in the steady-state microstructure, P_s is lower than P_0; the experimental data in fact suggest that $P_0/P_s \approx 2$. Then, from Eqs. (6),

$$\frac{N_0}{N_s} = \frac{P_0}{P_s}\frac{D_s}{D_0} \approx 2\frac{D_s}{D_0}. \qquad (7)$$

Thus the relative-grain-size condition $D_0 = 2D_s$ is associated with the *nucleus-density condition*

$$N_0 = N_s. \qquad (8)$$

The transition between single- and multiple-peak behavior can now be rationalized with the help of the above criterion.

When $D_0 > 2D_s$ or $N_0 < N_s$, there is a *deficit* in the initial nucleus density with respect to its steady-state value. Because nucleation occurs at the existing grain boundaries, a "necklace" mechanism operates as illustrated in Fig. 9. Since $D_s < D_0/2$, the new grains reach their equilibrium size D_s before the whole structure has recrystallized. After the formation of the first strand of new grains, DRX continues to spread progressively toward the interiors of the deformed initial grains (Fig. 9). According to this model, at any instant in time, the different volume fractions of the sample are at different stages of recrystallization. DRX is thus a very heterogeneous process and the occurrence of softening is not at all synchronized at any

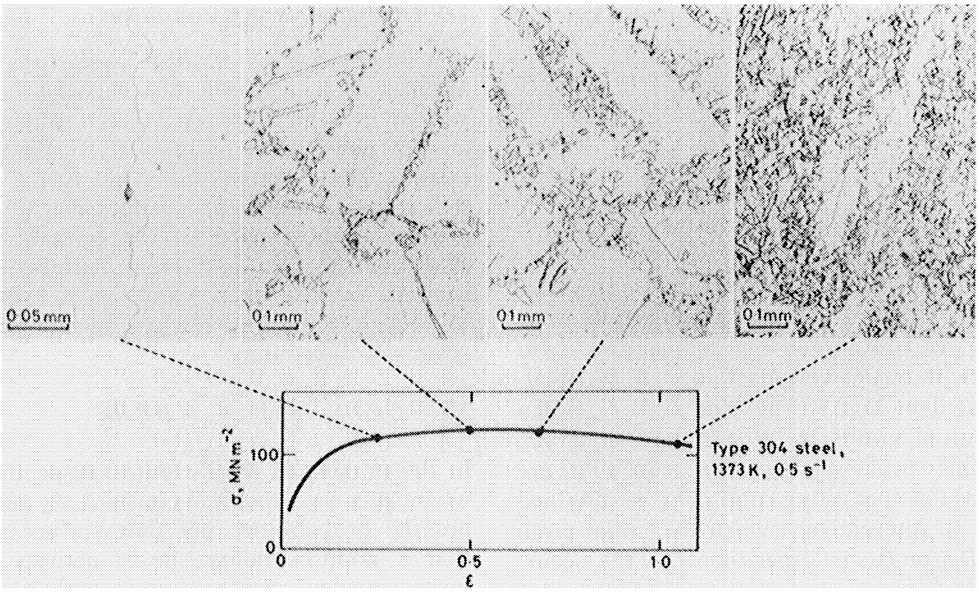

FIG. 9. Microstructures illustrating the progress of necklace dynamic recrystallization in type 304 austenitic stainless steel with a coarse initial grain size. The associated single-peak stress–strain curve is also shown. (After Roberts *et al.*, 1979.)

particular moment. Nevertheless, there is overall flow softening until the equilibrium grain size has been attained everywhere within the material, i.e., single-peak DRX occurs. The limiting case for this mechanism is a necklace containing a single strand, which corresponds to the relative–grain-size condition $D_0 = 2D_s$ or to the nucleus-density condition $N_0 = N_s$.

When $D_0 < 2D_s$ or $N_0 > N_s$, there is an *excess* in nucleus density. Since $D_s > D_0/2$, the growth of recrystallized grains is stopped by mutual impingement before they have reached their steady-state size D_s. Once the first cycle of recrystallization is complete, work hardening begins again, followed by a second cycle of recrystallization, and so on, until grain coarsening finally produces the stable grain size D_s. Such coarsening also progressively reduces the excess nucleus density until the stable level given by N_s is attained. It should be noted that, although this process generally leads to an increase in grain size (i.e., when $D_0 < D_s$), it can also be associated with a small amount of grain refinement (i.e., when $D_s < D_0 < 2D_s$), as illustrated in Fig. 5. Under these conditions, the progress of DRX is highly synchronized and the macroscopic multiple-peak flow curve readily reflects the local cycles of work hardening and recrystallization.

Unresolved Issues. Since the steady state is only attained at large strains ($\epsilon > 1$) and is rarely achieved during industrial processing, its characteristics have only been investigated experimentally in a few materials, such as Cu, Ni, and stainless steels (Ryan and McQueen, 1990). With regard to mathematical treatments, only a few tentative models have been proposed (Stüwe and Ortner, 1974; Sandström and Lagneborg, 1975). Although these can account for the stress dependence of the steady-state grain size, in their present states of development they are unable to distinguish between the grain-refinement and grain-coarsening modes of recrystallization. More recently, numerical models based on the Monte Carlo simulation technique have been used to study DRX (Rollett *et al.*, 1992). Although many of the essential features of the latter are faithfully represented, the relationship between flow-stress oscillations and grain coarsening has not yet been clearly reproduced.

During steady-state flow, both the flow stress and the microstructural parameters (e.g., the distributions of grain size and dislocation density) remain stationary (Fig. 10).
